WATER.

WATER. This important fluid was believed by the ancients to be one of the four elements out of which they imagined every other fubftance is compofed. This opinion maintained its ground for a very long period. At length, however, it began to be fufpected, from the experiments of Van Helmont, Boyle, and others. Van Helmont fhewed that plants would grow for a very long time in pure water, whence it was concluded that water was capable of being changed into all the fubftances found in vegetables. Mr. Boyle fuppofed, that by long digeftion and boiling in glafs-veffels, he had converted water partly into an earth. Margraaff, who repeated his experiment, drew the fame conclufion; but the opinion was never very generally admitted, and at length was proved to be erroneous, the earth being fhewn to be derived from the glafs-veffels employed in the experiments.

The combuftible nature of hydrogen gas was obferved about the beginning of the 18th century, and the celebrated Scheele, many years afterwards, was the firft who attempted to difcover what was produced by this combuftion. In this, however, he did not fucceed; nor were Macquer, Bucquet, Lavoifier, Dr. Prieftley, and others, who fubfequently repeated the experiment with fimilar views, more fortunate. The diftinguifhed honour of difcovering the compofition of water was referved for Mr. Cavendifh, who, in 1781, proved beyond a doubt that the combuftion of hydrogen and oxygen produced this fluid, and nothing elfe. Water, therefore, fince the period juft mentioned, has been univerfally admitted to be compofed of thefe two gafeous principles.

Water is found in abundance in every part of the globe, and is abfolutely neceffary for the exiftence of organized beings. When quite pure, as obtained by diftillation, it is perfectly tranfparent and colourlefs, and free from tafte and fmell.

A cubic foot of diftilled water, according to the beft experiments, weighs, at a temperature of 40°, 437102.4946 grains troy. Hence, a cubic inch of water at the fame temperature weighs 252.952 grains; and at the temperature of 60°, 252.72 grains. The fpecific gravity of water is always fuppofed to be 1.000, and it is made the meafure of the fpecific gravity of every other body. (See *Specific* GRAVITY, and HYDROSTATICS.) Water, at a temperature of 32°, becomes folid, and affumes the form of ice. In this ftate it poffeffes confiderable hardnefs and elafticity, and its fpecific gravity is diminifhed to .94. See FREEZING, and ICE.

When water is raifed to the temperature of 212° it boils, and is gradually converted into fteam, which is an invifible and highly elaftic fluid like air. The fpecific gravity of fteam, according to the moft recent obfervations, is .625, that of air being reckoned 1.000. See BOILING, EBULLITION, and STEAM.

Water is capable of undergoing a flight degree of compreffion. See COMPRESSION.

Water undergoes no alteration by expofure to heat or light. Thus it may be made to pafs through a red-hot tube without fuffering any change.

On expofure to the atmofphere, it abforbs a portion of air, the greater part of which is capable of being again driven off by boiling. To expel the whole, however, it is ftated to be neceffary to continue the operation at leaft two hours in a flafk, with its mouth inverted over mercury. To this fmall proportion of air which it holds in folution, water chiefly owes its agreeable flavour, boiled water being infipid. See ABSORPTION, and GAS.

Printed by A. Strahan,
New-Street-Square, London.

Hydrogen gas, even at a red heat, has no action upon water. Charcoal, when cold, does not decompoſe it. But when red-hot charcoal is brought in contact with water, carbonic acid and carburetted hydrogen are formed in abundance. Sulphur and phoſphorus do not appear to be capable of decompoſing water, even when aſſiſted by heat; but potaſſium and ſodium, and doubtleſs alſo the metallic baſes of the alkaline earths, decompoſe it rapidly. Of the other metals, iron, zinc, antimony, and tin, decompoſe it, when aſſiſted by heat. Silver, gold, copper, and platina, produce no effect upon it.

Water diſſolves the alkalies and alkaline earths. The acids alſo, and many ſaline compounds, are ſoluble in this fluid; but it is incapable of diſſolving the earths properly ſo called.

Water combines with bodies in two different ways. It either diſſolves them, in which caſe the proportion of water is unlimited, or it combines with them, and forms ſolid compounds, termed *hydrates*, into the compoſition of which the water enters in a definite proportion. The metallic hydrates, in general, are remarkable for the brilliancy of their colours. They are more ſoluble in acids than the oxyds, and in ſome inſtances affect the organs of taſte even more perceptibly than the metallic ſalts. This ſubject has been particularly inveſtigated by M. Prouſt. See HYDRATE.

According to the lateſt and moſt perfect experiments, water is compoſed of two volumes of hydrogen gas, and one volume of oxygen gas. Hence, its combining weight or atom will be 1.125, oxygen being reckoned 1; or, if we conſider the ſpecific gravity of hydrogen gas to be .6944, and of oxygen gas 1.1111, it is compoſed of one part by weight of hydrogen, and eight parts by weight of oxygen. The union of oxygen and hydrogen gaſes to form water is attended by the extrication of much light and heat. See COMBUSTION and DETONATION.

WATERS, *Natural.* "Water," ſays Dr. Saunders, "is found throughout the earth in every degree of purity, except the higheſt, for ſuch is never procured, except by artificial diſtillation, as all natural waters are conſtantly coming into contact with ſome ſubſtance which they can either diſſolve or hold ſuſpended." Waters to which the epithet *mineral* is applied, in many inſtances differ from other natural waters in the degree only in which they are impregnated with ſimilar foreign ſubſtances: in other inſtances, they differ in the nature of the impregnating ingredient; but for the moſt part they differ in both theſe circumſtances. In preſenting our readers with an account of natural waters in general, we ſhall commence with an enumeration and ſhort account of the different foreign ingredients uſually met with in waters, and influencing their operation on the animal economy.

1. *Caloric.*—The temperature of natural ſpring-waters is the ſame, in general, as the mean annual temperature of the particular place in which they occur. It is evident, therefore, that this temperature muſt vary with the latitude. (See the articles CLIMATE, TEMPERATURE, &c.) Waters rarely occur of a temperature much lower than the mean annual temperature of the latitude in which they are found; but inſtances are met with in every part of the globe in which they occur of a higher temperature. This degree of increaſed temperature is very different in different inſtances. Commonly it is not very ſtriking, while in other caſes it is very remarkable: thus, the waters of Carlſbad, in Bohemia, have the extraordinary temperature of 165°. In this country, the hotteſt ſprings are thoſe of Bath and Buxton, the higheſt temperatures of which are ſtated to be 116° and 82° reſpectively. In ſome inſtances, theſe deviations from the natural temperature are obviouſly referrible to the neighbourhood of volcanoes, but generally their cauſe is very obſcure, as we can hardly form any idea of agents operating for ſuch a length of time, and ſo uniformly, as thoſe of neceſſity muſt do which give origin to the phenomena in queſtion: all we can infer is, that although local, they are deep-ſeated and permanent.

2. *Atmoſpheric Air: Azote.*—All natural waters of a mean temperature hold a portion of common air in ſolution. The quantity, however, has been ſtated by Bergman not to exceed $\frac{1}{18}$th of the bulk of the water; and even this can only be retained at a mean temperature, and under the ordinary preſſure of the atmoſphere, for the greater part of it eſcapes under the air-pump, or on ſubmitting the water for a ſhort time to a temperature of 212° or 32°. It is the oxygen contained in this ſmall portion of atmoſpheric air, retained by water, that ſupports the reſpiration of fiſhes, and other aquatic animals, which ſpeedily die from ſuffocation in water deprived of air. It is this air alſo, as before obſerved, which renders water ſapid and grateful to the palate; for by boiling or diſtillation, this fluid is rendered inſipid and diſagreeable, "and has long been in diſrepute," ſays Dr. Saunders, "for lying heavy on the ſtomach, and even producing ſcrofulous tumours and obſtructions." The preſence of atmoſpheric air in water is eaſily accounted for, from the affinity which ſubſiſts between the two ſubſtances, and which is ſuch, that they ſoon become mutually impregnated by being expoſed to each other.—Azotic gas has been found to exiſt in ſmall quantity in ſome waters, and in theſe inſtances it has been obſerved to be extricated from the ſpring itſelf in union with the water. As far as is at preſent known, this gas imparts no medicinal or even ſenſible property to the waters containing it.

3. *Carbonic Acid.*—This gas is likewiſe ſtated by Bergman to exiſt in greater or leſs quantity in all natural ſpring-waters. The limits in which it occurs is ſaid to lie between about $\frac{1}{100}$, and an equal bulk of the water. In mineral waters it is a moſt important ingredient, not only from its operation upon the animal economy, but from its being the ſolvent of various other active ingredients. When waters contain this principle in exceſs, they aſſume a bright and ſparkling appearance to the eye, have an agreeable pungent acidulous taſte, and ſometimes exert a kind of intoxicating power when largely drunk. Fiſhes are unable to exiſt in them, and ſpeedily die from ſuffocation. On expoſure to the air, however, theſe properties in a ſhort time become ſenſibly diminiſhed, and at length almoſt totally diſappear, owing to the ſeparation of the gas—an operation which may ſtill more ſpeedily be effected by boiling. The preſence of this gas in water is eaſily explained, from its natural affinity to that fluid. In almoſt every inſtance it is extricated from the ſpring in union with the water; but the ſource from whence it is derived is, in general, obſcure and inexplicable.

4. *Hydrogen and its Compounds, carburetted, ſulphuretted, and phoſphuretted Hydrogen.*—Hydrogen gas is barely ſoluble in water, and probably, therefore, never exiſts alone in that fluid. The ſame is true of carburetted hydrogen. Both theſe gaſes, however, are often extricated from waters, eſpecially when ſtagnant, and containing organic ſubſtances in a ſtate of putrefaction. Sulphuretted hydrogen is a frequent ingredient in mineral waters, and gives them ſo characteriſtic a feature, that they are inſtantly recognized. Waters holding this gas in ſolution have an offenſive ſmell, like that of rotten eggs, or a foul gun-barrel, and which is more or leſs ſtrong, according to the degree in which they are impregnated. Such waters alſo have a taſte ſomewhat ſweetiſh, and they generally appear turbid. Water, at a mean

mean temperature, is stated to absorb from $\frac{2}{3}$ds to $\frac{3}{4}$ths of its bulk of this gas, and by long agitation more than its bulk. At a temperature of 80° or 90°, however, this fluid can with difficulty be made to dissolve any of it. Sulphuretted waters, therefore, on exposure to heat, or even to the open air without heat, soon lose their characteristic properties, and become turbid, the hydrogen being dissipated, and the sulphur deposited. The source of this gas, in general, is not obscure, it being formed in great abundance during the decomposition of pyrites, and other minerals containing sulphur. Phosphuretted hydrogen is said to be occasionally extricated from marshes and stagnant pools, but it is not known to constitute an ingredient in mineral waters.

5. *The Alkalies and their Salts.*—The fixed alkalies seldom, if ever, occur in natural waters in a free state. Even the number of their salts is so limited, that Dr. Saunders thinks it necessary to enumerate only two, namely, the sulphate and muriate of soda. The first of them is a very common ingredient in mineral waters, but rarely occurs alone in any quantity, so that it can hardly be said ever to give a peculiar character to a water. Muriate of soda is so extensively and abundantly diffused through nature, that we rarely meet with a natural water which does not contain more or less of it. Sea-water, and many natural waters or *brines*, owe their peculiar characters to this salt, which has been known from the earliest times, and seems to be almost a necessary ingredient in our food. The muriate of soda, however, never occurs alone in natural waters, but is commonly accompanied by some of the earthy salts, especially the sulphate of lime. Chemists have been puzzled to account for the origin of the vast quantity of this salt which is met with in the sea and elsewhere; but a little reflection will shew, that the existence of this substance is not more difficult to be accounted for than that of any other ingredient of our globe. From its property of being soluble in water, it is, perhaps, more generally diffused than any other principle; but it is doubtful if it actually exists in greater abundance than silex, and many other solid substances, and which, in a geological point of view, differ from it only in the mechanical circumstance of their insolubility in water. The carbonate of soda is occasionally met with in waters. Its distribution, however, is very partial, being usually in very minute quantities, or in very large ones. When in small quantity, it is generally supersaturated with carbonic acid. The most remarkable instance of an excess of this salt is in "the natron lakes of Upper Egypt. It is here often mixed with common salt, and they both are largely dissolved in the water, and form a crust of several feet in thickness at the edge of the lake, owing to the copious evaporation of their water of solution effected by a tropical sun." Potash, or its salts, very seldom occur in mineral waters. Carbonate of ammonia is occasionally found in small quantities in some waters, arising probably, as Dr. Saunders conjectures, from decomposed animal or vegetable substances.

6. *The Earths and their Salts.*—The earth most frequently occurring in natural waters is lime, and so generally is this the case, that very few instances are known in which this earth is not met with in some state or other. The neutral carbonate of lime, or *chalk*, is one of the most insoluble substances known; but the supercarbonate of lime is very soluble, and is a frequent ingredient in many springs. "It is one source of *hardness* in waters," says Dr. Saunders, "but is easily got rid of by boiling, which drives off the excess of carbonic acid, and thus causes the chalk to be precipitated; hence the earthy crust or *furr* on kettles in which hard water has been boiled for a number of times. Some natural waters contain an unusual quantity of this calcareous earth, which is rapidly deposited as soon as they become exposed to the air, and thereby give an earthy lining to every tube through which they flow, and encrust with the same material every substance that accident or design may put in their way. Of this kind are the various petrifying springs that form part of the natural curiosities of several mountainous districts, and have been applied to use in a very ingenious manner at the baths of St. Philip, in Tuscany, and still more extensively at Gualecavelica, in Peru."—"The sulphate of lime (the gypsum or selenite of the older writers) is one of the commonest of all the earthy salts that are found in natural waters, and generally accompanies every saline substance, except where there is an excess of alkali. It is almost invariably found in conjunction with the carbonate of lime; and hence the calcareous depositions, petrifactions, and the like, frequently contain a small admixture of selenite." This salt imparts very little taste to water, but gives it "that rough and harsh feel to the fingers and tongue, which characterize the insipid *hard* waters." The muriate of lime commonly accompanies the other salts of lime, but especially the muriate of soda. When in excess in any water, it imparts to it a bitter and disagreeable taste, and active medicinal properties. The great bitterness of "the waters of the Dead sea is owing to the muriates of lime and magnesia, and not to bitumen, as was erroneously supposed." The carbonate of magnesia is insoluble in water; the supercarbonate of magnesia, when it occurs in waters, is always accompanied by the supercarbonate of lime, both the earths being held in solution by an excess of carbonic acid. The supercarbonate of magnesia, however, is more soluble than the supercarbonate of lime, and is not, therefore, so easily separated by boiling. The sulphate of magnesia, or *Epsom* salt, as it was formerly denominated, is the most important of the salts of this earth. It almost always accompanies the sulphate of soda; and to these two salts most of the natural purging waters owe their cathartic properties. It is likewise frequently combined with the sulphate of lime, and also with iron. The sulphate of magnesia imparts to the waters containing it in any considerable quantity a strongly bitter and saline taste. It was first discovered in a spring at Epsom, whence its name; but is usually prepared at present from the refuse salt of sea-water, after the common salt has been separated. The muriate of magnesia, as before-mentioned, commonly accompanies the muriates of soda and lime; hence it is found in various brine-springs, and forms a considerable part of the saline contents of sea-water, to which fluids, especially when concentrated by evaporation, it imparts a strong bitter taste. Salts of alumina are not of very frequent occurrence in waters. The most common is the supersulphate of alumina, or common alum, which is usually associated with the sulphate of iron. The source of this salt is for the most part alum-slate, the sulphur contained in which becomes acidified on exposure to the air, and forms sulphuric acid, which, uniting with the alumina, produces the salt in question. The presence of the sulphate of iron is easily accounted for upon similar principles, since more or less of iron pyrites almost invariably accompanies alum-slate. Silex, in a state of minute division, is sometimes found suspended in small quantity in running waters, but is soon deposited on their remaining at rest. This earth, however, occasionally occurs in a state of solution in hot and tepid springs, especially in the neighbourhood of volcanoes. The menstruum appears to be usually a little free or carbonated alkali, the solvent

powers

powers of which are doubtlefs much increafed by heat, or by fome unknown caufe.

7. *Metals and their Salts.*—The metal moft ufually met with in natural waters is *iron;* never, however, in its metallic ftate, but in a ftate of oxyd combined with an acid. The carbonate of iron is a frequent ingredient of natural waters, the bafe of which is the black or protoxyd of the metal, for the red oxyd does not feem capable of combining with carbonic acid, or at leaft of forming with it a foluble compound. This is, doubtlefs, a wife provifion of nature; for, as Dr. Saunders juftly obferves, if the contrary were the cafe, almoft every natural water would be a chalybeate. The carbonate of iron, like all the other falts of this metal, imparts to waters containing it a peculiar inky tafte, "which," fays Dr. Saunders, "is very perceptible, even when the proportion of iron is fo fmall as hardly to be eftimable by any chemical procefs." Waters containing the carbonate of iron depofit this metal readily on expofure to the air, partly from the efcape of the carbonic acid, and partly from the further oxydation of the metal. The fulphate of iron or green vitriol is met with occafionally in waters in confiderable quantity. This falt, as before obferved, generally occurs in union with the fulphate of alumina, or alum, and is the natural production of the decompofition of iron pyrites. Waters containing this falt in any quantity, poffefs the properties of chalybeates in a high degree, and are peculiarly ftyptic. The muriate of iron is occafionally met with in natural waters; but its exiftence in any confiderable quantity is a rare occurrence. *Copper,* or rather its falts, and efpecially the fulphate of *copper,* is occafionally met with in natural waters. This generally, however, occurs in the neighbourhood of copper-mines; and the fulphate of copper, as Dr. Saunders obferves, is probably formed, like the fulphate of iron, by the decompofition of copper pyrites. Waters containing this metal are highly poifonous, and are never ufed internally. *Manganefe* is occafionally found in fmall quantity in natural waters. It appears, in general, to be affociated with iron; but the ftate in which it exifts is not accurately known. As far as prefent obfervation goes, it imparts no fenfible or other properties to the waters containing it. *Lead,* perhaps, never naturally occurs in waters; but fome waters have the property of diffolving, or holding in fufpenfion, a minute portion of this pernicious metal, when expofed to it in the metallic ftate. Pure foft waters are faid to poffefs this property in the moft ftriking degree.

8. *Mineral Acids.*—Both the muriatic and fulphuric acids are occafionally met with in mineral waters in a free ftate. Such fprings ufually occur in volcanic countries.

9. *Bitumen.*—Bitumen is faid by many of the older writers to be a frequent ingredient in mineral waters. This ftatement, however, has been generally found erroneous by modern chemifts, who have in moft cafes demonftrated the fuppofed bituminous principles of their predeceffors to be fubftances of a very different nature. There are fome fprings, however, which yield a real bitumen; but this, from its infolubility in water, is never diffolved in that fluid, except in a few rare inftances, through the medium of an alkali.

Such is a fhort account of the principal mineral fubftances which are met with in natural waters when they iffue from the earth. "When," fays Dr. Saunders, "they flow within a channel over the furface of the ground, they often become much changed in their chemical compofition, lofing fome of their contents by evaporation, others by flow depofition, or by being decompofed through the influence of light and air. At the fame time they often acquire new contents, which are furnifhed by the foil over which they flow. Thus the ftreams which pafs over a country covered with vegetable matter, or which water large towns, will contain a fenfible quantity of mixed alluvial contents, or a heterogeneous compound of animal and vegetable extract of mucilage.

Different authors have chofen different principles of arrangement in treating of natural waters. An arrangement purely chemical, or purely medicinal, cannot be effected in the prefent ftate of our knowledge; we fhall not therefore attempt either, but fhall confider them under the following heads:

1. Potable waters.
2. Saline waters.
3. Chalybeate waters, fimple and compound.
4. Acidulous waters, fimple and compound.
5. Sulphureous waters, fimple and compound.
6. Thermal waters, fimple and compound.

This arrangement of natural waters, according to their *fenfible* properties, coincides likewife, as well perhaps as the prefent ftate of the fubject will admit, with their *chemical* and *medicinal* properties. It may, however, be objected to the divifions *fimple* and *compound,* that neither of them is accurately correct, and this muft be admitted in a ftrictly chemical point of view; but taken in the enlarged and general fenfe here underftood, there feems to be no ferious objection to this mode of divifion.

1. *Potable Waters.*—Under this divifion we wifh to include every variety of this fluid ordinarily ufed by mankind and other animals for fatisfying their thirft. Thefe may be comprehended under the heads of, *a,* pure or diftilled water; *b,* atmofpheric water; *c,* fpring-water; *d,* running water; and *e,* ftagnant water.

a. The chemical properties of pure water have been already defcribed at the head of this article. As before obferved, it never occurs in nature, and was therefore probably never intended as an article of drink for mankind; certainly, at leaft, not as one abfolutely neceffary for their exiftence, or even healthy condition.

b. Under *atmofpheric* waters are included rain-water, fnow-water, dew, &c.

Rain-water, collected at a diftance from large towns, or any other object capable of impregnating the atmofphere with noxious materials, approaches more nearly to a ftate of purity than perhaps any other natural water. Even collected under thefe circumftances, however, it invariably yields traces of the muriatic acid, and, according to Margraaff, of the nitric alfo. Rain-water of courfe differs according to the ftate of the atmofphere through which it paffes. "The heterogeneous atmofphere of a fmoky town," fays Dr. Saunders, "will communicate fome impregnation to rain as it paffes through; and this, though it may not be at once perceptible on chemical examination, will yet render it liable to fpontaneous change: and hence rain-water, if long kept, efpecially in hot climates, acquires a ftrong fmell, becomes full of animalculæ, and in fome degree putrid." Rain-water in general, in warm climates, is much more impure and liable to become offenfive than in cold and temperate ones. Rain alfo that falls in the fpring and fummer, or after a long-continued drought, or very hot weather, is faid to be more impure than that which falls at other feafons of the year, or after a long-continued moift feafon; circumftances, doubtlefs, owing to the exiftence of a greater proportion of animal and vegetable principles in the atmofphere in fuch climates and feafons. Thefe foreign fubftances have fometimes been fo abundant and peculiar in their appearance, as to have given origin to many marvellous ftories, fuch as the raining of blood, &c. (See the article RAIN.) The fpecific gravity of rain-water hardly differs from that of diftilled water; and from the minute portions of the foreign ingredients which it generally contains, it is very *foft*, and admirably adapted for many culinary purpofes, and various proceffes in different manufactures and the arts.

Snow-water equals, if not furpaffes, rain-water in purity, when collected under the fame circumftances, it being for obvious reafons more free from animal and vegetable impregnations; thus Dr. Rutty found it perfectly fweet after keeping it in a clofe veffel for eighteen months. Snow-water, like rain-water, even in its pureft ftate, yields traces of muriatic acid, and perhaps alfo of the nitric.

Hail-water may be compared to fnow-water, which it clofely refembles: indeed

Ice-water in general is very pure, as the air and faline fubftances are feparated by freezing. Common ice-water, however, is lefs pure than rain and fnow water, as the foreign fubftances, though perhaps feparated by freezing, ftill remain incorporated with the ice, fo that it is impoffible to melt the ice without retaining at leaft a portion of thefe foreign matters.

Dew, being depofited chiefly from the lower parts of the atmofphere, is commonly much more impure than rain or fnow water. According to Dr. Rutty's obfervations, it foon becomes fœtid and offenfive. It yields alfo more fenfible traces of the prefence of muriatic acid than rain-water. This fluid, however, collected at different places and times, differs exceedingly in its properties, as might be naturally expected.

c. Spring-water includes *well*-water, and all others that arife from fome depth below the furface of the earth, and which are ufed at the fountain-head, or at leaft before they have run any confiderable diftance expofed to the air. Although all fpring-waters are originally of atmofpheric origin, yet they differ from one another according to the nature of the foil or rock from which they iffue; for though the ingredients ufually exifting in them are in fuch minute quantities as to impart to them no ftriking medicinal or fenfible properties, and do not render them unfit for common purpofes, yet they modify their nature very confiderably. Hence the water of fome fprings is faid to be *hard*, others *foft*, fome *fweet*, others *brackifh*, &c. according to the degree and nature of the impregnating ingredients. Common fprings pafs infenfibly into mineral or medicinal fprings, as their foreign contents become larger or more unufual; or in fome inftances they derive medicinal celebrity from the abfence of thofe ingredients ufually occurring in fpring-water; as, for example, is the cafe with the Malvern and other fprings. Almoft all fpring-waters poffefs the property termed *hardnefs* in a greater or lefs degree. This hardnefs, as we formerly mentioned, depends chiefly upon the fulphate and carbonate of lime which they hold in folution. The quantity of thefe earthy falts varies very confiderably in different inftances; but Dr. Saunders obferves, that when they exift in the proportion of five grains in the pint, fuch water will be hard, and from its property of decompofing foap will be unfit for wafhing, and many other purpofes of houfehold ufe or manufactures. The water of deep wells, according to Dr. S., is always, *cæteris paribus*, much harder than that of fprings which overflow their channel; but there are many exceptions to this rule. The *foftnefs* of fpring-waters depends on their containing fmaller proportions of the earthy falts above-mentioned. Spring-waters are faid to be brackifh, when they contain a fmall proportion of the muriates of foda, magnefia, or lime, as is frequently the cafe in the neighbourhood of the fea. *Sweetnefs* is generally underftood as oppofed to *brackifhnefs* or *fœtor* when applied to fpring-waters. The fpecific gravity of fpring-waters in general is greater than that of diftilled or any other potable water. See SPRING.

d. Running waters include *river*-waters, and every other fpecies of water expofed to the air, and moving in an open channel. On this part of our fubject we cannot do better than quote from Dr. Saunders. "River-water," fays Dr. S., "in general is much fofter, and more free from earthy falts than fpring-waters, but contains lefs air of any kind; for by the agitation of a long current, and, in moft cafes, a great increafe of temperature, it lofes common air and carbonic acid, and with this laft much of the lime which it held in folution. The fpecific gravity thereby becomes lefs, the tafte not fo harfh, but lefs frefh and agreeable, and out of a hard fpring is often made a ftream of fufficient purity for moft of the purpofes where a foft water is required. Some ftreams, however, that arife from a clean filecious rock, and flow in a fandy or ftony bed, are from the outfet remarkably pure, fuch as the mountain lakes and rivulets in the rocky diftricts of Wales, the fource of the beautiful waters of the Dee, and numberlefs other rivers that flow through the hollow of every valley. Switzerland has long been celebrated for the purity and excellence of its waters, which pour in copious ftreams from the mountains, and give rife to fome of the fineft rivers in Europe."—"Some rivers, however, that do not take their rife from a rocky foil, and are indeed at firft confiderably charged with foreign matter, during a long courfe, even over a richly cultivated plain, become remarkably pure as to faline contents, but often fouled with mud and vegetable or animal exuviæ, which are rather fufpended than held in true folution. Such is that of the Thames, which, taken up at London at low water, is very foft and good water, and after reft and filtration it holds but a very fmall portion of any thing that could prove noxious, or impede any manufacture. It is alfo excellently fitted for fea-ftore, but it here undergoes a remarkable fpontaneous change. No water carried to fea becomes putrid fooner than that of the Thames. When a cafk is opened, after being kept a month or two, a quantity of inflammable air (carburetted or fulphuretted hydrogen) efcapes, and the water is fo black and offenfive as fcarcely to be borne. Upon racking it off, however, into large earthen veffels, and expofing it to the air, it gradually depofits a quantity of black flimy mud, becomes clear as cryftal, and remarkably fweet and palatable. The Seine has a high reputation in France, and appears, from the experiments of M. Parmentier, to be a river of great purity. It might be expected that a river which has paffed by a large town, and received all its impurities, and been ufed by numerous dyers, tanners, hatters, and the like, that crowd to its banks for the convenience of plenty of water, fhould acquire thereby fuch a foulnefs as to be very perceptible to chemical examination for a confiderable diftance below the town; but it appears from the moft accurate examination, that where the ftream is at all confiderable, thefe kinds of impurity have but little influence in permanently altering the quality of the water, efpecially as they are for the moft part only fufpended, and not truly diffolved; and therefore mere reft, and efpecially filtration, will reftore the water to its original purity. Probably, therefore, the moft accurate chemift would find it difficult to diftinguifh water taken up at London from that procured at Hampton-court, after each had been purified by fimple filtration." The water of the Ebro alfo, notwithftanding this river paffes through feveral large towns, is remarkable for its purity. In general, thofe rivers which iffue from lakes are moft pure and tranfparent, while thofe chiefly

fupplied

supplied by springs and rain are the reverse. The water of some rivers is remarkable for its colour: thus that of the Tinto, in Spain, at its source is of a fine topaz, a circumstance from which the river takes its name. Others are of a yellowish or greyish-white, and the water of all such rivers usually holds a large proportion of some salt of lime in solution. In countries where bogs and marshes abound, the rivers are often tinged of a brownish colour.

e. Stagnant Waters.—Under this head are included the waters of lakes, pools, and reservoirs of every description, in which this fluid is exposed to the air in a state of rest. Stagnant waters, in general, present greater impurities to the senses than any others, from their usually containing a large proportion of animal and vegetable matters in a state of decomposition. Their taste in general is vapid, and destitute of that freshness and agreeable coolness which distinguish spring-water. Stagnant waters have various origins, but usually they are a mixture of rain, spring, and river water; and hence, besides the animal and vegetable matters they contain, may be supposed to be impregnated with the various saline matters usually met with in such waters. Many stagnant waters are said to contain the nitrate of potash; others, and especially some lakes, abound in the sulphate of magnesia; others in the carbonate of soda, as, for example, the natron lakes of Egypt and Hungary, which are generally very shallow. A lake in Thibet is impregnated with the borate of soda mixed with the muriate of soda, the waters of which seem to have a subterranean origin. Some lakes also are found impregnated with sulphuretted hydrogen gas. Stagnant waters are seldom perfectly colourless and transparent. Lakes, when deep, are usually of a blueish tinge, mixed with green; and when the neighbouring hills are covered with peat, &c. their water is always of a muddy-brownish tinge, as, for example, is the case with most of the lakes in Scotland.

1. *Uses of Potable Waters.*—If we were to be directed by the evidences of the senses alone, *spring*-waters would undoubtedly be pronounced to be the most wholesome, for they are universally admitted to be the most agreeable. All other waters have more or less of a flat insipid taste. This is especially the case with *distilled* and *rain* water; the first of which is quite pure, and the second nearly so. *Distilled* water, therefore, is seldom employed for drinking; and the difficulty of procuring it in large quantities almost precludes its use to any extent in the preparation of food, or in manufactures. Much, however, has been lately said of its medicinal powers by Dr. Lambe, who has recommended it in cancerous and other affections; and, as Dr. Saunders justly observes, water, when not already loaded with foreign matters, may become a solvent for concretions in the urinary passages; and as much good has been obtained from the use of very pure natural springs, a course of distilled water may be considered as a fair subject of experiment. *Distilled* water is an essential ingredient in the composition of many medicines, and often absolutely necessary in the prosecution of all nicer chemical processes in the liquid way. *Snow* and *ice* water form almost the constant drink of the inhabitants of cold climates during winter; and the masses of ice which float on the polar seas afford an abundant supply of fresh water to the mariner. "*Snow*-water," says Dr. Saunders, "has long lain under the imputation of occasioning those strumous swellings in the neck which deform the inhabitants of many of the Alpine valleys; but this opinion is not supported by any well-authenticated indisputable facts, and is rendered still more improbable, if not entirely overturned, by the frequency of the disease in Sumatra, where ice and snow are never seen, and its being quite unknown in Chili and Thibet, though the rivers of those countries are chiefly supplied by the melting of the snow with which the mountains are always covered." *Dew*, especially when collected in the month of May, was formerly in great repute as a cosmetic, and for many other purposes; but its use has been long entirely laid aside. *Spring*-waters, as before observed, from the air they contain, and from their grateful coolness, constitute by far the most agreeable of the potable waters, and are in more general use than any others. Their use, however, is stated sometimes to occasion in delicate stomachs an uneasy sense of weight, followed by a degree of dyspepsia. They have also been accused, especially when of the description termed *hard*, of inducing calculous affections; but this notion by most modern writers is considered as ill-founded. *Spring*-waters, in general, also, from their property of hardness, are, as before observed, very ill adapted for many domestic and other purposes; while, in particular instances, this quality is of advantage. Hard *spring*-waters, for example, are very ill adapted for the purposes of the dyer or bleacher. "On the other hand," says Dr. Saunders, "there are several saline substances which are very readily soluble in any kind of water, and here a hard water may be employed when the object is only to procure these particular salts. For culinary purposes, water is used either to soften the texture of animal or vegetable matter, or to extract from it, and present in a liquid form some of its soluble parts. Soft pure water will fulfil both these objects better than hard water; and at the same time the colour of the substance employed will vary as well as its solution. Green vegetables and pulse are rendered quite pale, as well as tender, by boiling in soft water; whereas in a hard water, the colour is more preserved, and the texture less altered, because in the former case the colouring matter of the vegetable is readily extracted by the menstruum, whilst in the latter more of it remains, and is likewise altered by the chemical action of the earthy or neutral salts." Dr. S. then relates some comparative experiments he made with hard and pure water upon tea; from which he concludes that hard water is less powerful in softening the texture of vegetable leaves than soft water, and that it is not able to exert its full effect in heightening their colour till assisted by heat; and also, that the gallic acid (or tannin) is equally well extracted by hard as by soft water, when by raising the temperature, the power of the former as a solvent is fully exercised. It may be therefore laid down as a general rule in domestic economy, that when the object is to extract the virtues of any substance, and to retain them in solution, *soft* waters should be used; but that when the object is the reverse, or to preserve as entire as possible the article used as food, *hard* waters are preferable.

Some fine springs of very pure and soft water have been long celebrated for their medicinal properties; as, for example, the *Malvern* springs, in Worcestershire, and *St. Winifrid's Well*, at Holywell, in Flintshire. *Malvern* water is used both externally and internally. Externally applied, it is stated to be a most useful application to deep-seated ulcerations of a scrofulous nature, and to various cutaneous affections. Its internal use is often of advantage "in painful affections of the kidneys and bladder, attended with the discharge of bloody, purulent, or fœtid urine; the hectic fever produced by scrofulous ulcerations of the lungs, or very extensive and irritating sores on the surface of the body; and also fistulas of long standing, that have been neglected, and have become constant and troublesome sores." The internal use of this water sometimes induces nausea at first, and occasionally drowsiness, vertigo, and head-ache, which soon go off, or may be readily removed by a mild purgative.

purgative. This water occafionally purges, but moft commonly the body becomes coftive under its ufe. "In all cafes, it increafes the flow of urine, and improves the general health of the patient; fo that his appetite and fpirits almoft invariably improve during a courfe of the water, if it agrees in the firft inftance." The duration of a courfe of this water depends in a great degree upon the nature of the difeafe under which the patient labours. Thefe obfervations upon the effects of the Malvern water are perhaps equally applicable to all fpring-waters of a fimilar degree of purity.

What has been faid of fpring-waters may be applied perhaps with little modification to *running* waters, which in general differ from *fpring*-waters only in being fofter, in containing lefs air, and in being therefore better qualified for many purpofes for which fpring-waters cannot be employed. *Stagnant* waters in general, efpecially in marfhy countries and hot climates, are ufually efteemed unwholefome, and perhaps defervedly fo. This arifes chiefly from the large quantity of vegetable and animal exuviæ which they contain, and perhaps from other circumftances of which we are at prefent ignorant. They fhould never be ufed, therefore, till they have been boiled and filtered; by which proceffes moft of the foreign fubftances will be probably removed. In general ftagnant waters, as Dr. Saunders obferves, are unpalatable; and this circumftance has probably caufed them to be fometimes in worfe credit than they actually deferve to be on the fcore of falubrity.

2. *Simple faline Waters.* — Under this denomination we include all thofe waters impregnated with neutral, alkaline, and earthy falts only. Waters of this defcription may be arranged under the following heads: — *a.* Brines, or waters whofe principal faline ingredients are the muriates of foda and magnefia; and *b.* Bitterns, or waters containing principally the fulphates of foda and magnefia.

a. Sea-water, which may be confidered as an example of the faline waters termed brines, is one of the moft abundant and extenfively diffufed compounds occurring upon our globe. When taken up at a confiderable diftance from the fhore it is quite tranfparent and colourlefs, and free from any fmell. Its tafte is ftrongly faline, and at the fame time naufeous and bitter. When kept for a fhort time it becomes highly offenfive, from the putrefaction of the animal and vegetable matters which it holds in folution. Its fpecific gravity varies in different latitudes and circumftances, but may be faid to lie between 1.0269 and 1.0285. The fpecific gravity is faid to be lefs within the polar circles than at the tropics, owing probably to the vaft quantities of ice found in thofe regions. The waters of inland feas alfo, that have little connection with the ocean, and the water of bays, &c. into which frefh-water rivers empty themfelves, contain in general lefs faline matters than the open ocean. This is particularly the cafe with the Baltic, efpecially when the wind blows from the eaft. The Mediterranean fea, on the contrary, is faid to be more faline than the Atlantic. Water taken from a confiderable depth is more faline than that taken from the furface, particularly after much rain, for rain-water being lighter appears to move upon the furface for a confiderable time before it becomes quite incorporated. The quantity of faline matter alfo is ftated to be greater in fummer than in winter. The water of the Britifh coafts is faid to contain upon an average about one-thirtieth of its weight of faline matter, and its temperature to vary between 40° and 65°. Sea-water does not freeze till cooled down to 28.°5. The following is one of the lateft analyfes of fea-water by Dr. Murray. A wine pint of water collected in the Firth of Forth was found to contain

	Grains.
Of lime - - - -	2.9
Magnefia - - - -	14.8
Soda - - - -	96.3
Sulphuric acid - - -	14.4
Muriatic acid - - -	97.7
	226.1

Or, fuppofing the elements to be combined in the modes in which they are obtained by evaporation; that is, as muriate of foda, muriate of magnefia, fulphate of magnefia, and fulphate of lime, the proportions of thefe falts in a pint will be,

	Grains.
Muriate of foda - - -	180.5
——— of magnefia - -	23.0
Sulphate of magnefia - -	15.5
——— of lime - - -	7.1
	226.1

Or, fuppofing that the lime exifts as muriate of lime, (which is the moft probable conclufion with regard to it); and farther, fuppofing that the fulphuric acid exifts in the ftate of fulphate of magnefia, the proportions will be,

	Grains.
Muriate of foda - - -	180.5
——— of magnefia - -	18.3
——— of lime - - -	5.7
Sulphate of magnefia - -	21.6
	226.1

Or, laftly, fuppofing that the fulphuric acid exifts in the ftate of fulphate of foda, the proportions will be,

	Grains.
Muriate of foda - - -	159.3
——— of magnefia - -	35.5
——— of lime - - -	5.7
Sulphate of foda - - -	25.6
	226.1

The bitter tafte of fea-water is owing chiefly to the muriate of magnefia which it contains. It may alfo arife, in part, from the prefence of decayed vegetable and animal fubftances. See the articles SALT, SALTNESS, and SEA.

Many attempts have been made to render fea-water potable. Of thefe the beft, and indeed the only good one, is diftillation.

The method of obtaining frefh water from the diftillation of fea-water was practifed by fir R. Hawkins, in the reign of queen Elizabeth, who thus obtained water that was wholefome and nourifhing. See Purchas's Collect. of Voyages, book vii. chap. 5.

Experiments were afterwards made by Hales, Lifter, Hanton, Lind, and others, to fimplify and render more perfect the procefs of diftillation, and at length it attained a great degree of perfection, both in France and England. Thus M. de Bougainville, in his Voyage round the World, bore ample teftimony to the utility of the machine for diftilling fea-water, which had been made public in 1763 by M. Poiffonnier, its inventor; and lord Mulgrave, in his

Voyage towards the North Pole, in 1773, did equal juſtice to the method of obtaining freſh water from the ſea by diſtillation, which had been introduced into the Engliſh navy in 1770, by Dr. Irving, and for which he obtained a parliamentary reward of 5000*l*.

Dr. Irving's contrivance conſiſted in converting the ſhip's kettle into a ſtill. Every ſhip's kettle is divided into two parts, by a partition in the middle; one of theſe parts is only in uſe when peas or oatmeal are dreſſed, but water is at the ſame time kept in the other, to preſerve its bottom. Dr. Irving availed himſelf of this circumſtance; and by filling the ſpare part of the copper with ſea-water, and fitting on the lid and tube, ſhewed that ſixty gallons of freſh water could be drawn off, during the boiling of either of the above-mentioned proviſions, without the uſe of any additional fuel. He recommended alſo the preſerving of the water diſtilled from the coppers in which peas, oatmeal, or pudding, are dreſſed, as both a ſalutary beverage for the ſcorbutic, and the moſt proper kind of water for the boiling of ſalt proviſions. Dr. Irving particularly directed that only three-fourths of the ſea-water ſhould be diſtilled, as the water diſtilled from the remaining concentrated brine was found to have a diſagreeable taſte; and as the farther continuation of the diſtillation proved injurious to the veſſels. For an account of the ſeveral experiments made on ſome of the beſt diſtilled water, prepared by Dr. Irving from ſea-water, by Dr. Watſon, ſee his Chem. Eſſ. vol. ii. p. 168, &c.

The ſhips of diſcovery lately ſent out by the French government are furniſhed with an economical diſtilling apparatus, and inſtead of water have taken with them a ſupply of fuel.

Dr. Prieſtley ſuggeſted a plan to give to diſtilled water the briſkneſs and ſpirit of freſh ſpring-water, and at the ſame time to render it, perhaps, a remedy or preventive againſt the ſcurvy, by impregnating it with carbonic acid gas. Diſtilled water alſo acquires, in a conſiderable degree, the grateful flavour of common water, by ſimple expoſure for ſome time to the atmoſphere.

Sea-water may be likewiſe rendered potable by converting it into ice. In the polar regions, therefore, there can be no want of freſh water. In warm climates, the ingenious freezing apparatus of Mr. Leſlie may be employed to procure a ſupply of freſh water from the ocean.

b. As an example of the bitterns we may ſelect the *Sedlitz water*, which is one of the beſt known, and ſtrongeſt of this deſcription of ſimple ſaline waters. Sedlitz is a village in Bohemia, and its waters, as well as thoſe of Seydſchutz in the immediate neighbourhood, and which cloſely reſemble them, were firſt brought into note about a century ago by the celebrated Bergman. The taſte of theſe waters is ſtrongly bitter and ſaline, but not in the leaſt briſk or acidulous, as they uſually contain a ſmall proportion of gaſeous matters. Thus the Seydſchutz water above-mentioned was found by Bergman to yield only 6 *per cent*. of gaſeous products, two-thirds of which only were carbonic acid. Its ſpecific gravity, as ſtated by the ſame chemiſt, is 1.006, and an Engliſh wine pint was found to contain of

	Grains.
Carbonate of lime - -	.944
Sulphate of lime - -	5.140
Carbonate of magneſia - -	2.622
Muriate of magneſia - -	4.567
Sulphate of magneſia - -	180.497
	193.770

Sulphate of ſoda is not mentioned as an ingredient in this water, although it doubtleſs exiſts in it; at leaſt this ſalt almoſt always occurs in waters of this deſcription.

Medicinal Properties and Uſes of the ſimple ſaline Waters.—All waters of this deſcription act more or leſs ſtrongly upon the bowels, according to the quantity of ſaline ingredients which they contain; hence they are often of the greateſt uſe in complaints where alvine evacuations are particularly indicated. They generally act alſo as diuretics. Sea-water and all brines have the property of inducing a ſenſation of thirſt. "Sea-water," ſays Dr. Saunders, "when uſed internally, ſhould be taken in ſuch doſes as to prove moderately purgative, the increaſe of this evacuation being the peculiar object for which it is employed: about a pint is generally ſufficient, and this ſhould be taken in the morning, at two doſes, with an interval of about half an hour between each. It is ſeldom neceſſary to repeat the doſe at any other time of the day. This quantity contains half an ounce of purgative ſalt, of which about three-fourths are muriate of ſoda."—"There is very little danger ever to be apprehended from an exceſſive doſe of ſea-water, except the inconvenience of a temporary diarrhœa, and ſometimes a ſoreneſs at the extremity of the rectum, which all ſaline purgatives are now and then apt to produce." The internal uſe of ſea-water, beſides its general uſe in diſeaſes where cathartics are indicated, has been recommended in various forms of ſcrofulous affection, eſpecially in indolent glandular tumours in the neck and other parts, which are commonly ſlow in ulcerating and in their cure; alſo in deep-ſeated ſcrofulous inflammations, followed by caries of the bones, profuſe diſcharges, and tedious exfoliation, and particularly in ſcrofulous ophthalmia. "In all ſuch caſes, the internal uſe of ſea-water is almoſt entirely confined to thoſe periods of the diſeaſe when there is no general fever and hectic tendency, when no ſymptoms of danger are preſent, and when the object is rather to prevent a relapſe than oppoſe any preſent diſeaſe. The external uſe of ſea-water either as a general cold bath, or as a topical application to indolent ſwellings, or granulating ulcers, when the healing proceſs has commenced, coincides perfectly well in theſe caſes with the general intention." The moſt important advantages of ſea-water are indeed probably derived from its external uſe as a bath. (See the articles BATH and BATHING.) With reſpect to the medicinal properties of the bitterns, we ſhall attempt to illuſtrate them by relating thoſe of the Sedlitz water, which we before ſelected as an example of the whole tribe. A pint of this water, taken in divided portions, is generally a full doſe for an adult, and the ſtrongeſt perſon ſeldom requires more than two pints. It operates very ſpeedily, and without producing griping or flatulency; and is ſtated by Hoffmann, as quoted by Dr. Saunders, to be of the utmoſt advantage in a foul ſtate of the ſtomach, and general torpor of the inteſtinal canal, as it not only ſtimulates theſe organs to expel their morbid contents, but by its bitterneſs reſtores their tone, and with it the appetite and digeſtive powers. "When the preſence of hypochondriaſis is marked by anxiety, general languor, perturbed dreams, a livid hue on the face, difficulty of breathing, pain of the back and head, vertigo and coldneſs of the extremities; when a bilious humour and a depraved ſecretion of the ſtomach impairs its tone and healthy action, and is attended with obſtinate coſtiveneſs; this water, by evacuating its contents and reſtoring the due force of contraction, enables it to throw off the offending matter."—"Numerous trials alſo have ſhewn the efficacy of this ſaline water in that cachexy of females attended with a ſuppreſſion of the menſtrual diſcharge, whereby

whereby are produced a general languor, difficult reſpiration, febrile heat and irritation, waſting of the body, and loſs of appetite. Alſo when women have arrived at that time of life when this periodical evacuation begins to ceaſe, and is ſucceeded by a number of anomalous diſorders, ſuch as proſtration of appetite, flatulent pains, irregular fluſhings, pains in the back and ſwelling of the feet, a courſe of Sedlitz water reſtores the wavering appetite, and diſperſes the tumours and other morbid ſymptoms. Men of from forty to fifty years of age, who have led a very ſedentary life, and have been accuſtomed to intenſe thought and profound meditation, become frequently affected with œdematous tumours in the extremities, a want of due action in the ſtomach, eructations after taking food, and a generally impaired ſtate of health; all of which are for the moſt part very certainly removed by a liberal uſe of this water. Perſons alſo of a plethoric habit of body, who from ſome obſtruction of blood in the abdominal viſcera, and have acquired a ſtrong diſpoſition to hæmorrhoidal affections, become thereby often expoſed to very ſerious evils. To ſuch perſons a ſaline water like that of Sedlitz is often of great utility, eſpecially if accompanied by blood-letting when requiſite, and a general antiphlogiſtic plan of cure. Another important uſe of theſe waters is in removing from the ſyſtem thoſe impurities and acrid humours which are uſually termed ſcorbutic." Such are the properties of the Sedlitz ſaline waters according to the celebrated Hoffmann, whoſe account, as quoted by Dr. Saunders, we have extracted, becauſe it preſents in few words a comprehenſive and rational view of the medicinal properties of this important tribe of waters in general. We wiſh however to obſerve, that when the ſtomach is in a very weak ſtate, and dyſpepſia is preſent in a very great degree, ſaline purgatives and waters in general may do harm by increaſing theſe affections; their uſe, therefore, in ſuch caſes is rather contra-indicated, or at leaſt ſhould be combined with other remedies calculated to invigorate theſe organs, eſpecially chalybeates.

3. *Simple chalybeate Waters.*—Chalybeate waters are either *ſimple* or *compound*. Under this head of *ſimple chalybeates* we include all waters whoſe characteriſtic ingredient is one or more of the neutral ſalts of iron. Theſe may be conſidered as of two general deſcriptions:—*a*. Waters containing the carbonate of iron, without any ſtriking exceſs of carbonic acid; and *b*. Waters containing the ſulphate or muriate of iron, generally in combination with a large proportion of the ſulphate of alumina. Waters of this laſt deſcription are much more rare than the former, and are uſually formed from the decompoſition of iron pyrites.

a. As an example of the firſt of theſe varieties of ſimple chalybeate waters, we may adduce that of Tunbridge Wells. This water has been lately ſubmitted to a careful and accurate analyſis by Dr. Scudamore, from whoſe pamphlet on the ſubject we chiefly take the following account. The temperature of the ſpring throughout the year is uniformly 50°; and its ſp. gr. in the month of Auguſt, at its natural temperature, was 1.0007. The freſh water is perfectly tranſparent, and does not ſend forth air-bubbles. It exhales a ſmell which is diſtinctly chalybeate. Its taſte in this reſpect is ſtrongly marked, but is neither acidulous nor ſaline. It has an agreeable freſhneſs, and is by no means unpalatable. Submitted to analyſis, one gallon was found to contain,

	Cubic Inches.
Of carbonic acid	8.05
Oxygen	.50
Azote	4.75
	13.30

	Grains.
Of muriate of ſoda	2.47
——— of lime	.39
——— of magneſia	.29
Sulphate of lime	1.41
Carbonate of lime	.27
Oxyd of iron	2.29
Traces of mangaueſe, inſoluble matter (vegetable fibre, ſilex, &c.)	.44
Loſs in proceſſes	.13
	7.69

Or, ſtating the reſults according to Dr. Murray's view, which will be particularly explained when we treat of the *analyſis* of mineral waters, the following eſtimate will appear:

	Grains.
Muriate of ſoda	1.25
Sulphate of ſoda	1.47
Muriate of lime	1.54
——— of magneſia	.29
Carbonate of lime	.27
Oxyd of iron	2.29
Traces of manganeſe, &c.	.44
Loſs, &c.	.13
	7.68

This latter eſtimate, which renders the carbonate of iron the moſt abundant ingredient in the water, appears much more probable than the former, and to account more ſatiſfactorily for its medicinal effects.

b. One of the moſt ſtriking examples of the ſecond variety of ſimple chalybeate waters is that occurring in the Iſle of Wight, and lately analyſed by Dr. Marcet. This ſpring iſſues from a cliff on the S.S.W. ſide of the iſle, immediately under St. Catherine's Down, in the pariſh of Chale, between which village and the village of Niton it is nearly equidiſtant. The diſtance from the ſea-ſhore is about 150 yards, and elevation about 130 feet above the level of the ſea. Its properties, &c. are the following:—When it firſt iſſues from the rock it is perfectly tranſparent, and remains ſo if kept in cloſe veſſels; but when expoſed to the air, reddiſh flakes are ſoon depoſited in it. It has a ſlight chalybeate ſmell, and a highly aſtringent and ſtyptic taſte. Its ſpecific gravity, in a courſe of ſeveral experiments, was found to be 1007.5. One pint or ſixteen-ounce meaſures yielded

Of carbonic acid $\frac{3}{10}$ths of a cubic inch,

	Grains.
Sulphate of iron, in the ſtate of cryſtallized green ſulphate	41.4
Sulphate of alumina, a quantity of which, if brought to the ſtate of cryſtallized alum, would amount to	31.6
Sulphate of lime dried at 160°,	10.1
Sulphate of magneſia cryſtallized	3.6
Sulphate of ſoda cryſtallized	16.0
Muriate of ſoda cryſtallized	4.0
Silica	0.7
	107.4

This therefore is the ſtrongeſt aluminous chalybeate known.

Medicinal Properties and Uſes of ſimple chalybeate Waters.—*a*. The ſeaſon for drinking the Tunbridge water, which we have ſelected as an example of the ſimple carbonated chalybeates,

lybeates, is uſually from May to November. On entering upon the uſe of this water ſome aperient ſhould be premiſed; and Dr. Scudamore recommends that the firſt doſe ſhould be taken at ſeven or eight o'clock in the morning, the ſecond at noon, and the third about three in the afternoon. The exact quantity to be taken muſt be varied according to circumſtances; but "as a general ſtatement," ſays Dr. S., "I would ſay that half a pint daily is the extreme ſmalleſt quantity, and that two pints daily is the extreme largeſt amount to found a juſt expectation of benefit; and further, in the way of general outline of direction, I conceive that half a pint, a pint, a pint and a half, and two pints, ſhould form the progreſſive ratio of the total daily quantity to be taken at the three intervals. As the patient arrives at the larger proportions, they may with advantage be ſubdivided with the interval of a quarter or half an hour, which ſhould be occupied in exerciſe." Tea at breakfaſt is directed to be avoided; and in caſes when the water diſagrees at its natural temperature, it is recommended to be adminiſtered warm. "On the firſt employment of the water, either cold or warm, ſome inconvenient ſenſations very commonly ariſe, ſuch as fluſhing of the face, ſlight fulneſs of the head, with drowſineſs and an uneaſy diſtenſion of the ſtomach, together with continued flatulence. In general theſe effects are not of importance, either in degree or duration, and are much to be prevented by previous attention to the ſtomach and bowels."—"As a general ſtatement, it may be added, that the employment of this water is improper in a very plethoric ſtate of the circulation; alſo when there is an inflammatory determination to any particular organ, or even when local congeſtion exiſts without inflammation. In caſes of ſimple debility of the conſtitution, the water promiſes to produce its happieſt effects. The proofs of its immediately agreeing with the patient are increaſed appetite and ſpirits, and theſe auſpicious ſymptoms are followed by a gradual improvement in the general energy and ſtrength." The bowels uſually become conſtipated under its uſe, and require the aſſiſtance of medicine. The warm bath is occaſionally of ſervice in conjunction with this water, as was long ago pointed out by Hoffmann. Exerciſe alſo after its uſe is generally of great importance. In dyſpepſia depending on debility of the ſtomach, and accompanied with general languor and nervouſneſs, this water is remarkably reſtorative. In uterine debility alſo, and chloroſis, its uſe is often of the utmoſt ſervice. It has been much recommended likewiſe in ſome cutaneous affections. For the complaints of children, eſpecially when young, (that is to ſay, under ſix or ſeven years of age,) it is not in general adapted, for reaſons ſufficiently obvious. A courſe of this water may vary from three weeks to two or three months, according to circumſtances. *b.* With reſpect to the medicinal properties of waters containing the ſulphates of iron and alumina, as the Iſle of Wight and Hartfell waters above-mentioned, they differ little perhaps, except in degree, from thoſe of the ſimple chalybeate waters. The Iſle of Wight water is ſo ſtrong, that it is always proper to dilute it at firſt with twice its quantity of common water; and even then the doſe cannot well exceed two or three ounces, which may be gradually increaſed to about a pint in twenty-four hours. Dr. Saunders recommends the ſame quantity as the maximum doſe of the Hartfell water. Both theſe waters are often much improved by being gently heated, eſpecially in caſes where the ſtomach is very delicate and irritable. Dr. Lempriere, who has written a pamphlet on the Iſle of Wight water, ſtates, that he found it particularly ſerviceable in the debility induced by the Walcheren fever, chronic dyſentery, &c. as well as in every inſtance when the conſtitution had been undermined by previous illneſs, and the ordinary tonics had failed. It is particularly neceſſary to guard againſt coſtiveneſs during the uſe of theſe waters.

Compound Chalybeate Waters.—Theſe may be divided into *a. Saline chalybeates*, and *b. Acidulous chalybeates.*

a. The Cheltenham waters, properly ſo called, are a good example of the *ſaline chalybeates.* (For the hiſtory of theſe waters, ſee CHELTENHAM.) Since that article was written, however, ſeveral ſprings of different qualities and powers have been diſcovered by Mr. Thomſon; an abſtract of the compoſition and properties of which, as lately publiſhed, we ſhall now take the opportunity of laying before our readers.

The ſprings which have been deſcribed and analyſed by Meſſrs. Brande and Parkes are ſix, *viz.*

1. The ſtrong chalybeate ſaline water. Sp. gr. 1009.2.
2. The ſtrong ſulphuretted ſaline water. Sp. gr. 1008.5.
3. The weak ſulphuretted ſaline water. Sp. gr. 1006.
4. The pure ſaline water. Sp. gr. 1010.
5. The ſulphuretted and chalybeated magneſia ſpring, or bitter ſaline water. Sp. gr. 1008.
6. Saline chalybeate, drawn from the well near the laboratory.

The following Table preſents a view of the contents of a wine pint of theſe different ſprings.

The

The *medicinal properties* of theſe different ſprings of courſe vary according to their compoſition and ſtrength. Mr. Thomſon, the proprietor, procures from them ſix different ſaline preparations, neither of which, however, is preciſely ſimilar to the water drank at the ſpa. Theſe he denominates, cryſtallized alkaline ſulphates; ditto effloreſced and ground to an impalpable powder for hot climates; magneſian ſulphate in a ſtate of efloreſcence; a murio-ſulphate of magneſia and iron in brown cryſtals, highly tonic; ſub-carbonate of magneſia in powder, and calcined magneſia.

b. As an example of the *acidulous chalybeates*, we may adduce the celebrated waters of Spa. (See SPA.) Dr. Jones has lately publiſhed an intereſting paper on theſe waters, which contains, among other things, analyſes of the different ſprings, of the reſults of which the following table preſents a ſummary view.

TABLE exhibiting the Nature and Proportion of the Subſtances contained in One Gallon of the reſpective Spa Waters.

* Quantity not appretiable.

With reſpect to the *medicinal properties* of the compound chalybeates, they are, as might be expected, of a mixed character, and uſually correſpond with the nature of the predominant impregnating ingredients; hence their properties will be readily underſtood from what has been advanced. For further particulars reſpecting the medicinal properties of the CHELTENHAM and SPA waters, we refer our readers to theſe articles.

4. *Simple Acidulous Waters.*—Under this denomination may be included all waters whoſe characteriſtic ingredient is an acid. They may be conſidered as of two deſcriptions: *a.* Thoſe impregnated with a volatile acid, as the carbonic and ſulphurous acids; and *b.* Thoſe containing a fixed acid, as the muriatic and ſulphuric acids.

a. The waters of Seltzer may be adduced as an example of the firſt variety of acidulous waters. "Seltzer is a village ſituated in a fine woody country, about ten miles from Frankfort, and thirty-ſix from Coblentz, in a diſtrict which abounds with valuable mineral ſprings." This water has been examined by Hoffmann, Bergman, and others. When freſh from the well, it is perfectly clear and pellucid, and ſparkles much when poured into a glaſs. Its taſte is ſlightly pungent, but at the ſame time gently ſaline and alkaline. On expoſure to the air for a ſhort time, the carbonic acid eſcapes, and the alkaline taſte becomes more perceptible. According to Bergman, an Engliſh pint contains of

		Cub. Inches.
Carbonic acid upwards of	-	17
		Grains.
Carbonate of lime about	-	3
Carbonate of magneſia	-	5
Carbonate of ſoda	- -	4
Muriate of ſoda	- -	17.5
		29.5

b. Waters containing a free mineral acid in exceſs are very rare, and chiefly confined to volcanic countries. Mr. Garden has lately examined a water of this deſcription from White iſland, on the coaſt of New Zealand: it was of a pale yellowiſh-green colour; its odour reſembled that of a mixture of muriatic and ſulphurous acids. Its taſte was ſtrongly acid and ſtyptic, like that of a chalybeate. Its ſpecific gravity 1.073. On being ſubmitted to analyſis, its contents were found to conſiſt chiefly of muriatic acid, a ſlight trace of ſulphur, ſmall proportions of alum, muriate of iron, and ſulphate of lime. Waters impregnated with

ſulphuric

ſulphuric acid are ſometimes met with likewiſe in the vicinity of volcanoes.

As to the *medicinal properties* of theſe waters, they probably differ little from thoſe of a dilute ſolution of the different acids which they contain. For the particular properties of the Seltzer water, ſee SELTZER.

Compound Acidulous Waters.—Acidulous waters ſometimes contain ſo large a proportion of ſaline matters, that the nature of their operation is conſiderably modified. Such waters may be denominated *ſaline acidulous* waters. The nature of their *compoſition* and *medicinal properties* will be readily underſtood from what has been already advanced.

5. *Sulphureous Waters.*— Theſe are either *ſimple* or *compound*. A good example of a *ſimple* ſulphureous water is the Moffat ſpring. The village of Moffat is ſituated in Dumfriesſhire, on the banks of the Annan, about fifty miles ſouth-weſt of Edinburgh. The ſulphureous waters for which this village is noted, iſſue from a rock a little below a bog, whence, ſays Dr. Saunders, they probably derive their ſulphureous ingredient. This water, even when firſt drawn, appears ſomewhat milky. Its taſte is ſulphureous, and ſlightly ſaline. It ſparkles a little when poured from one glaſs into another. On expoſure to the air, it becomes more turbid, and throws up a thin film, which is pure ſulphur, and it thus loſes its diſtinguiſhing properties as a ſulphureous ſpring. This change even takes place in cloſe veſſels, ſo that it cannot be exported with any advantage. According to Dr. Garnett's analyſis, a wine pint of this water contains

	Cubic Inches.
Of ſulphuretted hydrogen -	1.25
Of carbonic acid - -	.625
Of azote - - -	.5
	2.375

And of muriate of ſoda 4.4 grains.

With reſpect to the *medicinal properties* of ſimple ſulphureous waters, they have been always celebrated for their good effects in cutaneous affections in general, and alſo in ſcrofula. They are applied externally in the form of a warm bath, as well as taken internally. They have been alſo recommended in bilious complaints, dyſpepſia, general want of action in the alimentary canal, and calculous caſes. The quantity of the Moffat waters uſually preſcribed internally varies from one to three bottles every morning. But Dr. Saunders juſtly obſerves, that few delicate ſtomachs can bear ſo much. On the other hand, the ſame eminent phyſician informs us, that the common people not unfrequently ſwallow from ſix to ten Engliſh quarts in one morning.

For further particulars reſpecting this ſpring, ſee MOFFAT.

Sulphureous waters frequently contain ſo conſiderable a proportion of ſaline ſubſtances as to merit the name of *compound*. An example of ſuch waters we have in the celebrated ſprings of Harrowgate, in Yorkſhire. (See HARROWGATE.) This water, when firſt taken up, appears perfectly clear and tranſparent. It emits a few air-bubbles. Its ſmell is very ſtrong, ſulphureous, and fœtid, like that of a foul gun-barrel. Its taſte is bitter, nauſeous, and ſtrongly ſaline; though it is remarkable that moſt perſons ſoon become reconciled to it. On expoſure to the air, it becomes turbid, the ſulphureous odour is diminiſhed, and the ſulphur is gradually depoſited. According to Dr. Garnett, its ſpecific gravity is 1.0064. A wine pint, according to the experiments of the ſame chemiſt, was found to contain about

	Cubic Inches.
Of ſulphuretted hydrogen -	2.375
Carbonic acid gas - -	1.000
Azote - - - - -	.875
	4.25

And of

	Grains.
Muriate of ſoda - - -	76.9
Muriate of lime - - -	1.6
Muriate of magneſia - -	11.4
Carbonate of lime - -	2.3
Carbonate of magneſia - -	.7
Sulphate of magneſia - -	1.3
	94.2

With reſpect to the *medicinal properties* of waters of this deſcription, and particularly of Harrowgate water, they are of the greateſt uſe in all thoſe complaints that require purgatives, and at the ſame time are benefited by ſulphur; hence they have been long celebrated in cutaneous affections, in piles, worms, &c. They have alſo been found of great uſe in that obſtinately coſtive habit of body which uſually accompanies hypochondriaſis. Harrowgate waters were formerly principally applied externally, but now they are generally recommended to be taken internally, in ſuch doſes as to produce a ſenſible effect upon the bowels; for which purpoſe it is commonly neceſſary to take in the morning three or four glaſſes, of rather more than half a pint each, at moderate intervals.

6. *Thermal Waters.*—There is ſomething ſo myſterious and remarkable in the circumſtances of thermal ſprings, that they have in all ages attracted great attention, and been ſuppoſed to poſſeſs extraordinary medicinal properties. Hence, by moſt writers on mineral waters, thermal ſprings have been arranged under a diſtinct head; and as there appears to be no ſerious objection to this arrangement, we have thought proper to adopt it. The inveſtigation of the *cauſe* of thermal ſprings belongs to the geologiſt, and will be found under EARTH, HOT *Springs*, TEMPERATURE, VOLCANO, and analogous articles.

They may be divided into *ſimple* and *compound*.

Simple thermal waters are either *tepid*, that is, poſſeſſing a temperature below that of the human body; or *warm*, poſſeſſing a temperature above that point. A good example of the ſimple tepid waters are thoſe of Buxton. (See BUXTON *Water*.) *Tepid* waters uſually occur in lime-ſtone diſtricts. *Warm* waters of every degree of temperature, even to the boiling point, are occaſionally met with in the neighbourhood of volcanoes. See VOLCANO.

With reſpect to the *medicinal properties* of the ſimple thermal waters, it is extremely doubtful if they poſſeſs any other powers than thoſe of common water artificially raiſed to the ſame temperature.

Thermal ſprings are liable to be impregnated with all the different ſubſtances which uſually enter into the compoſition of cold mineral waters; hence they are very various in their nature. Such *thermal* waters may be called *compound*, and without any great ſacrifice of the principles of arrangement we have adopted, may be compriſed under three heads; namely, *a*. Saline thermal waters, *b*. Acidulo-chalybeate thermal waters, and *c*. Sulphureous thermal waters;

waters; each of which varieties may be either *tepid* or *warm*.

a. Thermal waters fimply *faline* are very rare. Their properties can in no refpect be fuppofed to differ from cold faline waters raifed to the fame temperature. Sea-water, therefore, heated artificially, is a good example of this variety. It is generally ufed externally as a bath. See BATHING.

b. A good example of the *acidulo-chalybeate* thermal waters we have in the fprings of Carlfbad. For a full account of the chemical properties of thefe fprings, fee CARLSBAD.

c. The celebrated waters of Aix-la-Chapelle, or Aken, afford a good example of the *fulphureous* thermal waters. See AIX-LA-CHAPELLE.

With refpect to the *medicinal properties* of the compound thermal waters, they have all been in much repute as baths, which was, perhaps, the original mode in which the two laft varieties in particular were employed. In later times, they have been much ufed internally. The difeafes, fays Dr. Saunders, to the cure of which the internal ufe of Carlfbad waters are applicable, are as various as the nature of their foreign contents; and from the union of feveral valuable qualities in one water, it may be made ufe of in cafes of very oppofite natures, without incurring the cenfure of employing it indifcriminately as an univerfal medicine. In common with the other purgative chalybeates, it is found to be eminently ferviceable in dyfpepfia and other derangements of the healthy action of the ftomach, in obftructions of the abdominal vifcera, not connected with great organic difeafe, and in defect or depravation of the biliary fecretion. It is alfo of ufe in calculous affections, and is highly efteemed for reftoring the uterine fyftem to a healthy ftate. The fame precautions againft its internal ufe in plethoric and irritable habits, and thofe who are fubject to hæmoptyfis, or liable to apoplexy, require to be obferved here as with any of the other active thermal waters. The Aix-la-Chapelle waters, taken internally, are likewife found effentially ferviceable in the numerous fymptoms of diforders in the ftomach and biliary organs, that follow a life of high indulgence in the luxuries of the table. It alfo much relieves painful affections of the kidneys and bladder. The fame precautions in its ufe are to be attended to, as thofe abovementioned refpecting the Carlfbad waters. For the external ufes of thefe waters, fee BATHING, and the articles CARLSBAD and AIX-LA-CHAPELLE, before referred to.

Our readers will readily perceive, from the above fyftematic fketch, that the infinite variety which exifts among mineral waters abfolutely precludes a *perfect* arrangement of them: we truft, however, that no mineral water can occur which may not be referred to one or other of the above heads or their fubdivifions, without any great facrifice of our principles of arrangement; and, confequently, whofe general medicinal properties cannot be eftimated with tolerable accuracy *à priori* from its chemical compofition.

On the general Ufes of Water in a dietetic and medicinal Point of View.—No organic procefs nor interchange of elements can be fuppofed to take place without the intervention of a fluid; organized beings, therefore, contain a large proportion of fluid in their compofition, through the medium of which that endlefs feries of changes, effential to their exiftence, is principally effected. The bafis of this fluid is univerfally water, which of all other fluids is the moft eminently fitted for diffolving and holding in folution every variety of animal and vegetable matter. See FOOD *of Plants*.

In animals, the firft great ftep in the feries of vital proceffes is *digeftion;* and here nature appears to render the prefence of a fluid particularly neceffary, in order, as it were, to infure for herfelf a fufficiency for her future operations. Accordingly, we find that all animals inftinctively take in a certain proportion of fluid, either in the form of fimple water, or fucculent food. Man alone is the only animal accuftomed to fwallow unnatural drinks, or to abufe thofe which are natural; and this is the fruitful fource of a great variety of his bodily and mental evils.

We know little of the intimate nature of the digeftive procefs, but we know that it is chiefly effected by means of a highly animalized fluid fecreted by the ftomach itfelf. Now this important fluid, by drinking too little or too much, or by other caufes, may be rendered too concentrated or too dilute for the due performance of its operations; and dyfpepfia, and all its confequences, may thus enfue from habitual errors in the quantity of drink only. The remedy in fuch cafes is obvious, and confifts perhaps in nothing more than in duly regulating the quantity of watery aliment, as dictated by inftinct, or the fenfation of thirft only.

An eminent modern phyfiologift recommends to abftain from drinking during meals, and for fome time afterwards; and as a general rule, this may, perhaps, be proper, fince a healthy ftomach may be fuppofed to be always able to fecrete fluid enough for its own immediate operations: there can be no doubt, however, but many exceptions to this rule may be met with, arifing either from the nature of the food or condition of the ftomach, in which moderate dilution is not only grateful but falutary.

With refpect to the choice of water as an article of diet, (for our readers will underftand that we fpeak of water only in this place,) thofe which are hard and impure have long lain under the imputation of producing calculous affections; and we have good authority for ftating, that, in many inftances, the ufe of fuch waters actually increafes the painful fymptoms of thefe diftreffing complaints. It is not perhaps an eafy tafk to explain this, fince, with the exception of lime, the fubftances found in hard waters never enter into the compofition of calculi: their operation, therefore, muft be rather of a predifpofing nature, and is probably exerted upon the organs of digeftion, which are well known to be intimately connected with the kidney. A fact which renders this opinion the more probable is, that hard waters are often pofitively noxious to irritable ftomachs, by inducing dyfpepfia. In fhort, pure water, as we formerly obferved, muft obvioufly be much better adapted for the important purpofes of dilution and folution, than water already faturated as it were with foreign fubftances; and upon this principle may probably be fatisfactorily explained the good effects of Malvern and other waters, whofe only characteriftic property is, their remarkable degree of purity.

In a medicinal point of view, the ufe of water as a diluent is moft important; and, as Dr. Saunders juftly obferves, the long lift of ptifans, decoctions, &c. ufually prefcribed by phyficians in acute difeafes, owe their virtues almoft entirely to the watery diluent itfelf.

The inftinctive defires or averfions, continues the fame eminent writer, of perfons labouring under any fpecies of difordered functions, have been juftly confidered as deferving the higheft attention from the phyfician, and in moft cafes will furnifh him with ufeful hints for his treatment of the patient. In acute difeafes, the thirft after water is peculiarly remarked as a characteriftic fymptom, and is a direct inftinctive indication of increafed heat and want of dilution; and this is fo uniform, that the degree of fever may often be pretty well eftimated by the eagernefs of the fufferer after cold drink. The benefits arifing from large dilution in acute difeafes, however, are not confined to the mere

mere quenching of thirſt, though this is in itſelf highly advantageous; but it is after ſo much liquid is added to the circulating maſs, that the truly diluent effects are produced. Theſe conſiſt, in Dr. S.'s opinion, in diminiſhing the morbid heat and violence of reaction in the ſolids; in preſerving all the ſecretory organs in a pervious ſtate; and in checking that tendency to ſpontaneous change, which renders the fluids poſitively noxious to the veſſels in which they are contained, and unfit to perform thoſe functions, on which the health of the body ſo eſſentially depends.

It appears poſſible, however, in the opinion of the ſame author, to carry dilution in active fever to exceſs. In fever, as is well known, the exhalent veſſels are comparatively inactive, or morbidly conſtricted, and the ſecretion of urine is defective in quantity. In ſuch caſes, it is often better to take liquids in ſmall divided doſes, which has the effect of moderating the thirſt, without overloading the arterial ſyſtem, and bringing on that tenſion and plenitude liable to be produced by ſwallowing too large a proportion of liquids.

In the uſe of water in acute diſeaſes, the temperature ſhould be particularly attended to. As a general rule it may be laid down, that the temperature of diluents at the different periods of a cold, hot, and ſweating ſtage of a ſimple febrile paroxyſm, ſhould be hot in the firſt caſe, cold in the ſecond, and tepid in the third; and it is chiefly in the ſecond ſtage that the quantity may be moſt liberal.

Moſt of the above remarks are equally applicable to the uſe of water in chronic diſeaſes in general, but more eſpecially in the deranged functions of the ſtomach and bowels and biliary organs, occaſioned by a long and habitual indulgence in high food, ſtrong drink, and all the luxuries of the table, and which are well known to be ſo decidedly benefited by the uſe of water as a medicine. As in acute diſeaſes, ſo in chronic affections likewiſe, it is often of great importance to attend to the temperature of the water. A draught of cold water, for example, will often induce ſickneſs and other diſtreſſing ſymptoms in delicate dyſpeptic habits, while water rendered ſlightly tepid may be taken with impunity and even advantage. On the other hand, the habitual uſe of warm water or drinks is to be avoided, and doubtleſs always does much harm.

We ſhall cloſe theſe remarks by a quotation from Dr. Saunders on the habitual uſe of water. "Water-drinkers," ſays this eminent writer, "are in general longer livers, are leſs ſubject to decay of the faculties, have better teeth, more regular appetites and leſs acrid evacuations, than thoſe who indulge in a more ſtimulating diluent for their common drink."

For the *external* uſes of water, ſee the articles BATH and BATHING, where this part of the ſubject is treated at length.

On the general Contents of Mineral Waters and their Operation.—The proportions of ſaline and other ingredients in mineral waters are for the moſt part ſo ſmall, as apparently to be inſufficient for explaining the effects they often produce upon the animal economy. Many attempts, therefore, have been made to explain this circumſtance by different writers, and the ſubject is ſo intereſting, that we cannot let it paſs without making a few remarks upon it.

Dr. Saunders, one of the lateſt and beſt writers on mineral waters, very properly ridicules the idea of *ſpecific* and other myſterious properties, by which the older authors attempted to explain their operation. This intelligent phyſician ſuppoſes, that a very great proportion of their effects depends ſolely upon the diluent operation of the water itſelf. Of this, as we formerly obſerved, there can be no doubt, in many inſtances; and even in all, the mere bulk and temperature of the water muſt be allowed to produce a certain proportion of the effects. Still, however, innumerable inſtances occur, in which theſe are inſufficient to explain the whole, even when aided by the additional circumſtance of great dilution, on which the above eminent phyſician likewiſe lays great ſtreſs. The matter, therefore, has always appeared ſufficiently puzzling, and it is only lately that a little light has been thrown upon it by the ingenious views of Dr. Murray, which will be more fully explained in the next ſection.

There can be no doubt that ſoluble ſalts in general are capable of exerting a much more powerful effect upon the animal economy, *cæteris paribus*, than thoſe which are inſoluble. The muriates are the moſt ſoluble claſs of ſalts occurring in waters, and are moreover, independently of this, the moſt active; at leaſt, this is the caſe with the earthy muriates, eſpecially the muriate of lime. Now this ſalt, Dr. M. has rendered it probable, exiſts in all mineral waters found by the uſual analytic method to contain the ſulphate of lime and muriate of ſoda, which comprehend by far the greater number. The ſame ingenious author has alſo rendered it probable, that iron not unfrequently exiſts in the ſtate of muriate inſtead of carbonate, as commonly believed, as for example, in the Bath waters. With theſe views in general we perfectly coincide, and have no doubt that, in many inſtances, a large proportion of the good effects of mineral waters ariſes from the muriates they contain; but we muſt confeſs that many difficulties ſtill appear to us to remain on this obſcure ſubject, which cannot, in the preſent ſtate of our knowledge, be ſatisfactorily explained.

Analyſis of Mineral Waters.—The analyſis of mineral waters has been juſtly deemed one of the moſt difficult problems in practical chemiſtry. This ariſes partly from the diverſified nature of the ingredients, and partly from the minute proportions in which ſome of them exiſt. The celebrated Bergman was the firſt chemiſt who preſented the world with a general method or formula for analyſing mineral waters. This was eſteemed excellent in its day, and even at the preſent time may be conſidered valuable. Twenty years afterwards, Mr. Kirwan publiſhed an eſſay on the ſubject, which not only compriſed all that had been previouſly done, but contained many valuable additions made by himſelf. He alſo propoſed a new method of analyſis, of which we ſhall give a ſhort account hereafter.

a. The firſt ſtep in the examination of a mineral water, is to notice accurately its ſenſible properties, ſuch as its temperature, colour, tranſparency, taſte, ſmell, &c.

b. The ſecond ſtep is to aſcertain its ſpecific gravity, the ſpontaneous changes it undergoes on expoſure to the air, the application of heat, &c.

c. Theſe preliminary operations being performed, the next object of inquiry, is to endeavour to obtain a knowledge of the different ingredients preſent by means of *reagents*, or *teſts*, as they are uſually termed. We have already mentioned the different ingredients commonly met with in mineral waters, and ſhall now proceed to give a liſt of the different *teſts* by which their preſence may be detected. For this liſt we are chiefly indebted to Dr. Thomſon, who has compiled it from Kirwan and others.

1. The *Gaſeous Subſtances* may be ſeparated from water, by boiling it in a retort connected with a pneumatic apparatus, and their nature and proportions may be aſcertained in the manner to be preſently deſcribed.

2. *Hydrogen and its Compounds.*—*Sulphuretted* hydrogen is readily diſtinguiſhed by its peculiar ſmell, by its reddening litmus fugaciouſly, and by its blackening paper dipped in ſolution

lution of lead. *Carburetted* hydrogen may be detected by its inflammable nature, and by its yielding carbonic acid by combuftion. *Phofphuretted* hydrogen may be known by its peculiar fmell and fpontaneous inflammability.

3. *Atmofpheric Air: Oxygen and Azote.*—The prefence of *oxygen gas* may be known by its power of fupporting combuftion, and by the diminution which takes place on mixing it with nitrous gas or phofphorus. There is no teft for *azote*, but it is fufficiently characterized by its negative properties.

4. *Alkalies and Alkaline Earths.*—The *alkalies* and *alkaline earths*, as well as their *carbonates*, are diftinguifhed in general by the following tefts. Turmeric paper is rendered brown by alkalies, or reddifh-brown, if the quantity be minute. Brazil wood is rendered blue not only by the alkalies, but alfo by the alkaline and earthy carbonates. Litmus paper reddened by vinegar is reftored to its original colour by alkalies, and alfo by the alkaline and earthy carbonates. If thefe changes are fugacious, we may conclude that the alkali is ammonia. *Fixed* alkalies are indicated when a precipitate is produced by muriate of magnefia after being boiled. The *volatile* alkali, or ammonia, may be readily diftinguifhed by its fenfible properties. The *earthy* and *metallic* carbonates are precipitated by boiling the water containing them, except carbonate of *magnefia*, which is only precipitated imperfectly. With refpect to the individual fubftances of this clafs—*Potafh* may be diftinguifhed by the precipitate it produces with the muriate of platina, the fulphate of alumina, and tartaric acid. For *foda* there is no good teft, but its falts are eafily diftinguifhed from thofe of potafh. *Ammonia* may be known from its odour and other properties above-mentioned. *Lime* is detected by means of the oxalic acid, which occafions a white precipitate. To render its operation certain, however, the mineral acids, if prefent, muft be faturated with an alkali. *Magnefia* and *alumina*. Pure ammonia precipitates both thefe earths and no other, provided the carbonic acid has been previoufly feparated. Lime-water alfo precipitates only thefe two earths, provided the carbonic and fulphuric acids be previoufly removed. The *alumina* may be feparated from the *magnefia* by boiling the precipitate in pure potafh, which diffolves the alumina and leaves the magnefia. *Silica* may be afcertained by evaporating a portion of the water to drynefs, and rediffolving the precipitate in muriatic acid. The *filica* remains behind undiffolved.

5. *Metals.*—The prefence of *metals* may be fufpected, if precipitates are produced by the pruffiate of potafh and fulphuretted hydrogen. *Iron* may be difcovered by the following tefts. The addition of tincture of nut-galls gives water containing iron a purple or black colour. If the tincture has no effect upon the water after boiling, though it coloured it before, the iron is in a ftate of carbonate. Pruffiate of potafh produces a fine blue precipitate in water containing iron, provided no excefs of alkali be prefent, which muft be faturated with an acid. *Manganefe* is occafionally prefent in minute quantity, efpecially in chalybeate waters. It may be precipitated by ammonia with proper precaution, and is known by the beautiful violet hue it imparts to borax, on being fufed with that fubftance. *Copper* is occafionally met with in waters. It may be detected by the fine blue colour produced on the addition of ammonia; by the red-coloured precipitate produced by the pruffiate of potafh; or it may be obtained in the *metallic* ftate by plunging into the water a piece of polifhed iron. *Lead* is fometimes found in waters that have traverfed leaden pipes. Such waters are blackened by a current of fulphuretted hydrogen gas; but to render the prefence of the metal more certain, a portion of the water is to be evaporated to drynefs; the remainder is to be tefted with nitric acid, and afterwards tefted with folutions of the carbonate and fulphate of potafh, which produce white precipitates, from which the lead may be readily obtained in the metallic ftate.

6. *Acids.*—*Carbonic acid*, in a free or uncombined ftate, may be detected by lime-water, which occafions a precipitate foluble with effervefcence in muriatic acid; or by the infufion of litmus, which is reddened, but becomes again blue on expofure to the air. Water containing free carbonic acid lofes this property of reddening litmus by boiling. The *fulphuric acid* is readily diftinguifhed by the muriate, nitrate, or acetate of barytes, ftrontian, and lime, and alfo by the nitrate or acetate of lead. The moft delicate of thefe tefts is the muriate of barytes: this produces a white precipitate, infoluble in muriatic acid. To enfure the operation of this teft, it is neceffary that no earthy or alkaline combination be prefent in the water. The *muriatic acid* is detected by the nitrate of filver, which occafions a white curdy precipitate, infoluble in nitric acid. To enfure the operation of this teft, the alkaline and earthy carbonates muft be previoufly faturated with nitric acid; and the fulphuric acid, if any be prefent, muft be feparated by the nitrate of barytes. *Boracic acid* is detected by means of the acetate of lead. The precipitate formed is infoluble in acetic acid. To render this teft certain, the alkalies and earths muft previoufly be faturated with acetic acid, and the fulphuric and muriatic acids removed by means of the acetate of ftrontian and the acetate of filver.

Such is a brief account of the different *tefts* ufually employed to detect the ingredients prefent in mineral waters, and the moft obvious precautions to be obferved in their ufe. It is proper, however, to obferve, that there are many circumftances to be attended to, in the ufe of tefts in general, which can only be learnt by perfonal obfervation and practice, and that the inexperienced chemift is very liable to be mifled by them.

d. Having thus acquired, by the employment of tefts, a general knowledge of the ingredients contained in a mineral water, the next object is to endeavour to afcertain the quantities and modes of combination in which they exift; and this conftitutes by far the moft difficult part of the inquiry.

There are two general modes of conducting the analyfis of a mineral water: one is to feparate, by various appropriate manipulations, the different ingredients in the fame compound forms in which they are fuppofed to actually exift in the water. The other, recommended particularly by Dr. Murray, is to afcertain, chiefly by means of tefts, the quantities of the different *fimple* fubftances, and afterwards to *eftimate* from them the quantities of the compounds. The firft of thefe modes, and in fome inftances a combination of both, is the one which has hitherto been generally adopted by chemifts; we fhall, therefore, give a fhort account of the manipulations had recourfe to for feparating a few of the fubftances moft ufually occurring in mineral waters.

1. The gafeous matters are firft to be feparated in the manner formerly mentioned, and their grofs amount afcertained by admeafurement in a jar graduated into cubic inches. Sulphuretted hydrogen, if it be prefent with other gafes, is firft to be feparated by immerfing the jar in warm water, and introducing nitric acid, which abforbs the fulphuretted hydrogen, and the diminution of bulk denotes its quantity.

quantity. If ſulphurous acid be preſent, the above ſtep is unneceſſary, for ſulphuretted hydrogen never exiſts in water containing this acid. Sulphurous acid may be ſeparated by introducing into the gaſeous mixture a quantity of the peroxyd of lead, in a ſtate of powder. This will gradually abſorb the whole, and the diminution of bulk, as before, will denote its quantity. The introduction of a little potaſh, after this, will abſorb the carbonic acid. The remaining gaſes muſt be oxygen and azote. The oxygen may be ſeparated by introducing a piece of phoſphorus, or by other well-known eudiometrical means; and the azote will remain laſt of all, unaffected by any of theſe proceſſes.

2. The earthy carbonates, if any be preſent, are firſt to be ſeparated by boiling a given portion of the water for a quarter of an hour. The precipitate thus obtained may conſiſt of a mixture of the carbonates of lime, of magneſia, of iron, and of alumina, and even of the ſulphate of lime. Suppoſing all theſe to be preſent, the precipitate is to be treated with dilute muriatic acid, which will diſſolve the whole, except the alumina and ſulphate of lime. Dry this reſiduum in a red heat, and note the weight. Then boil it in a ſolution of carbonate of ſoda; ſaturate the ſoda with muriatic acid, and boil the mixture for half an hour: carbonates of lime and alumina will be precipitated; the lime may be then diſſolved by acetic acid, while the alumina will remain; and thus the weight of each may be aſcertained.

The muriatic ſolution contains lime, magneſia, and iron. To ſeparate theſe, add ammonia, which will precipitate the iron and part of the magneſia. Dry the precipitate, and expoſe it to the air for ſome time in a temperature of about 200°. The magneſia may be then ſeparated by acetic acid, and the acetate thus formed is to be added to the muriatic ſolution. The iron is now to be rediſſolved in muriatic acid, precipitated by an alkaline carbonate, and dried and weighed.

Muriate of lime and magneſia ſtill remain in ſolution. To ſeparate them, add ſulphuric acid as long as any precipitate appears, then heat the ſolution, and concentrate. The ſulphate of lime thus obtained is to be heated to redneſs, and its weight aſcertained. Laſtly, the magneſia may be ſeparated by an alkaline carbonate, or, what is much better, by the phoſphate of ammonia.

3. To aſcertain the quantity of the alkaline carbonates, ſuppoſing them to exiſt in waters, determine how much of any dilute acid, whoſe ſtrength has been previouſly carefully aſcertained, is neceſſary to ſaturate them; and from this the quantity of alkali can be readily eſtimated.

4. The alkaline and earthy ſulphates may be eſtimated by the following methods.

The alkaline ſulphates may be determined by precipitating their acid by means of the nitrate of barytes, having previouſly ſeparated all the earthy ſulphates.

Sulphate of lime is readily eſtimated by evaporating the water to a few ounces, the earthy carbonates being previouſly ſaturated with nitric acid, and precipitating the ſulphate of lime by means of dilute alcohol.

If the ſulphate of magneſia or alumina be the only ſulphate preſent, the quantity of either can be readily eſtimated. If they exiſt together, the two earths may be precipitated by ſoda, and afterwards ſeparated by acetic acid in the manner above-mentioned. If ſulphate of lime be alſo preſent, this may be previouſly ſeparated in a great degree, as above; or, what is preferable, the lime may be precipitated by an alkali along with the other earths, and afterwards ſeparated. The ſame holds good alſo with the ſulphate of iron; or the iron may be ſeparated by expoſing the water for ſome days to the air, and mixing with it a portion of alumina. The oxyd of iron and ſulphate of alumina are precipitated together, and may be eaſily ſeparated, and the quantity of iron aſcertained.

5. If muriate of potaſh or ſoda exiſt alone in water, its quantity can be readily eſtimated by precipitating the muriatic acid with the nitrate of ſilver. The ſame proceſs may be followed, if the alkaline carbonates be preſent; only theſe carbonates muſt be previouſly ſaturated with ſulphuric acid, and, inſtead of uſing the nitrate, the ſulphate of ſilver is to be employed.

If the alkaline muriates exiſt along with more or leſs of the earthy muriates, or with the muriate of iron, without any other ſalts, the whole of the earths may be ſeparated by barytes water, and their quantities eſtimated as before. To diſcover the proportion of the alkaline muriates, the barytes is to be ſeparated by ſulphuric acid, and the muriatic acid expelled by heat. The quantity of the alkaline muriates may be then aſcertained by evaporation.

When ſulphates and muriates exiſt together, they may be ſeparated by evaporating the whole to dryneſs, and diſſolving the earthy muriates in alcohol; or, when the water has been duly concentrated, by precipitating the ſulphates with the ſame fluid.

When alkaline and earthy muriates exiſt with ſulphate of lime, this laſt ſalt is to be decompoſed by means of the muriate of barytes. The eſtimation is then to be conducted as if nothing but muriates are preſent, only the proportion of muriatic acid which united in the muriate of barytes, added, muſt be allowed for.

When muriates of ſoda, magneſia, and alumina, are preſent, together with ſulphates of lime and magneſia, the water is better examined by two diſtinct operations. To one portion add carbonate of magneſia, till the whole of the lime and alumina be precipitated. Aſcertain the quantity of lime, which gives the proportion of ſulphate of lime. Precipitate the ſulphuric acid by muriate of barytes: this gives the quantity contained in the ſulphate of magneſia and ſulphate of lime; and the quantity of ſulphate of lime being previouſly known, that of the ſulphate of magneſia can be eaſily eſtimated. To a ſecond portion of the water add lime-water, till the whole of the magneſia and alumina be ſeparated. From the weight of theſe earths the quantity of their muriates may be eſtimated, that portion of the magneſia previouſly found to be in union with ſulphuric acid being deducted. After this, remove the ſulphuric acid by barytes water, and the lime by carbonic acid, and the liquid evaporated to dryneſs will leave the common ſalt.

6. Laſtly: If the fixed mineral acids ſhould alone be found to exiſt in a water, it need ſcarcely be obſerved that their quantities can be readily aſcertained; the ſulphuric acid by means of a barytic ſalt, and the muriatic acid by means of a ſalt of ſilver.

All theſe different precipitates ſhould be dried uniformly, or at leaſt at ſome known degree of temperature. It is not eaſy to fix this point, which muſt in a great degree be regulated by the nature of the ſalt, and the peculiar views of the analyſt; ſome chooſing to reduce the ſalts to an anhydrous, others to a cryſtallized ſtate. As a ſort of check alſo to the analyſis, it is proper to evaporate a known quantity of the water to dryneſs, in order to learn the groſs amount of the ſaline matters it contains, which amount is to be compared with the reſults as obtained by the different proceſſes of the analyſis.

Such are a few of the moſt common methods recommended for ſeparating and aſcertaining the proportions of the different ſaline ſubſtances contained in a mineral water. They muſt of courſe be varied according to circumſtances; but this, as well as the application of other methods, muſt depend upon the practical knowledge and judgment of the analyſt.

The principles, however, upon which many of the above analytical proceſſes are founded, have been lately called in queſtion by Dr. Murray of Edinburgh, and we think very juſtly. That gentleman has endeavoured to ſhew, that we by no means arrive at a juſt knowledge of the conſtituents of a mineral water by theſe proceſſes, and that many of the compounds obtained by them are determined by the proceſſes themſelves. The following quotation, from a paper by Dr. Murray, entitled "A general Formula for the Analyſis of Mineral Waters," in the eighth volume of the Tranſactions of the Royal Society of Edinburgh, will convey a diſtinct idea of his opinions and mode of reaſoning upon the ſubject.

Two methods of analyſis have been employed for diſcovering the compoſition of mineral waters, what may be called the *direct* method, in which, by evaporation, aided by the ſubſequent application of ſolvents, or ſometimes by precipitants, certain compound ſalts are obtained; and what may be called the *indirect* method, in which, by the uſe of reagents, the principles of theſe ſalts, and baſes of which they are formed, are diſcovered, and their quantities eſtimated, whence the particular ſalts and their proportions may be inferred.

Chemiſts have always conſidered the former of theſe methods as affording the moſt certain and eſſential information. They have not neglected the latter, but they have uſually employed it as ſubordinate to the other. The ſalts procured by evaporation have been uniformly conſidered as the real ingredients; and nothing more was required, therefore, it was imagined, for the accuracy of the analyſis, than the obtaining them pure, and eſtimating their quantities with preciſion. On the contrary, in obtaining the elements merely, no information, it was believed, was gained with regard to the real compoſition; for it ſtill remained to be determined in what mode they were combined: and this, it was ſuppoſed, could be inferred only from the compounds actually obtained. This method, therefore, when employed with a view to eſtimate quantities, has been had recourſe to only to obviate particular difficulties attending the execution of the other, or to give greater accuracy to the proportions, or, at furtheſt, when the compoſition is very ſimple, conſiſting chiefly of one genus of ſalts.

Another circumſtance contributed to lead to a preference of the direct mode of analyſis,—the uncertainty attending the determination of the proportions of the elements of the compound ſalts. This uncertainty was ſuch, that even from the moſt exact determination of the abſolute quantities of the acids and baſes exiſting in a mineral water, it would have been difficult, or nearly impracticable, to aſſign the preciſe compoſition and the real proportions of the compound ſalts: and hence the neceſſity of employing the direct method of obtaining them.

The preſent ſtate of the ſcience leads to other views.

If the concluſion was juſt, that the ſalts obtained by evaporation, or any analogous proceſs from a mineral water, are its real ingredients, no doubt could remain of the ſuperiority of the direct method of analyſis, and even of the abſolute neceſſity of employing it. But no illuſtrations, I believe, are required to prove that this concluſion is not neceſſarily true. The concentration by the evaporation muſt, in many caſes, change the ſtate of combination; and the ſalts obtained are hence frequently products of the operation, not original ingredients. Whether they are ſo or not, and what the real compoſition is, are to be determined on other grounds than on their being actually obtained; and no more information is gained, therefore, with regard to that compoſition, by their being procured, than by their elements being diſcovered; for when theſe are known, and their quantities are determined, we can, according to the principle from which the actual modes of combination are inferred, whatever this may be, aſſign with equal facility the quantities of the binary compounds they form.

The accuracy with which the proportions of the conſtituent principles of the greater number of the compound ſalts are now determined, enables us alſo to do this with as much preciſion as by obtaining the compounds themſelves; and if any error ſhould exiſt in the eſtimation of their proportions, the proſecution of theſe reſearches could not fail ſoon to diſcover it.

The mode of determining the compoſition of a mineral water, by diſcovering the acids and baſes which it contains, admits in general of greater facility of execution, and more accuracy, than the mode of determining by obtaining inſulated the compound ſalts. Nothing is more difficult than to effect the entire ſeparation of ſalts by cryſtallization, aided even by the uſual methods of the action of alcohol, either as a ſolvent or a precipitant, or by the action of water as a ſolvent at different temperatures: in many caſes, it cannot be completely attained, and the analyſis muſt be deficient in accuracy. No ſuch difficulty is attached to the other method. The principles being diſcovered, and their quantities eſtimated in general from their precipitation in inſoluble compounds, their entire ſeparation is eaſily effected. Nothing is eaſier, for example, than to eſtimate the total quantity of ſulphuric acid by precipitation by barytes, or of lime by precipitation with oxalic acid; and this method has one peculiar advantage with regard to accuracy, that if any error is committed in the eſtimation of any of the principles, it is diſcovered in the ſubſequent ſtep of inferring the binary combinations: ſince, if all the elements do not bear that due proportion to each other, which is neceſſary to produce the ſtate of neutralization, the exceſs or deficiency becomes apparent, and of courſe the error is detected. The indirect method, then, has every advantage over the other, both in accuracy and facility of execution.

Another advantage is derived from theſe views, if they are juſt, that of precluding the diſcuſſion of queſtions, which otherwiſe fall to be conſidered, and which muſt often be of difficult determination, if they are even capable of being determined. From the ſtate of combination being liable to be influenced by evaporation, or any other analytic operation, by which the ſalts exiſting in a mineral water are attempted to be procured, diſcordant reſults will often be obtained, according to the methods employed: the proportions at leaſt will be different, and ſometimes even products will be found by one method, which are not by another. In a water which is of a complicated compoſition, this will more peculiarly be the caſe. The Cheltenham waters, for example, have in different analyſes afforded reſults conſiderably different: and on the ſuppoſition of the ſalts procured being the real ingredients, this diverſity muſt be aſcribed to inaccuracy; and ample room for diſcuſſion with regard to this is introduced. In like manner, it has often been a ſubject of controverſy whether ſea-water contains ſulphate of ſoda with ſulphate of magneſia. All ſuch diſcuſſions, however, are ſuperfluous. The ſalts procured are not neceſſarily the real ingredients, but in part, at leaſt, are products of the operation; liable, therefore, to be obtained or not, or to be obtained in different proportions, according to the

 method

method employed: and all that can be done with precifion is to eftimate the elements, and then to exhibit their binary combinations, according to whatever may be the moft probable view of the real compofition.

The method propofed by Mr. Kirwan, formerly alluded to, confifts in determining, chiefly by tefts, the quantity of the different faline fubftances prefent. But the complicated nature of many of the formulæ, befide the very principle of the method itfelf, being liable to moft of the objections above urged by Dr. Murray againft that in common ufe, render its application difficult, and refults uncertain. Upon the whole, therefore, we have no hefitation in faying, that we confider Dr. Murray's views and methods as by far the beft, and moft likely to lead to correct conclufions, that have yet appeared, and which may be ftated in few words, as follows:

"Determine by precipitants the weight of the acids and bafes prefent in a mineral water. Suppofe them united in fuch a manner that they fhall form the moft foluble falts: thefe falts will conftitute the true faline conftituents of the water under examination."

Dr. Murray illuftrates his method of procedure by fuppofing, as an example, a water found, by the ufual tefts, to contain the carbonates, fulphates, and muriates of lime, magnefia, and foda. The water is to be reduced by evaporation as far as can be done, without occafioning any fenfible precipitation or cryftallization. A faturated folution of muriate of barytes is then directed to be added as long as any precipitate falls, and no longer. This precipitates the whole of the fulphuric and carbonic acids, and the carbonate of barytes is to be feparated from the fulphate by diluted muriatic acid. Add to the refidual liquor a folution of oxalate of ammonia as long as any turbid appearance is produced. By this the whole of the lime is feparated. The oxalate of lime is to be calcined, and converted into fulphate of lime, from which the quantity of pure lime may be readily eftimated. The next ftep is to precipitate the magnefia; and for this purpofe, Dr. Murray recommends a modification of Dr. Wollafton's procefs. This confifts in adding, firft, a folution of neutral carbonate of ammonia, and afterwards a ftrong folution of phofphoric acid, or phofphate of ammonia; taking care to leave an excefs of the carbonate of ammonia. By thefe proceffes, the whole of the magnefia is obtained in the ftate of triple phofphate, and its quantity can be readily eftimated. Muriate of foda now remains in folution, and its quantity can be obtained by evaporation. As a check, however, to the different proceffes, it may be proper to afcertain the quantity of muriatic acid prefent by means of the nitrate of filver.

If alumina, filica, or iron be prefent, they are beft feparated by diftinct proceffes, in the manner formerly defcribed.

Laftly, Dr. Murray recommends that the refults of an analyfis be ftated in three modes: 1ft, The quantities of the acids and bafes; 2dly, The quantities of the binary compounds, as inferred from the principle that the moft foluble compounds are the ingredients; and 3dly, The quantities of the binary compounds, fuch as they are obtained by the ufual modes of analyfis. The refults will be thus prefented in every point of view. As an inftance of this method of ftating the refults of an analyfis, we refer our readers to what we have faid on *fea-water* in the prefent article.

Mineral Waters, artificial Preparation of.—Chemiftry had no fooner developed the compofition of mineral waters, than it fuggefted methods of preparing them artificially. Accordingly, Bergman and others have given many formulæ for this purpofe, fome of which approach the truth, while others are very imperfect. When the compofition of a water is very fimple, nothing more is required to form it artificially than to know the nature and quantity of the faline fubftances prefent, and to diffolve fimilar quantities of the fame faline fubftances in the fame proportion of water. In the earlier periods of chemical inveftigation, before the nature of gafeous fubftances was underftood, no attempts of courfe could be made to imitate the important clafs of waters which derive their chief properties from the prefence of fuch fubftances; but chemifts no fooner became acquainted with the nature of gafes, than they began to devife methods of imitating thefe alfo; and artificial carbonated waters have been long fince prepared as an article of commerce, under the name of *foda water*, fuperior in point of impregnation to any acidulous waters known. See PYRMONT.

It is true that there are fome inftances of natural chemical folution, which art has not even yet been able to imitate. Of this kind is the folution of filex, which occafionally occurs in mineral waters. It is doubtful, however, if this earth is capable of exerting any falutary effects on the animal economy; and, therefore, we have little occafion perhaps to regret our inability to effect its folution. Another defect in the formation of artificial mineral waters is, that many of the more important ones cannot be obtained in large quantities for bathing, &c. without fo great a degree of expence and trouble, as to entirely preclude their ufe.

On the other hand it feems plaufible, in theory at leaft, that we can improve upon the compofition of many mineral waters. Thus, many mineral waters contain ingredients, which, either from the minutenefs of the proportion in which they exift, or from their inert nature, may be deemed as fuperfluous, or in fome inftances as injurious. Again, others contain their active ingredient in fuch fmall quantities, as to require an inconvenient bulk of the water to produce the defired effect: all which defects may be remedied in the artificial preparation, by leaving out the ufelefs or noxious matter, and increafing that in which the proper medicinal virtue refides. Befides thefe advantages alfo, we have it in our power to form new and valuable compounds, which are no where to be met with in a natural ftate.

The firft ftep to the artificial formation of a mineral water is, of courfe, to know the exact compofition of the water we would imitate. Many of the ingredients, however, obtained from mineral waters by the ufual modes of analyfis, are very little foluble in water: fuch, for example, are the fulphate and carbonate of lime, &c. which we fhould attempt in vain to diffolve directly in water. Other modes, therefore, muft be devifed for this purpofe; and Dr. Murray's views of the compofition of mineral waters in general will enable us to effect our object, in moft inftances, very readily and completely, as the following example will fhew.

Suppofe we wifhed to imitate the Seltzer water, an Englifh pint of which, according to Bergman's analyfis, contains, as before mentioned, of

	Cub. Inches.
Carbonic acid	17
	Grains.
Carbonate of lime	3
Carbonate of magnefia	5
Carbonate of foda	4
Muriate of foda	17.5
	29.5

Of

Of theſe ingredients, neither the carbonate of lime nor magneſia are ſoluble in water, nor can be rendered ſo, without a tedious proceſs of impregnating the water, through which they are diffuſed, with carbonic acid gas. But if we adopt Dr. Murray's views, and conſider a pint of this water as actually containing of

	Cub. Inches.	
Carbonic acid gas	17	
	Grains.	
Muriate of lime -	3.3	
Muriate of magneſia	5	
Muriate of ſoda -	7.8	
Carbonate of ſoda	10.3	dry, or 18 cryſtallized.
	26.4	

we can eaſily imitate its compoſition in the following manner:

About 35 grains of muriatic acid, of the ſtrength uſually met with in the ſhops, are to be put into a ſtrong bottle, with a pint of water, the acid being introduced to the bottom of the water by a long funnel. Three grains of pure white marble in coarſe powder are then to be dropped in, and the bottle cloſed. When theſe are diſſolved, five grains of the common carbonate of magneſia in powder are to be added; and after the ſolution of this, 32 grains of cryſtallized carbonate of ſoda, or what is equivalent to this, and preferable, as affording more carbonic acid, 27 grains of bicarbonate of ſoda, are to be put in. The bottle is to be cloſed accurately, ſhaken, and inverted. In a ſhort time a perfect ſolution takes place, and a liquor is obtained tranſparent, which ſparkles when poured out, has a pleaſant taſte, and in its compoſition reſembles the Seltzer water.

It might be ſuppoſed, ſays Dr. Murray, that ſo large a proportion of carbonate of ſoda could not exiſt with the muriates of magneſia and lime, without decompoſing them; but on making the experiment, it was found that the above quantities might be diſſolved in a pint of water, independently of the exceſs of carbonic acid, without any apparent decompoſition; the ſolution remaining tranſparent, even on expoſure to the air.

Upon ſimilar principles may the compoſition of almoſt every other mineral water be readily imitated.

We have an agreeable imitation of acidulous waters, under the term of what is called the *effervеſcing draught.* This conſiſts of two ſolutions, one of an alkaline carbonate, and the other of the citric or ſome other vegetable acid, which are directed to be mixed together, and ſwallowed during the act of effervеſcence. A more portable form of this grateful draught is to be obtained in the ſhops, under the name of *Sodaic powders*, *Seidletz powders*, &c. in which the requiſite proportions of alkali and acid in their dry ſtate are formed into ſeparate little packets, one of each of which is directed to be diſſolved ſeparately in water, and the two ſolutions to be then mixed, and ſwallowed during the act of effervеſcence, as before.

The following, therefore, may be laid down as a general rule for the artificial preparation of mineral waters:—Aſcertain, upon Dr. Murray's principles, the preciſe proportions of the *moſt ſoluble* ſalts that *can* be preſent in any given water; diſſolve ſimilar proportions of the ſame ſalts in an equal quantity of water, and a compound water will be obtained, preciſely ſimilar in its compoſition to the original.

Catalogue of the moſt important mineral Waters.—The following catalogue is intended to compriſe the principal mineral waters of Great Britain, and ſome of the more important ones of other countries. Our readers will recollect that, in the preceding article, we divided natural waters into *potable*, *ſaline*, *chalybeate*, *acidulous*, *ſulphureous*, and *thermal*, and deſcribed the general chemical and medicinal properties of each claſs, as well as of their compounds. To prevent repetition, and to ſave room, therefore, we have attempted to refer the different ſprings, mentioned in the following catalogue, to one or other of the above claſſes: thus, when a ſpring is ſtated to be *ſaline*, its general compoſition and properties are to be underſtood to reſemble the claſs of *ſaline* waters; and ſo of the reſt.

The moderns have very properly exploded the old notion of the myſterious and *ſpecific* operation of particular ſprings. But even if this cogent reaſon for generalization did not exiſt, it would be impoſſible, in a work of the preſent deſcription, to deſcend to all the minutiæ of analyſis, &c. ſuppoſing them to be known, which is far from being the caſe: we have thought proper, however, to give a few of the more intereſting and inſtructive recent analyſes of ſome of the moſt important ſprings.

Thoſe ſprings marked thus *, in the following liſt, are more particularly deſcribed in the preceding article, as examples of the different claſſes.

Abcourt. An acidulous chalybeate ſpring. See Abcourt.

Aberbrothick, or *Arbroath.* An acidulous chalybeate ſpring. See Aberbrothick.

Acton. A ſaline ſpring. See Acton.

Aghaloo, Tyrone, Ireland. A ſulphureous ſpring ſlightly ſaline.

* *Aix-la-Chapelle.* Sulphureous thermal ſprings. See Aix-la-Chapelle.

Alford. A ſaline ſpring. See Alford.

Alkerton, near Glouceſter. A ſaline ſpring.

Anaduff, Leitrim. A weak ſulphureous ſpring ſlightly ſaline.

Aſhwood, Fermanagh. A ſulphureous ſpring ſlightly ſaline.

Aſkeron, Yorkſhire. A ſtrong ſulphureous ſpring ſlightly ſaline.

Aſtrope, Oxfordſhire. An acidulous chalybeate ſpring.

Aſwarby, Lincolnſhire. A ſaline chalybeate ſpring.

Athlone, Weſtmeath. A chalybeate ſpring ſlightly ſaline.

d'Ax-en-foix, France. Sulphureous thermal ſprings, in repute as baths.

Baden. Sulphureous ſprings, formerly in much repute as baths. See Baden.

Bagnigge-Wells. Two ſprings, one ſaline, the other chalybeate. See Pancras.

Baiæ. Thermal ſprings, in much repute among the Romans. See Baiæ.

Balaruc. Saline thermal ſprings. See Balaruc.

Ballycaſtle. Two chalybeate ſprings, one in which the iron is in combination with carbonic acid, the other with ſulphuric acid. See Ballycastle.

Ballynahinch, Downſhire. A ſulphureous ſpring, ſaid to contain iron.

Bagneres, France. Thermal ſprings, in much repute as baths. See Bagneres.

Balſton, North America. A highly acidulous chalybeate ſpring. According to the recent analyſis of a French chemiſt, 25 fluid ounces contain of

	Cub. Inches.
Carbonic acid	75
	Grains.
Muriate of soda	31
Carbonate of lime	22
Muriate of magnesia	12.5
Muriate of lime	5
Carbonate of iron	4
	74.5

Barege. Sulphureous thermal springs, in considerable repute. See BAREGE.

Barnet, Hertfordshire. A weak saline spring. At North-hall, about three miles from Barnet, is another of the same description, but a little stronger.

Bath. Celebrated saline thermal springs, containing likewise a little iron. (See BATH.) One of the most recent and probably correct analyses of these waters is by Mr. Phillips. According to this gentleman, a wine pint contains of

	Cub. Inches.
Carbonic acid	1.2
	Grains.
Sulphate of lime	9
Muriate of soda	3.3
Sulphate of soda	1.5
Carbonate of lime	0.8
Silex	0.2
Oxyd of iron	0.0147
	14.8147

Bilton, Yorkshire. A weak saline sulphureous spring.

Binley, Warwickshire. A saline chalybeate spring.

Borrowdale, Cumberland. A strong saline water. See BORROWDALE.

Borset. Sulphureous thermal springs, in considerable repute. See BORSET.

Brabach, Germany. An acidulous chalybeate spring.

Brandola, Italy. A weak acidulous chalybeate spring.

Brentwood, Essex. A saline spring.

Brighton. A chalybeate spring: sulphate of iron. (See BRIGHTHELMSTON.) According to Dr. Marcet's analysis, a wine pint contains of

	Cub. Inches.
Carbonic acid gas	2.5
	Grains.
Sulphate of iron	1.80
Sulphate of lime	4.09
Muriate of soda	1.53
Muriate of magnesia	0.75
Silex	0.14
Loss	0.19
	8.50

Bristol Hotwells. A simple thermal water. As this spring has not been described in its proper place, we shall insert the following short account of it here. This water is inodorous, perfectly limpid and sparkling, and sends forth air-bubbles when poured into a glass. It is agreeable to the palate, but has no decided taste. Its specific gravity is stated to be 1.00077. Its temperature, upon an average, is about 74°. A wine pint, according to Dr. Carrick's analysis, contains of

	Cub. Inches.
Carbonic acid gas	3.75
Common air	0.375
	4.125
	Grains.
Muriate of magnesia	0.9
Muriate of soda	0.5
Sulphate of soda	1.4
Sulphate of lime	1.47
Carbonate of lime	1.63
	5.9

It was formerly much celebrated in consumption, but its supposed good effects in this disease have been justly called in question by modern writers.

Bromley, Kent. A chalybeate spring. See BROMLEY.

Broughton, Yorkshire. A strong saline sulphureous spring, similar to that of Harrowgate.

Buch, near Carlsbad, in Bohemia. A weak acidulous water.

Buglawton, Cheshire. A saline sulphureous water.

Burlington, or *Bridlington*, Yorkshire. A chalybeate water slightly saline.

Burnley, Lancashire. A chalybeate water slightly saline.

**Buxton*. A simple thermal water. See BUXTON-*Water*.

Cannock, Staffordshire. A chalybeate water.

Cargyrle, near Chester. A weak saline water.

Carlsbad. Celebrated acidulo-chalybeate thermal springs. See CARLSBAD.

Carlton, Nottingham. A chalybeate water.

Castleconnel. A chalybeate water. See CASTLECONNEL.

Castlemain. A sulphureous spring said to contain iron. See CASTLEMAIN.

Cawley, Derbyshire. A sulphureous water slightly saline.

Cawthorp, Lincolnshire. A chalybeate spring slightly saline.

Chedlington, Oxfordshire. A sulphureous water slightly saline.

Chaude Fontaine, near Liege, Germany. Thermal springs celebrated as baths.

**Cheltenham*. Saline and saline chalybeate springs. See CHELTENHAM.

Chippenham, Wiltshire. A chalybeate spring.

Cleves. An acidulous chalybeate spring. See CLEVES.

Clifton, Oxfordshire. A saline spring.

Cobham, Surry. A chalybeate water.

Codsal Wood, Staffordshire. A sulphureous spring.

Colchester, Essex. A saline spring.

Colurian, Cornwall. A chalybeate spring.

Comner, or *Cumner*, Berkshire. A weak saline spring.

Corstorphine, near Edinburgh. A weak sulphureous spring slightly saline.

Coventry. A saline chalybeate spring. See COVENTRY.

Crickle Spa, Lancashire. A strong saline sulphureous water.

Croft, Yorkshire. A sulphureous water slightly saline.

Cross town, Waterford. A sulphureous spring.

Cunley-house, Lancashire. A strong sulphureous spring slightly saline.

Deddington. Saline sulphureous springs. See DEDDINGTON.

Derby. A chalybeate spring.

Derrindaff, Cavan. A fulphureous fpring flightly faline.

Derry-hinch, Fermanagh. A fulphureous fpring.

Dog and Duck, St. George's Fields, Southwark. A faline fpring.

Drig-well, Cumberland. An acidulous chalybeate fpring.

Drumafnave, Leitrim. A ftrong fulphureous fpring flightly faline.

Dublin. Several weak faline fprings.

Dulwich, Kent. Pretty ftrong faline fpring.

Dunblane, Perthfhire. Thefe fprings have been only lately difcovered. They have been accurately analyfed by Dr. Murray. There are two fprings, both of a fimilar nature, that is to fay, faline, with a minute proportion of iron. A wine pint of the *north fpring* was found by Dr. M. to contain of

	Grains.
Muriate of foda - - - -	24.3
Muriate of lime - - - -	18.
Sulphate of lime - - - -	3.1
Carbonate of lime with a trace of iron -	0.5
	45.9

The fame quantity of the *fouth fpring* yielded

	Grains.
Muriate of foda - - - -	22.5
Muriate of lime - - - -	16.
Sulphate of lime - - - -	2.3
Carbonate of lime - - - -	0.3
Oxyd of iron - - - -	.15
	41.25

Dunfe, Scotland. A chalybeate fpring.

Durham. A ftrong fulphureous water flightly faline.

Egra, Bohemia. A celebrated faline chalybeate fpring. See Egra.

Epfom. A celebrated faline fpring. See Epsom.

Felftead, Effex. A chalybeate fpring.

Filah, Yorkfhire. A faline chalybeate fpring.

Francfort on the Maine. Saline fulphureous fprings. See Francfort.

Galway, Ireland. A chalybeate fpring.

Geyfer, Iceland. Remarkable thermal fprings. See Iceland.

Glanmile, Ireland. A chalybeate fpring.

Glaftonbury. A chalybeate fpring flightly faline. See Glastonbury.

Glendy, Angusfhire. A ftrong chalybeate fpring.

Granfhaw, Downfhire. A chalybeate fpring.

Haigh, Lancafhire. A chalybeate fpring: fulphate of iron.

Hampftead. A chalybeate water. See Hampstead. The moft recent analyfis of this water is by Mr. Blifs, according to whom a wine gallon contains of

	Cub. Inches.
Carbonic acid - - - -	10.1
Atmofpheric air - - - -	90.9
	101.

	Grains.
Oxyd of iron - - - -	1.5
Muriate of magnefia - - -	1.75
Sulphate of lime - - - -	2.12
Muriate of foda nearly - - -	1.0
Of filex about - - - -	.38
	6.75

Hanbridge, Lancafhire. A chalybeate water flightly faline.

Hanlys, Shropfhire. Two fprings, one faline the other chalybeate.

**Harrowgate*. Saline fulphureous fprings. See Harrowgate.

Hartfell, Annandale. A chalybeate fpring: fulphate of iron. According to Dr. Garnett's analyfis, a wine pint of this water contains of

	Grains.
Sulphate of iron - - -	10.5
Sulphate of alumina - - -	1.5
Oxyd of iron - - - -	1.875
	13.875

Hartlepool. A chalybeate fpring. See Hartlepool.

Holt, Wiltfhire. A weak faline water.

Holt-nevil, Leicefterfhire. A chalybeate fpring: fulphate of iron. See Holt *Waters*.

Jeffop's Well, near Cobham, Surry. A ftrong faline water flightly chalybeate.

Ilmington, Warwickfhire. A chalybeate fpring.

Inglewhite, Lancafhire. A ftrong chalybeate fpring.

Ifle of Wight. A very ftrong chalybeate: fulphate of iron.

Iflington. A chalybeate fpring. See Islington.

Kanturk, Cork. A chalybeate fpring.

Kattrine Loch, Scotland. On the north fide of this lake is a ftrong chalybeate fpring.

Keddleftone, Derbyfhire. A ftrong fulphureous water moderately faline.

Kenfington. A faline fpring. See Kensington.

Kilbrew, Meath. A chalybeate water: fulphate of iron.

Kilburn, Middlefex. A faline fpring.

Kilroot, Antrim. A faline fpring.

Kiling-fhanvally, Fermanagh. A chalybeate water flightly faline.

Killafher, Fermanagh. A ftrong fulphureous water.

Kinalton, or *Kynolten*, Nottinghamfhire. A weak faline water.

Kincardine. A chalybeate fpring.

King's-cliff, Northamptonfhire. A chalybeate fpring weakly faline.

Kirby or *Kirkby-thower*, Weftmoreland. Two chalybeate fprings.

Knarefborough, the *Dropping-well*, contains lime held in folution by carbonic acid. See Knaresborough.

Knowfley, Lancafhire. A chalybeate fpring.

Korytna, Moravia. A very ftrong fulphureous fpring.

Kuka, Bohemia. A chalybeate acidulous water.

Lancafter. A chalybeate fpring flightly faline.

Latham, Lancafhire. A chalybeate fpring.

Leuk, Valois, Switzerland. Thermal fprings.

Llandrindod, Radnorfhire. Three fprings; one faline, another fulphureous, and the third chalybeate.

Llangybi, Carnarvonfhire. A faline fpring.

Leamington. A faline fpring. See Warwick.

Leez, Effex. A chalybeate fpring.

Lincomb, Bath. A chalybeate fpring flightly faline.

Lifbeak, Fermanagh. Two fulphureous fprings.

Lis-done-varna, Clare. A ftrong chalybeate water.

Loanfbury, Yorkfhire. A fulphureous fpring flightly faline.

Maccroom, near Cork. A chalybeate fpring.

Mahereberg, Kerry. A faline fpring.

Mallow,

Mallow, Cork. A pure thermal ſpring. See MALLOW.

Malton, Yorkſhire. A ſtrong chalybeate ſpring moderately ſaline.

**Malvern*, Worceſterſhire. Very pure ſprings. See MALVERN. One wine gallon of the Malvern Holywell waters, according to Dr. Wilſon, contains of

		Grains.
Carbonate of ſoda	- - -	5.33
Carbonate of lime	- - -	1.6
Carbonate of magneſia	- - -	.919
Carbonate of iron	- - -	.625
Sulphate of ſoda	- - -	2.896
Muriate of ſoda	- - -	1.553
Reſiduum, ſilex	- - -	1.687
		14.610

According to the ſame chemiſt, one gallon of the Malvern St. Ann's well contains of

		Grains.
Carbonate of ſoda	- - -	3.55
Carbonate of lime	- - -	.352
Carbonate of magneſia	- - -	.26
Carbonate of iron	- - -	.328
Sulphate of ſoda	- - -	1.48
Muriate of ſoda	- - -	.955
Reſiduum, ſilex	- - -	.47
		7.395

Markſhall, Eſſex. A chalybeate water.

Matlock, Derbyſhire. Thermal ſprings, temp. about 66°. See MATLOCK.

Maudſley, Lancaſhire. A ſulphureous water moderately ſaline.

Mechan, Fermanagh. Two ſulphureous ſprings.

Millar's Spa. A chalybeate ſpring.

**Moffat*, Annandale. Two ſulphureous ſprings. See MOFFAT.

Moſshouſe, Lancaſhire. A chalybeate ſpring.

Moreton, Shropſhire. A ſaline ſpring.

Mont d'Or, near Clermont, France. Sulphureous thermal ſprings.

Mount Pallas, Cavan. A chalybeate ſpring.

Nevil Holt. See HOLT.

Newnham Regis, Warwickſhire. Three chalybeate ſprings ſlightly ſaline.

Newton Dale, Yorkſhire. An acidulous water holding lime in ſolution.

Newton Stewart, Tyrone. A chalybeate ſpring.

Nezdenice, Germany. An acidulous water.

Nobber, Meath. A chalybeate ſpring: ſulphate of iron.

Normanby, Yorkſhire. A ſulphureous ſpring ſlightly ſaline.

Nottington, Dorſetſhire. A ſtrong ſulphureous water.

Orſton, Nottingham. A chalybeate ſpring.

Oulton, Norfolk. A weak chalybeate ſpring.

Owen Breun, Cavan. A ſulphureous ſpring ſlightly ſaline.

Pancras, Middleſex. A ſaline ſpring.

Paſſy, near Paris. A moderately ſtrong chalybeate ſpring.

Peterhead, Aberdeenſhire. A ſtrong chalybeate ſpring. See PETERHEAD.

Pettygoe, Donegal. A ſtrong ſulphureous water, ſaline.

Pitcaithly, Perthſhire. Theſe ſprings reſemble cloſely thoſe of *Dunblane*, and have been lately analyſed by Dr. Murray, according to whom a wine pint contains of

		Cubic Inches.
Atmoſpheric air	- - -	0.5
Carbonic acid gas	- - -	1.
		1.5
		Grains.
Muriate of ſoda	- - -	13.4
Muriate of lime	- - -	19.5

Plombiers, France. A thermal ſpring.

Pontgibault, France. A weak acidulous ſpring.

Pyrmont, Weſtphalia. A highly acidulous chalybeate ſpring. See PYRMONT.

Queen's Camel, Somerſetſhire. A ſulphureous ſpring.

Richmond, Surry. A ſaline ſpring.

Road, Wiltſhire. A chalybeate ſpring.

Rougham, Lancaſhire. A ſaline ſpring.

St. Bartholomew's Well, Cork. A chalybeate water ſlightly ſaline.

St. Bernard's Well, Edinburgh. A ſulphureous water ſlightly ſaline.

St. Eraſmus's Well, Staffordſhire. A weak ſaline water.

St. Winifrid's Well, Flint. A very pure ſpring. See HOLYWELL.

Scarborough, Yorkſhire. A ſaline chalybeate ſpring. See SCARBOROUGH.

Schooley's Mountain, United States. A weak chalybeate ſpring.

Scollienſes, Switzerland. An acidulous chalybeate ſpring.

**Sea-water*. See SEA and the former part of this article.

**Sedlitz*. A ſaline water. See SEDLITZ.

**Seltzer*. An highly acidulous water. See SELTZER.

Sene, or *Seend*, Wiltſhire. Two chalybeate ſprings.

**Seydſchutz*, near Sedlitz. A ſaline water. See SEDLITZ.

Shadwell. A ſaline chalybeate ſpring: ſulphate of iron?

Shapmoor, Weſtmoreland. A ſulphureous ſpring ſlightly ſaline.

Shettlewood, Derbyſhire. A ſulphureous ſpring ſlightly ſaline.

Shipton, Yorkſhire. A ſulphureous ſpring moderately ſaline.

Somerſham, Huntingdonſhire. A chalybeate ſpring: ſulphate of iron. See SOMERSHAM.

**Spa*. Highly acidulous chalybeate ſprings. See SPA.

Stanger, Cumberland. A ſaline chalybeate ſpring.

Stenfield, Lincolnſhire. A chalybeate ſpring ſlightly ſaline.

Streatham, Surry. A ſaline ſpring. See STREATHAM.

Suchaloza, Germany. An acidulous ſpring.

Sutton Bog, Oxfordſhire. A ſtrong ſulphureous ſpring ſlightly ſaline.

Swadlingbar, Cavan. A ſulphureous ſpring.

Swanſea, Glamorganſhire. A chalybeate ſpring: ſulphate of iron. See SWANSEA.

Sydenham, Kent. A weak ſaline ſpring.

Tarleton, Lancaſhire. A chalybeate ſpring ſlightly ſaline.

Tewkſbury, Glouceſterſhire. A ſaline ſpring.

Thetford, Norfolk. A chalybeate ſpring ſlightly acidulous.

Thoroton, Nottinghamſhire. A chalybeate ſpring ſlightly ſaline.

Thurſk, Yorkſhire. A ſaline chalybeate ſpring.

Tibſhelf,

Tibſhelf, Derbyſhire. A chalybeate ſpring ſlightly acidulous.

Tilbury, Eſſex. A ſaline ſpring ſlightly chalybeate.

Toberbony, near Dublin. A ſaline ſpring.

Tonſtein, Germany. A ſaline acidulous ſpring in conſiderable repute.

Tralee, Kerry. A chalybeate ſpring.

**Tunbridge Wells*, Kent. A chalybeate ſpring. See TUNBRIDGE *Wells*.

Upminſter, Eſſex. A ſtrong ſaline ſulphureous ſpring.

Vahls, France. A weak acidulous ſpring ſlightly ſaline.

Vichy, France. A highly acidulo-chalybeate thermal ſpring. See VICHY.

Wardrew, Northumberland. A ſaline ſulphureous ſpring.

Warmbrunn, Sileſia. Thermal ſprings.

Weatherſtack, Weſtmoreland. A ſaline chalybeate ſpring.

Wellenbrow, Northamptonſhire. A weak chalybeate ſpring.

Weſt Aſhton, Wiltſhire. A weak chalybeate ſpring.

Weſtwood, Derbyſhire. A chalybeate ſpring : ſulphate of iron.

Wexford, Ireland. A weak chalybeate ſpring.

White Acre, Lancaſhire. A chalybeate ſpring.

Wigan, Lancaſhire. A chalybeate ſpring.

Wiggleſworth, Yorkſhire. A ſulphureous ſpring ſlightly ſaline.

Wildungan, Germany. A weak acidulous water.

Witham, Eſſex. A chalybeate ſpring.

Wirkſworth, Derbyſhire. A ſaline ſulphureous ſpring.

Zahorovice, Germany. A weak ſaline acidulous water.

**Zealand, New*. An acidulous water : muriatic acid.

See the article AQUÆ, where many *thermal* and other ſprings are noticed, which have been omitted in the above catalogue.

Among the older writers on mineral waters, ſee Rutty, Monro, Elliot, and others. One of the beſt modern treatiſes on mineral waters is doubtleſs that of Dr. Saunders, to which we have been particularly indebted. Detached eſſays on particular waters are too numerous to be all noticed. Among the more recent publiſhed in this country may be enumerated thoſe of Phillips on the Bath waters ; Scudamore on the Tunbridge Wells water ; Jones on the Spa waters ; and Brande on the Cheltenham waters.

The chief of the older writers on the analyſis of mineral writers, are Bergman and Kirwan. Latterly, ſome very valuable eſſays have been publiſhed on this ſubject by Dr. Murray of Edinburgh, of which we have availed ourſelves in the above article.

WATER *of Cryſtallization*, in *Chemiſtry*, is a denomination applied to the water attracted by many ſaline bodies during the act of cryſtallization. Some ſalts contain no water of cryſtallization, while others contain a very large proportion. Water always appears to enter into the compoſition of cryſtals in a definite proportion. Water can be commonly ſeparated from ſalts without affecting their ſaline properties, and may be reſtored to them by diſſolving them in water, and ſuffering them to cryſtallize. See CRYSTALLIZATION and SALTS.

WATERS, *Diſtilled* or *Simple*, in *Medicine* and *Pharmacy*, conſiſt chiefly of ſimple water ſlightly impregnated with the eſſential oils of different plants, and are principally uſed as vehicles for more active remedies. They were formerly very numerous, but their numbers have been very properly much reduced by the moderns. See AQUÆ *Diſtillatæ*, where all thoſe in common uſe are enumerated.

WATER, *Spirituous*, *Cordial*, or *Compound*, in *Pharmacy*, &c. was the name formerly given to what are now denominated *ſpirits*, the menſtruum being alcohol, and the impregnating ingredients commonly various. See AQUÆ *Cardiacæ*, and SPIRIT. For the methods of preparing ſuch compounds, ſee alſo DISTILLATION, and OIL, *eſſential*.

WATER, in *Agriculture* and *Rural Economy*, is a fluid of great utility for many different purpoſes. The nature of the compoſition of water, and the great power and capacity which it poſſeſſes of taking up and holding a variety of different matters in the ſtate of diffuſion or ſolution, as well as the circumſtance of its being every where preſent amongſt almoſt all kinds of bodies, renders it particularly uſeful in the growth of plants as crops, and in many other ways. Dr. Woodward, indeed, from finding it to contain the particles of moſt ſorts of extraneous ſubſtances, was led to ſuppoſe that ſome of them were the proper matter of nutrition ; as water is conſtantly found to afford ſo much the leſs nouriſhment, the more it is purified by diſtillation, or other means. So that water, as ſuch merely, did not appear to be the proper nutriment of vegetables, but only the medium or vehicle that contains the nutritious particles or properties, and which conveys them along with it through all the parts of the plant. The more full and complete knowledge of the nature and properties of water which has ſince been acquired, have, however, ſet the matter in a more clear and ſatisfactory point of view. See the article WATER.

Water is ſeldom, if ever, met with in a ſtate of perfect purity, nor often in that even which is ſufficiently ſo for the different operations and uſes to which it may be neceſſary to apply it. Nor have all the trials that have ever been made been yet capable of producing it perhaps perfectly pure. There ſeems indeed to be no ſort of ſtandard by which the weight and purity of water can be readily and eaſily aſcertained. It is, in fact, a very difficult matter, however uſeful and advantageous it might be in many different intentions, as water ſcarcely ever continues for any length of time exactly of the ſame weight, or perhaps purity ; as by reaſon of the air and caloric, or matter of heat contained in it, much variation in reſpect to the former continually takes place. The effects which different degrees of heat have on the gravity of water are well ſhewn by the expanſion of it in boiling. It is this which makes the chief difficulty in fixing the ſpecific gravity of water, in the view of ſettling its degree of purity. The pureſt water that is capable of being obtained is, however, thought by ſome, as Mr. Hawkſbee, who has made many experiments on the ſubject, to be eight hundred and fifty times heavier than air. But others, whoſe trials have not been leſs numerous or correct, have made it not more than about eight hundred, or eight hundred and thirty-ſix times heavier than air. From whence this general proportion may perhaps be deduced, which may be conſidered as a ſort of ſtandard in the buſineſs, that when the barometer is at 30°, and the thermometer at 55°, then water is eight hundred and twenty times heavier than air ; and that in ſuch a ſtate the cubic foot of water weighs one thouſand ounces avoirdupois, and that of air 1.222, or $\frac{2}{9}$ths nearly. (See WATER.) There is not, however, any very exact ſtandard in air, as the more water there is contained in the air, the heavier it muſt of courſe be ; for indeed a conſiderable part of the weight of the atmoſphere appears to ariſe from the water that is contained in it. Conſequently, the nearer any water is found to approach the above ſtandards, the purer it may be concluded to be ; which may ſerve to guide and direct many practical uſes and applications of the fluid.

In regard to the properties and effects of water, it is well known to be extremely volatile and expanſive, being capable of reduction wholly into the ſtate of vapour, and of being diſſipated when expoſed to heat and unconfined. In

this

this ſtate, when properly confined, it is of great uſe and application for a variety of purpoſes. See Steam.

It is found, however, that water, when heated in an open veſſel, acquires no more than a certain determinate proportion or degree of heat, whatſoever may be the intenſity or the length of continuance of the fire to which it is expoſed; which greateſt proportion or degree of it is when it boils in the completeſt manner. The degree of heat, however, which is neceſſary to make water boil perfectly, is variable, according as the purity of the water, and the weight of the atmoſphere, may happen to be. A knowledge of this may be of conſiderable utility and benefit in the application of heat to this fluid, in a number of operations, as tending to ſave time, trouble, and the conſumption of fuel.

The ready penetrability and ſeparability of water from the bodies with which it may have united, as well as its properties and powers of coheſion, ſolution, and coagulation, render it ſtill more extenſively applicable and uſeful on many occaſions.

Water is a fluid which, in popular language, is diſtinguiſhed into many different kinds, according to the qualities of it, and the circumſtances under which it makes its appearance, or is found (ſee the preceding article Water); as *freſh* water, or that which is perfectly inſipid, without any ſaline or other taſte, and inodorous, being that which is the natural and pure ſtate of water: in this ſtate, it is well fitted for moſt ſorts of domeſtic as well as many other uſes: *hard* water, or that in which ſoap does not completely or uniformly diſſolve and diffuſe itſelf, but appears in a ſort of curdled or coagulated ſtate: it is certain from this that the diſſolving power of hard water is leſs than that of ſoft; and that hence it is leſs fit for waſhing, bleaching, dyeing, boiling culinary vegetables, watering plants and trees, and many other purpoſes. It is, for the moſt part, found, that the hardneſs of water proceeds either from ſaline matters, or from the preſence of gas. The hardneſs which ariſes from ſaline matters may moſtly be diſcovered and removed by the addition of ſmall quantities, as a few drops, of a ſolution of fixed alkali; and that which is cauſed by the latter by boiling, or expoſure to the open air for ſome length of time. That the waters of ſprings are hard; but thoſe of rivers ſoft. That hard waters are remarkably indiſpoſed to corrupt; they even preſerve putreſcible ſubſtances for a conſiderable length of time; hence they would ſeem to be beſt fitted for keeping, eſpecially as they are ſo eaſily capable of being ſoftened by a very little of the alkaline ſolution being added to them. *Putrid* water is that which has acquired an offenſive ſmell and taſte by the putreſcence of the animal or vegetable ſubſtances which are contained in it. This ſort of water is of a very pernicious quality, and quite unfit for any purpoſe. Cauſtic lime, when put into water, is uſeful in preſerving it longer in a ſweet ſtate; and even expoſure to the air in broad ſhallow veſſels has the ſame effect. And water in this putrid ſtate may be, in a great meaſure, rendered ſweet by having a current of freſh air paſſed through it, from the bottom to the top. Water in this condition is, of courſe, always to be avoided, except for the purpoſe of manure, for which, in ſome caſes, it is of great uſe. *Rain*-water, or that which may be conſidered as a pure ſort of diſtilled water, but as impregnated during its paſſage through the air with a conſiderable quantity of putreſcent matter, whence, in ſome meaſure, its great ſuperiority to any other in fertilizing the earth or ſoil, as well as in promoting the growth of trees and plants. Whence too its inferiority for ſome domeſtic purpoſes to that of the ſpring or river kind, even where it can be readily and well procured; but, more eſpecially, ſuch as is collected and gotten from ſpouts, trunks, and other contrivances put below the roofs of houſes and other buildings, which are the uſual modes of procuring it in this country, which is obviouſly very impure, and in a ſhort time becomes in the putrid ſtate. From its ſoftneſs, it, however, anſwers well in ſome uſes, after it has become pretty pure by ſtanding. *River*-water, or that which is next in purity to that of ſnow, or the diſtilled kind, and which, for moſt domeſtic and ſome other uſes, is ſuperior to either of them, as having leſs putreſcent matter, and more fixed air, or carbonic acid gas in it. Of this water, that, however, which runs over a clean, rocky, ſtony, or gravelly bottom, is by much the pureſt. River-waters, in general, are found to putrefy ſooner than thoſe of ſprings; and that during their putrefaction they throw off a part of the extraneous matter they contain, and at length become ſweet again, and purer than in their firſt ſtate; after which they will commonly preſerve ſweet a great length of time; this is particularly the caſe with ſome river-water, as that of the Thames. It is this ſort of water that is ſo extenſively uſeful in improving graſs-lands, when thrown over them in a proper manner. See Watering *Land*, and Water *Meadow*.

There are ſome other ſorts of water, as *ſalt* water, or that which contains large portions of ſalt in it, ſo as to be ſenſible to the taſte. This is of moſt uſe in the preparation of that ſubſtance from it, but may perhaps be applicable in ſome other ways. *Sea*-water, or that which is a ſort of an aſſemblage of bodies or ſubſtances, in which this fluid may be ſaid to have barely the principal part: it is, in ſhort, an univerſal collection of moſt of the matters in nature, ſuſtained and kept ſwimming in this fluid as a medium or vehicle: being a diffuſe ſolution of various ſubſtances, as common ſalt, bitter cathartic ſalt, different other ſaline matters, and a compound of muriatic acid with magneſia, mixed and blended together in a variety of proportions. It is capable of being freſhened by ſimple diſtillation, without any addition; and is about three parts in a hundred heavier than common water; the temperature of it at great depths being from thirty to forty degrees; but near the ſurface it follows the temperature of the air more nearly. It is probable, from ſome trials lately made with it, that it may be uſeful when applied to land in ſome caſes. Its greater weight and other properties would ſeem to be favourable for this in ſome intentions. It is the muddy material conveyed in the ſtate of diffuſion in this water, which is found ſo beneficial in the warping of land in ſome caſes and ſituations. (See Warping *of Land*.) *Snow*-water, or that which is the pureſt of all the common waters, when the ſnow has been collected in its pure ſtate, and kept in a dry place, in clean glaſs veſſels, not cloſely ſtopped, but covered from duſt and other ſuch matters; this water becomes in time putrid, although in well-ſtopped bottles it will continue unaltered for ſeveral years; but diſtilled water undergoes no alteration in either circumſtance. Snow-water will be ſeen below to be uſeful in promoting the nutrition of plants. *Spring*-water, or that which is commonly impregnated with ſome ſorts of materials or other, as a ſmall portion of imperfect neutral ſalt extracted and taken up from the different ſtrata through which it paſſes and percolates; great quantities of ſtony matter, which are depoſited as it runs along, and large maſſes of ſtone thus formed, ſometimes too incruſtating different ſubſtances of the animal and vegetable kinds, which it is ſaid to petrify. Spring-water is much uſed for domeſtic purpoſes in many caſes, and on account of its coolneſs and clearneſs forms a ſuitable drink for man and animals; but from its being uſually ſomewhat hard, is inferior in ſome intentions to that which has run a conſiderable diſtance in in an open channel, expofed to the action and influence of the air.

The water of fprings arifes and is caufed by rain, and from mifts and moifture in the atmofphere; which falling upon the hills and higher grounds, as well as other parts, foak in and fink down into the earth, paffing along between the different ftrata, until they find a vent or outlet in the form of a fpring. See DRAINING *of Land*, SPRING, and WALL. Alfo SPRING-*Draining*.

It is only under certain circumftances that fpring-water can be applied over the furface of grafs-land with much benefit; as where it is confiderably impregnated and loaded with particular forts of materials, as thofe of the calcareous, and perhaps fome other kinds.

A late philofophical writer has remarked, that the neceffity of much water in the progrefs of the growth of plants or their vegetation, is fhewn by the great quantity which exifts naturally in all parts of them; infomuch that many roots, as thofe of the fquill and rhubarb, are known to lofe about fix parts out of feven of their original weight, fimply by drying them before the fire; which quantity of moifture neverthelefs does not exhale in the common heat of the atmofphere during the life of the root; as may be feen in the growth of fquills in the fhop of the druggift, and of onions on the floors of the ftore-rooms of the feedfman. And that a fecond neceffity of much water in the economy of their vegetation or growth may be deduced from the great perfpiration of them, which appears from the experiments of Hales and others, who, like Sanctorius, have, it is faid, eftimated the quantity of perfpiration from their daily lofs of weight; which, however, it is fuggefted, is not an accurate conclufion, either in refpect to plants or animals, as they both abforb moifture from the atmofphere, as well as perfpire it. But that this great perfpiration of vegetables, like that from the fkin and lungs of animals, does not appear to confift of excrementitious matter, becaufe it has in general no putrefcent fmell or tafte, but feems to be fecreted firft for the purpofe of keeping the external furface of the leaves from becoming dry, which would prevent the oxygen of the atmofphere from entering into the vegetable blood or juice through them; fince, according to the experiments of Dr. Prieftley on animal membranes, the oxygen will only pafs through them when they are moift. A fecond ufe of this great perfpiration is, it is faid, to keep the bark fupple by its moifture, and thus to prevent its being cracked by the motion of the branches in the wind. And though a great part of this perfpirable matter is probably abforbed, as on the fkins of animals, yet as it exifts on fo large a furface of leaves and twigs, much of it muft neceffarily evaporate on dry and windy days.

And the difcovery of the decompofition of water has, it is faid, led to a third great ufe of water in the vegetable economy, which is probably owing to its ready decompofition by their organs of digeftion, fanguification, or juice-forming, and fecretion. This is evinced, it is thought, firft, by the great quantity of hydrogen which exifts in the compofition of many of their inflammable parts; and fecondly, from the curious circumftance which was firft difcovered by the ingenious Dr. Prieftley, that the water which they perfpire is hyper-oxygenated, and in confequence always ready to part with its fuperabundance of oxygen, when expofed to the fun's light; whence it may be concluded, it is thought, that a part of the hydrogen, which was previoufly an ingredient of this water, has been feparated from it, and ufed in the vegetable economy. And that, from the decompofition of water, when confined in contact with air beneath the foil, the nitrous acid feems to be produced, and ammonia, both of which are believed to be ufeful to vegetation and the growth of plants.

But that, befide thefe peculiar ufes of a great quantity of water, the more common ufes of it both to vegetable and animal life, along with caloric or the matter of heat, are to produce or preferve a due fupplenefs or lubricity of the folids, and a due degree of fluidity of liquids which they contain or circulate; and, laftly, for the purpofe of diffolving or diffufing in it other folid or fluid fubftances, and thus rendering them capable of abforption, circulation, and fecretion.

It is beneficial, too, in the view of promoting the fertility of grafs-lands, by the occafional fuffufion or flowing it over them, by which it not only fupplies fimple moifture for the purpofes above noticed in the drier parts of the feafon, but brings along with it calcareous earth and azotic air from the neighbouring fprings in many inftances, or other manures from the rivers and brooks. Still another beneficial confequence of it is to give a due penetrability to the foil or mould, which otherwife, in moft fituations, becomes fo ftiff and hard, as to ftop the elongation and diftenfion of the tender roots of plants; but neverthelefs, the cohefion of the foil or earthy particles may be too much or too greatly diminifhed or leffened, by great and perpetual moifture, fo as not to give fufficient firmnefs to the roots of trees or plants. It may alfo be injurious in fome cafes, as in very hafty fhowers, by wafhing off and taking away much of the decompofing animal and vegetable recrements, which are foluble or diffufible in it, and carrying them down the rivers and brooks into the fea; and from the fides of hills, injury in this way is produced by fmall fhowers; and the evaporation of water or moifture from the furface of the earth may produce fo much cold as to injure fuch terreftrial plants as are too long covered with it.

The author of the "Elements of Agricultural Chemiftry" has concluded, that water is abfolutely neceffary to the economy of vegetation, both in its elaftic and fluid ftate; and that it is not devoid of ufe, even in its folid form. Snow and ice are, it is faid, bad conductors of heat; and that, confequently, when the ground is covered with fnow, or the furface of the foil or of water is frozen, the roots or bulbs of the plants beneath are protected by the congealed water from the influence of the atmofphere, the temperature of which, in northern winters, is ufually very much below the freezing-point; and this water becomes the firft nourifhment of the plants in early fpring. The expanfion of water too during its congelation, at which time its volume increafes one-twelfth, and its contraction of bulk during a thaw, tend, it is obferved, to pulverize the foil, to feparate the parts of it from each other, and to make it more permeable to the influence of the air, and the fibres of the roots of vegetables.

Water alfo, as conftituting the daily neceffary drink of the different forts of domeftic animals which form the live-ftock of the farmer, is always to be particularly attended to, and to be provided as fully and of as good quality as can poffibly be met with; as fuch ftock conftantly do beft where they have plenty of water. See POND, and LIVE-*Stock*.

Application of water, whether of ponds, brooks, rivers, or other kinds, to the purpofe of fifheries, is likewife a matter of great individual utility and benefit, as well as general national advantage. It is the means of increafing a moft ufeful fort of food in almoft an unlimited manner, at very little coft or expence. It provides much profitable labour and employment to fome of the working claffes of fociety; and from the trifling charge incurred in providing it, and

and the readinefs of its difpofal, muft be a fource of great wealth to the country. It fhould, of courfe, be encouraged as much as poffible, wherever it can be done with convenience and fuccefs, in all parts of the kingdom. See FISH-*Pond*, POND-*Fifheries*, and SALMON-*Fifheries*.

WATER, *Afcent of*, in *Hydraulics*. See ASCENT and CAPILLARY *Tubes*.

WATER, *High* and *Low*. See FLUX, HIGH, and TIDE.

WATER, *Motion of*. The theory of the motion of running water is one of the principal objects of hydraulics, and many eminent mathematicians have applied themfelves to this fubject. But it were to be wifhed that their theories were more confiftent with each other, and with experience. The curious may confult fir Ifaac Newton's Principles, lib. ii. prop. 36. with the comment. Dan. Bernouilli's Hydrodynamica. Jo. Bernouilli, Hydraulica, Oper. tom. iv. p. 389, feq. Dr. Jurin, in the Phil. Tranf. N° 452, and in Dr. Martyn's Abridg. vol. viii. p. 282, feq. S'Gravefande, Phyfic. Elem. Mathemat. lib. iii. par. ii. Polenus, de Caftellis, and others.

Mr. Maclaurin, in his Fluxions, art. 537. feq., has illuftrated fir Ifaac Newton's doctrine on this intricate fubject, which ftill, notwithftanding the labours of all thefe eminent authors, remains in a great meafure obfcure and uncertain. Even the fimple cafe of the motion of running water, which is when it iffues from a hole in the bottom of a veffel kept conftantly full, has never yet been determined, fo as to give univerfal fatisfaction to the learned. We fhall here mention fome of the phenomena of this motion, as ftated by Dr. Jurin from Poleni; referring for other obfervations on this fubject to FLUIDS, and *Hydraulic Laws of* FLUIDS.

1. The depth of the water in the veffel, and the time of flowing out being given, the meafure of the effluent water is nearly in proportion to the hole.

2. The depth of the water, and the hole being given, the meafure of the effluent water is in proportion to the time.

3. The time of flowing out, and the hole being given, the meafure of the effluent water is nearly in a fubduplicate proportion to the height of the water.

4. The meafure of the effluent water is nearly in a ratio compounded of the proportion of the hole, the proportion of the time, and a fubduplicate proportion of the depth of the water.

5. The meafure of the water flowing out in a given time, is much lefs than that which is commonly affigned by mathematical theorems. For the velocity of effluent water is commonly fuppofed to be that which a heavy body would acquire *in vacuo* in falling from the whole height of the water above the hole; and this being fuppofed, if we call the area of the hole F, the height of the water above the hole A, the velocity which a heavy body acquires in falling *in vacuo* from that height V, and the time of falling T; and if the water flows out with this conftant velocity V, in the time T, then the length of the column of water, which flows out in that time, will be 2 A, and the meafure of it will be 2 A F. But if we calculate from Poleni's accurate experiments, we fhall find the quantity of water which flows out in that time to be no more than about $\frac{571}{1000}$ of this meafure 2 A F. Polen. de Caftellis, art. 35. 38, 39. 42, 43.

Poleni alfo found, that the quantity of water flowing out of a veffel through a cylindrical tube far exceeded that which flowed through a circular hole made in a thin lamina, the tube and hole being of equal diameter, and the height of the water above both being alfo equal; and he found it to be fo when the tube was inferted, not into the bottom, which others had obferved before, but into the fide of the veffel.

12

6. Since the meafure of the water running out in the time T, is 2 A F × $\frac{571}{1000}$, the length of the column of water, which runs out in that time, is 2 A × $\frac{571}{1000}$. Therefore if each of the particles of water, which are in the hole in the fame fpace of time, paffes with equal velocity, it is plain that the common velocity of them all is that with which the fpace 2 A × $\frac{571}{1000}$ would be gone over in the time T, or the velocity V × $\frac{571}{1000}$. But this is the velocity with which water could fpring *in vacuo* to near $\frac{1}{3}$d of the height of the water above the hole.

7. But when the motion of water is turned upwards, as in fountains, thefe are feen to rife almoft to the entire height of the water in the ciftern. Therefore the water, or at leaft fome portion of the water, fpouts from the hole with almoft the whole velocity V, and certainly with a much greater velocity than V × $\frac{571}{1000}$.

8. Hence it is evident, that the particles of water, which are in the hole in the fame point of time, do not all burft out with the fame velocity, or have no common velocity; though fome mathematicians have hitherto taken the contrary to be certain.

9. At a fmall diftance from the hole, the diameter of the vein of water is much lefs than that of the hole. For inftance, if the diameter of the hole be 1, the diameter of the vein of water will be $\frac{21}{25}$, or 0.84, according to fir Ifaac Newton's meafure, who firft obferved this phenomenon; and according to Poleni's meafure $\frac{20}{26}$, or $\frac{20\frac{1}{2}}{26}$, that is, taking the mean diameter 0.78, nearly.

As to the manner of accounting for thefe phenomena, we have already obferved that authors are not agreed; and it would be far beyond our defign to ftate their different theories, we muft therefore refer to the originals above quoted.

Neither are authors agreed as to the force with which a vein of water, fpouting from a round hole in the fide of a veffel, preffes upon a plane directly oppofed to the motion of the vein. Moft authors agree that the preffure of this vein, flowing uniformly, is equal to the weight of a cylinder of water, the bafis of which is the hole through which the water flows, and the height of which is equal to the height of the water in the veffel above the hole. The experiments made by Mariotte, and others, feem to countenance this opinion. But Mr. Daniel Bernouilli rejects it, and eftimates this preffure by the weight of a cylinder, the diameter of which is equal to the contracted vein (according to fir Ifaac Newton's obfervation above-mentioned), and the height of which is equal to twice the height of the water above the hole, or, more accurately, to twice the altitude correfponding to the real velocity of the fpouting water; and this preffure is alfo equal to the force of repulfion, arifing from the reaction of the fpouting water upon the veffel. For he fays that he can demonftrate, that this force of repulfion is equal to a preffure exerted by a vein of fpouting water upon a plane directly oppofed to its motion, if the whole vein of water ftrikes perpendicularly againft the plane. From whence it would follow, that the preffure or force of the vein will be greater in proportion, as its contraction is lefs; and this contraction vanifhing, as it does when the water fpouts through a fhort tube, and the vein being at the fame time fuppofed to have the whole velocity it can acquire by theory, the fpouting water will then exert a preffure double to what is commonly fuppofed. But the actual velocity of the water being always fomething lefs than it ought to be by theory, and the vein of water being not uncommonly contracted to almoft one half, experiments

riments have led authors to think, that the preffure, exerted by fpouting water, was equal to the weight of a cylinder of the fame diameter with the vein, and of the height of the water above the hole. The ingenious author remarks that he fpeaks only of fingle veins of water, the whole of which are received by the planes upon which they prefs; for as to the preffures exerted by fluids furrounding the bodies they prefs upon, as the wind, or a river, the cafe is different, though confounded with the former by writers on this fubject. Hydrodynamica, fect. 13. p. 289.

M. Bernouilli endeavours to confirm his theory by a differtation in the eighth volume of the Acta Petropolitana; where he obferves, that the experiments formerly made before the Academy of Sciences at Paris, to eftablifh the quantity of the preffure exerted by a vein of fpouting water, are very far from proving the truth of the rule they are brought to eftablifh. For inftance, in one of thofe experiments, the height of the water in the veffel above the hole from whence the vein fpouted was two feet Paris meafure; the diameter of the circular hole, which was cut in the horizontal bottom of the veffel, was four lines; and the force of the vein of water was obferved to be one ounce and three-quarters. But the weight of a cylinder of water of the diameter of the hole, and of the height of the water in the veffel, is fcarce equal to one ounce and three-eighths. The difference, therefore, is at leaft three-eighths of an ounce, which is about three-elevenths of the whole weight of the before-mentioned cylinder of water. So that it is furprifing, that this difference fhould have been afcribed to the removal of the plane, receiving the impulfe, to fome diftance from the hole; for this caufe, fuppofing the plane removed to the diftance of two inches, could not produce an increafe of one-fixteenth of an ounce. It appears, therefore, that the common opinion is rather overturned than confirmed by experience. Du-Hamel, Hift. Acad. Paris, ann. 1679, fect. 3. cap. 5.

M. Bernouilli, on the other hand, thinks his own theory fufficiently eftablifhed by the experiments he relates; for the particulars of which, we refer to the Acta Petropolitana, vol. cit. p. 122, feq.

This ingenious author thinks that his theory of the quantity of the force of repulfion, exerted by a vein of fpouting water, might be ufefully applied to move fhips by pumping; and he thinks the motion produced by this repulfive force would fall little, if at all, fhort of that produced by rowing. He has given his reafons and computations at length in his Hydrodynamica, p. 293 to 302.

The fcience of the preffures exerted by water, or other fluids in motion, is what M. Bernouilli calls *hydraulico-ftatica*. This fcience differs from hydroftatics, which confiders only the preffure of water and other fluids at reft; but hydraulico-ftatics confiders the preffure of water in motion. Thus the preffure exerted by water, moving through pipes, upon the fides of thofe pipes, is an hydraulico-ftatical confideration, and has been erroneoufly determined by many, who have given no other rules in thefe cafes, but fuch as are applicable only to the preffure of fluids at reft. See Hydrodynam. fect. 12. p. 256. feq.

WATER, *Raifing of*. Machines for this purpofe are fo numerous, that a minute defcription of fuch hydraulic machines as are in common ufe would fill a volume; and a fcientific account of their principles, with the maxims neceffary to be obferved in their conftruction, would form a very complete body of mechanical fcience: this is far beyond the limits of an article like the prefent, in which we can only introduce the moft ftriking machines which have not already been explained in different articles of this work; and for others, we muft refer to the original works in which they are defcribed.

The moft complete collection of hydraulic machines is that of Jacob Leopold, entitled "Theatrum Machinarum Hydraulicarum," publifhed at Leipzic, in 1724 and 1725, in 2 vols. folio; thefe form part of his voluminous "Theatri Machinarum," which may be confidered as containing all that was known in mechanics at that period.

M. Belidor, in his "Architecture Hydraulique," 1737, has defcribed many machines which were invented fince the date of Leopold's work. This eminent engineer was a good mathematician, and his work may be confidered as a ftandard for the theory of the hydraulic machines of which it treats. The "Experimental Philofophy" of Defaguliers contains fome chapters on hydraulic machinery, in which he generally follows Belidor very clofely, but has tranflated the mathematical inveftigations of the former into the ordinary proceffes of arithmetic, to adapt them to the comprehenfion of mechanics; and in this point of view, the works of Defaguliers have been of great ufe. On the other hand, M. Prony publifhed a modern edition of Belidor's work in 1790, in which, in moft cafes, he has tranfcribed the proceffes of the original into the modern modes of analyfis; but on the whole, he has added little to our real knowledge, except his defcriptions and fuperb plates of Mr. Watt's fteam-engine.

We do not recollect any complete collection of machines for raifing water fince Belidor, although the inventions of the laft century are both numerous and important. Much information relative to them may be derived from Gregory's "Mechanics," in 2 vols. 8vo.; Dr. Robifon's Works, and his excellent articles Hydrodynamics, Pump, and Water-works, in the Encyclopædia Britannica; and from various mifcellaneous publications, fuch as the Repertory of Arts, and the Tranfactions of different learned Societies; alfo the collection of Mr. Smeaton's Reports, in 3 vols. 4to. It is much to be regretted, that this excellent engineer never completed a defign which he formed, to publifh a complete collection of practical hydraulic machines founded on his own experience. Among his manufcript papers which have been lent to us by fir Jofeph Banks, we find an outline for this work, of which we have availed ourfelves in this article.

In confidering machines for raifing water, they may be claffed under two heads:

Firft, thofe machines which actuate fome kind of bucket or veffel adapted to contain water, which veffel is raifed up when full of water, and difcharges its contents into an elevated refervoir, then defcends empty in order to repeat its action: of this fpecies are, the buckets for wells, fcoops, Perfian and Chinefe wheels, chaplets or chains of buckets, the Noira, and the fcrew of Archimedes. It is evident from the nature of all this clafs, that they are incapable of raifing water to a greater height than that to which the machine is elevated, or provided with the means of drawing up the buckets or other veffels; and further, that they cannot raife conftant ftreams of water, but that the water muft be given out by a fucceffion of difcharges from the different buckets or veffels.

The fecond clafs comprifes thofe machines which act by means of valves and piftons moving in cylinders, or other equivalent contrivances, and force the water to afcend through pipes or tubes: thefe machines have the advantage of raifing the water to very great heights above the place where the machine is placed. The greater part of thefe machines we have already defcribed under the article PUMP, and

and there remain but few to be confidered in the prefent article; *viz.* the varieties of the hydraulic ram, of the Chremnitz fountain, and of the fyphon machines.

The moft obvious means of raifing water is by the operation called baling, that is, lifting up water in a bucket, or other veffel, by the force of a man's arm. This method is extremely fatiguing, and is only adapted to very fmall elevations, fuch as clearing the water from a boat, &c. The moft ancient hydraulic machine acts on this principle, fuch as the fcoop and troughs, the Fen wheel, Perfian wheel, the Noira, &c.: it is, therefore, with thefe machines we fhall commence.

The *Dutch water-fcoop*, or fhovel, is the beft means of baling out water. The fcoop is a kind of box, made of five pieces of board, with one end and one fide open: this box is fixed at the extremity of a long pole, which the workman holds in his hand, and the weight of the fcoop is borne by a cord tied to the pole near to the box, and fufpended from a tripod, formed of three poles tied together at the top. The man works the machine by fwinging the fcoop backwards and forwards in the direction of the length of the pole; in moving the box forwards, he depreffes the end of the pole, which caufes the box to dip into the water, and take up a quantity which it will throw forwards and rather upwards to a confiderable diftance. In bringing the fcoop back for another ftroke, he depreffes the end of the pole which he holds in his hand, and thus keeps the box out of the water. Of courfe this method is only applicable where the height to which the water is to be raifed, or rather thrown, is very fmall. M. Belidor informs us, that a workman can only remove half a cubic foot in two vibrations, which he will perform in four feconds; this is at the rate of $7\frac{1}{2}$ cubic feet *per* minute, or 450 cubic feet *per* hour: it is rarely applicable, except to throw the water over a bank which forms the boundary of a ditch, or other place of fmall depth, which is to be emptied.

The *laving gun*, which is ufed in falt-works from its fimplicity, comes next. It is a trough of five or fix feet in length, made fmall at one end like a fpout, and gradually increafing to the oppofite end, where it is about a foot or eighteen inches fquare. The fmall end is fupported on pivots upon the bank over which the water is to be raifed, and a lever is applied to it for a man to work it by. The large end of the trough will dip into the water, when it defcends and becomes filled; but when lifted the leaft above the horizontal pofition, the contained water will run along the trough, and be delivered over the bank through the fpout. This machine is much improved by making it double, or with two troughs, on the oppofite fides of the centre; thus when one afcends, the other will defcend fo as to raife up a conftant ftream, which it muft, in this cafe, deliver at a fpout fideways, near to the pivot or centre on which it plays. This double machine will raife a copious ftream of water, but is confined to fmall heights of three or four feet. If the large end of the trough has a valve opening into it to admit the water, it will fill itfelf more readily. A machine which operates on the fame principle as this, is called the fcoop-wheel, or tympanum, which is in fact feveral double laving machines arranged round the centre like a wheel. The advantage of this wheel is, that it always moves in the fame direction, whereas the fimple machine requires a reciprocating motion.

The *tympanum*, or *fcoop-wheel*, mentioned by Vitruvius, is a great hollow wheel formed by a kind of barrel or drum (as its name imports): it is compofed of feveral planks joined together, well caulked and pitched, and having a horizontal axle with pivots at the ends, on which it turns. The interior capacity of this drum is divided into eight equal fpaces, by as many partitions placed in the directions of the radii; each fpace or cell has an orifice of about fix inches in width in the rim of the drum or wheel. Thefe openings are fo fhaped, as to facilitate the admiffion of the water; moreover, there are eight hollow channels running along the axle of the wheel and contiguous to each other, each correfponding to one of the eight large cells; into thefe channels the water paffes out of the cells juft mentioned, and after running along the channels in the axis of the wheel to a convenient diftance, it efcapes through orifices into a refervoir placed juft under the axle. Thus when the wheel is turned round, the water is elevated through a vertical height equal to the radius of the hollow wheel.

When the tympanum is ufed to raife water from a running ftream, it is moved by means of float-boards fixed on the circumference, which are impelled by the ftream; but when it is employed to raife ftagnant waters, there is commonly a fmaller hollow wheel fixed on the fhaft at the fide of the tympanum, which is turned by men walking in it, as in the old walking-crane. The chief defect of this machine is, that it raifes the water in the moft difadvantageous fituation poffible, for the load of water is always towards the extremity of a radius of the wheel, and the length of the effective lever which anfwers to it muft continually increafe as the water is raifed through the whole quadrant, which the water defcribes in paffing from the bottom of the wheel to the altitude of its centre, fo that the power muft act in the fame manner as if it were applied to a winch or crank handle, and cannot act uniformly.

The *horn-wheel* was contrived to remedy this defect: it is fo called, becaufe the fegments which pafs from the circumferences of the large flat cylinder to its centre are not ftraight radii, as in the former inftance, but are curved fpirally. The fcoops, or mouths, by turns, dip into the water, and as they rife up caufe the water to pafs up the horn, or curved fegment, until it is as high as the centre of the wheel, and then it is difcharged into a trough placed under the end of the axis, which is hollow, and has its pivots faftened to a crofs.

M. de la Faye has inveftigated the proper curves for the fcoop fegments of this machine in the following manner:— When we evolve the circumference of a circle by unwrapping a ftring from the circumference, the end of the ftring will defcribe a curve called the involute of the circle, of which all the radii are fo many tangents to the circle, as is fhewn by the ftring in its different pofitions whilft tracing the curve, and likewife all the radii are refpectively perpendicular to the feveral points of the curve defcribed by the end of the ftring.

The greateft radius of this curve is a line equal to the periphery of the circle evolved. The truth of this ftatement is fhewn by geometricians, when treating of the generation of *Evolute* and *Involute Curves*. See thofe articles.

Hence, having an axle, whofe circumference a little exceeds the height to which the water is propofed to be elevated, let the circumference of the axle be evolved, and it will make a curve which will be the involute of the circle, as before mentioned. Now, let a number of pipes, or trunks, be made exactly with this curvature, and then put together around the axle, in form of a wheel, fo that the further extremities of thefe canals will fucceffively enter the water that is to be elevated, whilft the other extremities abut upon the fhaft which is turned. Then, in the courfe of the rotation of the wheel, the water taken in at the extremity of each canal will rife in a vertical line, which is a tangent

to

to the ſhaft, becauſe the curves of the ſeveral channels will be at right angles to this vertical line, in the points where the line interſects the curves; and this is true in whatever poſition the wheel may be. Thus the action of the weight continuing always beneath the extremity of the horizontal radius of the axle, will oppoſe the ſame reſiſtance, as though it acted upon the invariable arm of a lever, in the manner of a bucket of water, which is drawn up out of a well by a rope, winding on a roller, and the power required to raiſe the weight will be always the ſame.

If the radius of the wheel, of which theſe hollow canals ſerve as bent ſpokes, be equal to the height through which the water is to be raiſed, and conſequently equal to the circumference of the axle, or ſhaft, the power will be to the load of water reciprocally as the radius of a circle to its circumference, or directly as 1 to $6\frac{1}{4}$ nearly. M. de la Faye recommended the machine to be compoſed of four of theſe canals, but it has often been conſtructed with eight. The wheel is turned by the impulſion of the ſtream upon float-boards fixed on the circumference of the wheel, and the orifices of the curvilineal canals dip one after another into the water which runs into them; and as the wheel revolves, the fluid riſes in the canals, until it is as high as the centre: it then runs out in a ſtream from the holes in the axis, and is received into the trough fixed beneath the axis; from thence it may be conveyed by pipes or troughs to the required ſituation.

By this conſtruction, the weight to be raiſed offers always the ſame reſiſtance, and that is the leaſt poſſible, while the power is applied in the moſt advantageous manner which the circumſtances will admit of. Theſe conditions being both fulfilled at the ſame time, furniſh the moſt deſirable perfection in a machine. This machine raiſes the water by the ſhorteſt way, namely, the perpendicular or vertical line, and in this reſpect is preferable to Archimedes's ſcrew, where the water is carried up a crooked and inclined path; and beſides this each curved channel in this wheel empties all the water it receives in every revolution, while the ſcrew of Archimedes delivers only a ſmall portion of the fluid with which it is charged, being often loaded with twenty times as much water as is diſcharged at one rotation, and thus requiring an increaſe of labour when a large quantity is intended to be raiſed by it. The horn-wheel would be one of the moſt perfect machines for raiſing water, were not its powers confined to ſuch altitudes as the ſemi-diameter of the wheel.

The *flaſh*, or *fen-wheel*, comes next to be deſcribed.— This is a vertical wheel, made exactly like thoſe water-wheels for turning mills which are called breaſt-wheels, and in the ſame manner the wheel is ſurrounded at the lower quadrant by a curved ſweep of maſonry or breaſt, to which the floats of the wheel are fitted with the greateſt accuracy, but do not abſolutely touch. This wheel, being turned round in a direction contrary to that in which a water-wheel turns, will carry water before its floats, and raiſe it up againſt the breaſt until it runs over the ſame. The operation is juſt the reverſe of the water-wheel; and the only difference in the conſtruction of the two machines is, that the flaſh-wheel requires no ſhuttle to be placed at the top of the breaſt, becauſe the water muſt be allowed to run freely away from the top of the breaſt; but the water-wheel requires a ſhuttle or ſluice to regulate the quantity of water which ſhall flow to the wheel.

It is by this kind of machine that the extenſive fens of Holland are drained; and in Lincoln and Cambridgeſhire they are alſo uſed very extenſively. They are, in general, worked by the power of the wind, and are on a very large ſcale.

Mr. Smeaton made a horſe-machine on this plan, which raiſed thirty-three hogſheads *per* minute, to the height of four feet and a half, when it was worked by four horſes; but a ſluice was placed in the channel which admitted the water to the wheel, ſo as to ſupply the water in a greater or leſſer quantity; and by this means, the ſame machine could be adapted to the power of three or two horſes. The crown or top of the breaſt, over which the water was delivered, was not elevated to the full height to which the water was to be raiſed, but it was laid twelve inches beneath the ſurface, and the body of water which the wheel raiſed up was ſufficient to drive this depth of water before it; but to prevent the return of the water when the mill ceaſed working, two pointed doors were placed in the channel leading from the wheel, like the gates of a canal-lock: theſe doors opened freely, to let the water paſs, but would ſhut and ſtop the water from returning. The proportions of this machine were as follows:

Diameter of the track in which the horſes walked - - -	26 feet 8 inches.
Great cog-wheel fixed on the perpendicular axis - - -	72 teeth 9 feet diameter.
Trundle worked by the wheel -	35 teeth $4\frac{1}{2}$ feet diam.
Diameter of the water-wheel on the ſame axis as the trundle -	14 feet.
Breadth of the wheel - - -	2 feet 2 inches.
Number of its floats - - -	42

The floats did not point to the centre of the wheel, but formed tangents to a radius, equal to about half the radius of the wheel. The floats of the wheel were very exactly fitted to the channel or pit in which it worked, ſo as not to touch.

The *bucket-wheel* is a very ancient method of raiſing water; but it cannot lift water to a greater height than its own diameter. The laſt machine was the reverſe of the breaſt water-wheel, and the preſent is the reverſe of the over-ſhot water-wheel, for the circumference of the wheel is ſurrounded by buckets, which dip in the water beneath the wheel, and take up water, which they diſcharge at the top of the wheel into an elevated trough or reſervoir. The wheel is mounted upon an horizontal axis, and turns upon pivots; it is put in motion by the force of a current of water ſtriking the float-boards fixed on the circumference of the wheel; or if there is no current in the water, it may be moved by making the wheel hollow within for a man to walk in it, as is common in ſome kinds of cranes, or the wheel may be turned by horſes. The rim, or circumference of the wheel, is made hollow, and is divided into ſeveral compartments, to form a number of boxes or buckets; each bucket has an opening into it at that end which will be the moſt advanced when the wheel turns; and from this opening, a ſpout or trough projects in a direction parallel to the axis of the wheel. When the wheel revolves, the buckets dip into the ſtream, and become filled with water; but as the mouths or ſpouts are at the upper end when the buckets riſe out of the water, they cannot eſcape, and each bucket carries up its charge of water to the top of the wheel; but the buckets will have then become inverted, and the ſpouts or openings being at the loweſt part, that they diſcharge the water ſideways through the ſpouts into a trough properly placed to receive it, and then the buckets deſcend empty till they dip into the ſtream and are refilled. The objection to this machine is, that the buckets begin to pour out the water

ſome

ſome time before they arrive at the greateſt height of the wheel; and, therefore, the trough is of neceſſity placed lower than the diameter of the wheel, or a conſiderable portion of the water would be loſt, and in any caſe part of the water is raiſed above the level of the trough.

Spaniſh Bucket-Wheel.—Mr. Townſend, in his Travels through Spain, deſcribes a ſimple machine which is uſed at Narbonne for watering of gardens. The water is raiſed by a vertical wheel, which is twenty feet in diameter, on the circumference of which is fixed a number of little boxes or ſquare buckets, for the purpoſe of raiſing water out of the ciſtern communicating with the canal below, and to empty it in a reſervoir above, placed by the ſide of the wheel. The buckets have a lateral orifice to receive and to diſcharge the water. The axis of this wheel is embraced by four ſmall beams, croſſing each other at right angles, and tapering at the extremities ſo as to form eight little arms. This wheel is near the centre of the path in which the mule walks, and contiguous to the vertical axis, into the top of which the horſe-beam is fixed; but near the bottom of this axis it is embraced by four little beams, forming eight arms, ſimilar to thoſe above deſcribed, on the axis of the water-wheel. As the mule which they uſe goes round, theſe horizontal arms, ſupplying the place of cogs, take hold each in ſucceſſion of thoſe arms which are fixed on the axis of the water-wheel, and keep it in rotation. This machine may be made very cheap, and will throw up a great quantity of water, yet undoubtedly it has two defects; the firſt is, that part of the water runs out of the buckets, and falls back into the well after it has been raiſed nearly to the level of the reſervoir; and the ſecond is, that a conſiderable proportion of the water to be diſcharged is raiſed higher than the reſervoir, and falls into it only at the moment when the bucket is at the higheſt point of the circle, and ready to deſcend.

The *Perſian wheel with ſwinging buckets* is free from ſome of the defects of the laſt machine. The buckets are looſe, and each hangs from the circumference of the wheel by a pin, on which it ſwings or turns freely; and as the bucket is ſuſpended by its upper part, it will hang perpendicular, with the mouth upwards, in all poſitions of the wheel. From the time it dips in the water and is filled, until the bucket arrives at the upper part of the wheel, it is carried by the motion of the wheel againſt the edge of the trough, and inclined ſo far as to diſcharge its contents into the trough. (See Persian *Wheel.*) The pins are fixed into the circumference of the wheel, and project ſideways therefrom a ſufficient diſtance to ſupport the buckets, and carry them over the elevated trough. Sometimes the wheel is made with two rims, and each bucket is ſuſpended upon an axis between them: the end of each axis paſſes through the rim of the wheel, and is bent to form a ſhort lever, which is carried by the motion of the wheel againſt a fixed rail, and thus inclines the bucket to diſcharge the contents into a trough which is fixed to the rims of the wheel immediately beneath the bucket, and has a ſpout projecting at the ſide of the wheel, to carry the water ſideways and deliver it into the trough, which is fixed at the ſide of the wheel for its reception.

As the Perſian wheel is a very effective machine in ſituations where the elevation is required to be but ſmall, the following directions, given by M. Belidor for its conſtruction, are worthy of attention: firſt fix the diameter of the wheel ſomething greater than the altitude to which the water is to be raiſed; fix alſo upon an even number of buckets, to be hung at equal diſtances round the periphery of the wheel; and mark the poſition of their centres of motion in ſuch a manner, that they will ſtand in correſponding poſitions in every quarter of the circle. Suppoſe vertical lines drawn through the centre of motion of each bucket in the riſing part of the wheel, and they will interſect the horizontal diameter of the wheel in points, at which, if the buckets were hung, they would make the ſame reſiſtance to the moving force, as they do when hanging at their reſpective places on the rim of the wheel. Thus, ſuppoſing there are eighteen equidiſtant buckets, then while eight hung on each ſide of a vertical diameter of the wheel, there would be eight on the other ſide, and two would coincide with that diameter: in this caſe, the reſiſtance ariſing from all the full buckets would be the ſame as if one bucket hung on the prolongation of the horizontal diameter, at the diſtance of twice the ſine of 20° + twice the ſine of 40° + twice the ſine of 60° + twice the ſine of 80°, theſe being the ſines to the common radius of the wheel.

To know the quantity of water that each one ſhould contain, take four-ninths of the abſolute force of the ſtream, that is, four-ninths of the weight of a priſm of water whoſe baſe is the ſurface of one of the float-boards, and whoſe height is equal to that through which the water muſt fall in order to acquire the velocity with which the ſtream moves. This is the power which ſhould be in equilibrio with the weight of water contained in the buckets of the riſing ſemicircle. Then ſay, as the ſum of the ſines mentioned above is to the radius of the wheel to the centre of the float-board, ſo is the power juſt found to a fourth term, one-half of which will be the weight of water that ought to be contained in each bucket. Laſtly, the velocity of the float-board of the wheel will be to that of the ſtream nearly as one to two and two-fifths, and from this the number of revolutions it will make in any determinate times may be known, and of conſequence the quantity of water the wheel will raiſe in the ſame time, ſince we know the capacity of each bucket, and the number of them which will be diſcharged in every revolution of the wheel. See Persian *Wheel.*

The Chineſe Bucket-Wheel.—Sir George Staunton, in his account of the Embaſſy to China, gives the following deſcription of a bucket-wheel, which is different from any we have met with in the hydraulic collections, and conſtructed with that ſimplicity which diſtinguiſhes the Chineſe inventions. Two hard-wood poſts or uprights are firmly fixed in the bed of the river, in a line perpendicular to its banks. Theſe poſts ſupport the pivots of an axis of about ten feet in length: this is the axis of a large wheel conſiſting of two unequal rims, the diameter of the rim which is neareſt to the bank being about fifteen inches leſs than that of the outer rim; but both rims dip into the ſtream, while the oppoſite points or top of the wheel riſe above the elevated bank over which the water is to be raiſed. This double wheel is framed upon the axis, and is ſupported by ſixteen or eighteen ſpokes, inſerted obliquely into the axis near each extremity, and croſſing each other at about two-thirds of their length. They are there ſtrengthened by a concentric circle, and are faſtened afterwards to the two rims. The ſpokes inſerted in the interior extremity of the axis reach to the outer rim, and thoſe proceeding from the exterior extremity of the axis reach to the inner and ſmaller rim. Between the rims and the croſſings of the ſpokes is a triangular ſpace, which is woven with a kind of cloſe baſket-work, to ſerve as ladle-boards, or floats. Theſe ſucceſſively receiving the current of the ſtream, obey its impulſe, and turn round the wheel.

The buckets which take up the water are ſmall tubes or

ſpouts

ſpouts of wood attached to the two rims of the wheel, and having an inclination of about twenty-five degrees to the horizon, or to the axis of the wheel. The tubes are cloſed at their outer extremities, which are fixed to the larger rim, and open at the oppoſite end. By this poſition the tubes, which in the motion of the wheel dip into the ſtream, have their mouths or open ends uppermoſt, and fill with water. As that ſegment of the wheel riſes upwards, the mouths of the tubes attached to it will alter their relative inclination, but not ſo much as to let their contents flow out until ſuch ſegment of the wheel arrives at the top. The mouths of theſe tubes are then relatively depreſſed, and they pour the water into a wide trough placed on pivots, from whence it is conveyed, as may be wanted, among the plantations of canes.

The only materials employed in the conſtruction of this water-wheel, except the nave or axis, and the poſts on which it reſts, are afforded by the bamboo. The rims, the ſpokes, the ladle-boards or floats, and the tubes or ſpouts, or even the cords, are made of entire lengths, or ſingle joints, or large pieces, or thin ſlices, of the bamboo. Neither nails, nor pins, nor ſcrews, nor any kind of metal, enter into its conſtruction: the parts are bound together firmly by cordage of ſlit bamboo. Thus, at a very trifling expence, is conſtructed a machine, which, without labour or attendance, will furniſh, from a conſiderable depth, a reſervoir with a conſtant ſupply of water, adequate to every agricultural purpoſe.

Theſe wheels are from twenty to forty feet in diameter, according to the height of the bank, and conſequent elevation to which the water is to be raiſed. A wheel of thirty feet is capable of ſuſtaining with eaſe twenty tubes or ſpouts, of the length of four feet, and diameter of two inches in the clear. The contents of ſuch a tube would be equal to ſix-tenths of a gallon, and the twenty tubes would hold twelve gallons. A ſtream of a moderate velocity would be ſufficient to turn the wheel at the rate of four revolutions in one minute, by which would be lifted forty-eight gallons of water in that ſhort period; or in one hour, two thouſand eight hundred and eighty gallons; and ſixty-nine thouſand one hundred and twenty gallons, or upwards of three hundred tons in a day. This wheel is thought by ſir George to exceed, in moſt reſpects, any machine yet in uſe for ſimilar purpoſes. The Perſian wheel, with looſe buckets ſuſpended to the edge of the rim or fellies of the wheel, ſo common in the ſouth of France, and in the Tyrol, approaches neareſt to the Chineſe wheel, but is vaſtly more expenſive, and leſs ſimple in its conſtruction, as well as leſs ingenious in the contrivance. In the Tyrol there are alſo bucket-wheels for lifting water in a circumference of wood, hollowed into ſcoops; but they are much inferior either to the Perſian or Chineſe wheel.

Chain of Buckets.—This machine conſiſts of a number of buckets attached to a chain or rope, the ends of which are united together. The chain is conducted over a wheel, which is turned by ſome animal or mechanical power; and the chain hangs down from this wheel into the well from which the water is to be drawn. The buckets at the lower part of the chain become filled, and, by the motion of the chain, the buckets attached to one part of the chain will aſcend full of water, whilſt thoſe on the oppoſite ſide are deſcending empty, with their mouths downwards. When the full buckets of water turn over the upper wheel, they diſcharge their contents into a trough fixed near the wheel. The moſt convenient way of diſcharging the water is to make the upper wheel hollow, with diviſions in it like the tympanum; and the buckets, when they turn over, will pour their contents into the hollow ſegments of the wheel, and it will run off through a hollow in the axis made for that purpoſe. The advantage of the chain of buckets over the wheel is, that the chain can be made to deſcend in a well, or ſmall ſpace, where the wheel could not; alſo, that the chain may be uſed for greater depths than would be practicable for a wheel.

The *Spaniſh noira* is a chain of buckets or earthen jars. Mr. Townſend informs us, in his journey through Spain, that the noira conſiſts of an endleſs band or girdle, paſſing over a ſprocket-wheel: the band is long enough to reach eighteen inches or two feet below the ſurface of water in a well. All round this band, at the diſtance of about fifteen inches, are fixed jars of earthen-ware, which, as the band turns, take up water from the well, and pour it into a ciſtern fitted to receive it. A little aſs, going round in a circular walk with eaſe, turns a trundle, which gives motion to a cog-wheel, fixed on the ſame axis with the ſprocket-wheel, on which the band is hung, and with which it turns. This machine produces a conſtant and conſiderable ſupply of water, at a ſmall expence, and with very little friction. As the air would obſtruct the entrance of water into theſe earthen jars or bottles, each jar has a little orifice in its bottom, through which the air eſcapes; but then water runs out alſo, and a certain quantity falls back into the well.

It is true, as the jars riſe in one ſtraight line, the water which runs out of the ſuperior jar is caught by that which is immediately below it, yet ſtill there is a loſs; and, beſides this inconvenience, the whole quantity is raiſed higher than the upper reſervoir, at leaſt by the diameter of the ſprocket-wheel, becauſe it is only in their deſcent that the jars are emptied.

The *ſcrew of Archimedes* is a machine on a principle very cloſely allied to the horn-wheel; but the curved channels are wrapped ſpiralwiſe round an axis, which is placed on an inclined poſition, with the lower end immerſed in the water which is to be raiſed, and the upper end placed over the edge of the reſervoir into which the water is to be delivered. When this cylinder is turned round, it will take water up in its ſpiral channel, and raiſe it gradually to the elevated end, and diſcharge it into the reſervoir. (See Screw.) Although this machine is ſimple in its general manner of operation, its theory is attended with ſome difficulties.

If we conceive that a flexible tube is rolled regularly about a cylinder, from one end to another, this tube or canal will form a ſcrew or ſpiral, of which we ſuppoſe the intervals of the ſpires or threads to be equal to one another. Suppoſe this cylinder placed with its axis in a vertical poſition, if we put in at the upper end of the ſpiral tube a ſmall ball of heavy matter, which may move freely, it is certain that it will follow all the turnings of the ſcrew from the top to the bottom of the cylinder, deſcending always as it would have done, had it fallen in a right line along the axis of the cylinder; only it will occupy more time in running through the ſpiral.

If we ſuppoſe the cylinder placed with its axis horizontally, and we again put the ball into one opening of the canal, it will deſcend, following the direction of the firſt demi-ſpire, until it arrives at the loweſt point in this portion of the tube, and then it will ſtop: for the weight of the ball has no other tendency than to make it deſcend in the demi-ſpire. The oblique poſition of the tube, with reſpect to the horizon, cauſes the ball, in deſcending, to advance from that extremity of the cylinder whence it commenced its motion to the other extremity. When the ball is arrived at the bottom of the firſt demi-ſpire, if we cauſe the cylinder to turn on its axis, without changing the poſition of of that axis, and in ſuch manner that the loweſt point of the demi-ſpire on which the ball preſſes becomes elevated, then the ball falls neceſſarily from this point upon that which ſucceeds, and becomes loweſt; and as this ſecond point is more advanced towards the ſecond extremity of the cylinder than the former one, the ball will be advanced towards that extremity by this new deſcent, and ſo on, that it will at length arrive at the ſecond extremity. Moreover, the ball, by conſtantly following its tendency to deſcend, has advanced through a right line, parallel and equal to the axis of the cylinder; and this diſtance is horizontal, becauſe the ſides of the cylinder were placed horizontally.

But ſuppoſe the cylinder had been placed oblique to the horizon, and turned on its axis continually in the ſame direction, it is eaſy to ſee that the ball will move from the lower end of the ſpiral tube towards the upper end, although it is actuated ſolely by gravity, for this cauſes it to occupy the loweſt point of the firſt demi-ſpire; and when it is abandoned by this point, as it is elevated by the rotation, and will roll by its weight upon that point which has taken its place, this ſucceeding point is further advanced towards the elevated extremity of the cylinder than that which the ball occupied juſt before; conſequently the ball, while following its tendency to deſcend, will be always more and more elevated, by virtue of the rotation of the cylinder. Thus it will, after a certain number of turns, be advanced from the lower extremity to the upper, or through the whole length of the ſpiral; but it will only be raiſed through the vertical height, determined by the obliquity of the poſition of the cylinder.

Inſtead of the ball, let us now conſider water as entering by the lower extremity of the ſpiral canal, when immerſed in a reſervoir. This water deſcends at firſt in the canal ſolely by its gravity; but the cylinder being turned, the water moves on in the canal to occupy the loweſt place, and thus, by the continual rotation, is made to advance further and further in the ſpiral, till at length it is raiſed to the upper extremity of the ſpiral, where it is expelled. There is, however, an eſſential difference between the water and the ball; for the water, by reaſon of its fluidity, will adapt itſelf to the form of the ſpiral, and, after having deſcended by its heavineſs to the loweſt point of the demi-ſpire, will riſe up on the contrary ſide to the original level; on which account, more than half one of the ſpires may be filled with the fluid.

The moſt ſimple method of tracing a ſcrew or a helix upon a cylinder is well known to be this:—Take the height or length of a cylinder for the perpendicular leg of a right-angled triangle, and make the baſe or horizontal leg equal to as many times the circumference of the cylinder as the ſcrew is to make convolutions about the cylinder itſelf; then draw the hypothenuſe to complete the triangle. Suppoſe this triangle to be enveloped about the ſurface of the ſolid cylinder, the perpendicular leg being made to lie parallel to the axis of the cylinder, and the horizontal leg or baſe to fold upon the circumference of the cylinder, even with its baſe; then the hypothenuſe or ſloping ſide of the triangle will form the contour of the ſcrew. If a tube be formed according to the direction of this ſpiral, and a ſmall ball put into it when the cylinder is placed upright, the ball would roll to the bottom with the ſame velocity, and the ſame force, as it would have deſcended upon a plane ſurface, inclined in the ſame degree as the hypothenuſe of the triangle which we have ſuppoſed, when the baſe thereof is horizontal. But ſuppoſe the cylinder be inclined in ſuch degree, that the hypothenuſe of the ſaid triangle would be horizontal inſtead of the baſe, as the angle which the threads of the ſcrew make conſtantly with the baſe of the cylinder is juſt equal to that inclination, the threads at their point of ſmalleſt inclination will be parallel to the horizon; ſo that there being nothing to occaſion the ball to roll towards either end, it will remain immoveable, ſuppoſing the cylinder to be at reſt; but if the cylinder be turned on its axis in one direction, the ball (abſtracting from friction) will move the contrary way, in conformity with the firſt law of motion. The inclination which we have juſt aſſigned is the leaſt we can give, ſo that the ball ſhall not deſcend of itſelf; but if we augment this inclination, then, by turning the cylinder, the ball will always have a deſcent on one ſide, and will in conſequence roll towards the elevated end of the ſame, and will mount by deſcending. The reaſon is very ſimple: the plane which carries it makes it riſe more, in conſequence of the rotatory motion, than it deſcends by virtue of the force of gravity. It is obvious, from what has been remarked, that this ſcrew can never raiſe water, when the angle which the central line of the ſpiral makes with the baſe of the cylinder is larger than the angle which the baſe of the cylinder makes with the horizon.

The ratio of the weight of the ball to the force which is neceſſary to make it riſe by turning the ſcrew, is as the vertical ſpace through which the weight is raiſed to the ſpace paſſed through by the power in moving it. Suppoſe the moving force acts at the circumference of the cylinder, the ſpace paſſed over by that force will be equal to as many times the circumference of the cylinder as the number of convolutions of the helix. Let the diameter of the cylinder be 14 inches, the vertical altitude of the upper end of the cylinder above the lower end 12 feet, or 144 inches, and 12 convolutions of the ſpiral: let the cylinder be ſo placed, that the inclination of the axis is greater than the inclination of the ſpiral to the axis, and let the weight to be raiſed be a 48 lb. ball. The circumference of the cylinder will be nearly 44 inches, and the 12 turns equal to $12 \times 44 = 528$ inches, for the ſpace the power muſt move through. Hence we have 528 inches : 144 inches :: 48 lbs. : $13\frac{1}{11}$ lbs.; the meaſure of the requiſite force to be applied at the ſurface of the cylinder. If the moving force deſcribes a circle whoſe diameter is three times that of the cylinder, or acts at a winch whoſe diſtance from the axis of motion is 21 inches, that force will then be reduced to $\frac{1}{3}$ of $13\frac{1}{11}$ or $4\frac{4}{11}$ lbs. which is leſs than one-tenth of the weight of the ball. In this inveſtigation, no notice is taken of the friction upon the pivots, or of the effects of the air included in the ſpiral: yet if the ſpiral had been folded upon a cone inſtead of a cylinder, or if it had been formed of a flexible tube of varying diameter, theſe effects would have been important: ſome of them are conſidered in our account of the ſpiral pump.

The Archimedes' ſcrew is a machine ſo frequently employed in hydraulic architecture, as to deſerve particular directions for conſtructing it. The ſimple pipe wrapped round a cylinder will not afford any conſiderable ſupply of water, and therefore a hollow barrel muſt be made with one or two ſpiral partitions running in it, like the ſpiral ſtair caſes uſed in church ſteeples.

Vitruvius has given minute directions for the conſtruction of the water-ſcrew, and Mr. Smeaton's directions, which are very ſimilar, are as follow:—For a ſcrew of 18 inches diameter, uſe a ſolid cylinder of ſix inches diameter as an axis, upon the ſurface of which cut a double helix, forming two ſeparate grooves round the axis of about three-quarters of an inch wide and deep, ſo that the grooves in going once round will advance about ſixteen inches, and in conſequence confequence the two grooves will be eight inches apart from middle to middle, meafuring parallel to the length of the cylinder. Into thefe grooves drive and faften pieces of board, fo as to form radii or fectors of a circle of eighteen inches and a half diameter, and fo moulded as to be a little upon the twift, to anfwer the different inclinations of the helix, at the different diftances from the centre. Thefe pieces being jointed together, and to the axis, fo as to fill the whole groove from one end of the axis to the other, form a double fcrew; then apply narrow boards longitudinally, reaching from one end of the fcrew to the other. The boards fhould be about four inches broad, and formed concave withinfide, anfwerable to a circle of eighteen inches diameter. Thefe boards are marked one by one at the places where they touch the fpiral boards, and are then grooved about a quarter of an inch, to admit the ends of the radius pieces which form the fcrew. When all the boards are put together they form a cylinder of eighteen inches diameter, which is hooped on the outfide, in the manner of a tub or cafk; and in order that the hoops may properly drive on the outfide, at the fame time that the infide forms a complete cylinder, the longitudinal pieces are made rather thicker in the middle than at the ends.

Archimedes' fcrew may be ufed for other purpofes than raifing of water. It might be adapted with advantage in raifing cannon-balls from a fhip to a wharf, and with the addition of a bevel-wheel or two and their pinions, might be worked either by men or horfes. Sometimes Archimedes' fcrew inftead of being worked by men at a winch, is turned by means of float-boards fixed on the circumference of a wheel placed at its lower end, upon which a ftream of water acts. If the water has a moderate fall, it will have fufficient efficacy to turn two fcrews, one above another. The top of the lower fcrew and the bottom of the upper fcrew may act one upon the other, by means of a wheel upon each, with an equal number of teeth taking into each other. In this cafe the upper fcrew will turn in a contrary direction from the lower, and confequently the fpiral tube muft be wound about the cylinder in an oppofite direction. A folid wheel, or a light wheel with a heavy rim, turning upon the middle of the fcrew as an axis, will operate like a fly, and in fome cafes be very ufeful.

Mr. Smeaton made a machine to raife water by an Archimedes' fcrew for the royal gardens at Kew, which was on a large fcale. The fcrew was twenty-four feet long, two feet fix inches in diameter, and raifed the water perpendicularly fourteen feet nine inches. The central cylinder, or fhaft of the fcrew, was ten inches diameter; the diftance between the threads, including the thicknefs of the helix, was twelve inches and a half; and as there were two fpiral paffages, each fpiral advanced twenty-five inches along the cylinder at every turn; each fpiral contained twenty-feven quarts at every turn, the fcrew therefore gave out fifty-four quarts at every turn which it made.

This fcrew was turned by means of a trundle or pinion from a horfe-wheel, with the intervention of two moveable joints, to change the direction of the axis from the horizontal to the direction of the axis of the fcrew, which was inclined at an angle of about thirty-eight degrees to the horizon. The diameter of the horfe-track was twenty-five feet, half of which was the length of the effective lever upon which the horfes acted. The great cog-wheel on the axis of the levers was fourteen feet diameter, with 144 cogs, and the trundle which it turned twenty-three cogs, fo that the fcrew made about fix turns for one of the horfe-wheel.

This machine was worked by two light horfes, with very great eafe, and they made three turns *per* minute; but if at all urged, could make the fcrew turn twenty turns *per* minute, and at that rate of working raifed 300 hogfheads *per* hour.

The *Water-fcrew*, defcribed in our article Screw, does not differ from the fcrew of Archimedes in its principle, but as the fcrew turns round within a fixed barrel, the water is liable to leak back in part.

Drawing Water by Buckets.—The methods which we have hitherto defcribed are only adapted to raife water to fmall elevations; but by means of buckets, water may be drawn from very great depths. The moft fimple cafe is that of a man with a bucket or other veffel in his hand, ftooping down to lower the empty bucket into a pond, as low as he can reach, and drawing it up full of water.

The firft improvement which would occur would be to fufpend the bucket by a rope, and draw it up by means of a long lever, or otherwife, if the depth was greater, by continuing the rope over a pulley, fo that the man could eafily draw the end of it; and this would be farther improved when two buckets were fufpended at the oppofite ends of the rope or chain, fo that one being drawn up full of water, an empty one would be let down at the fame time. This method is applicable to the deepeft well, and is very effective. The addition of a windlafs and crank would be a fucceffive improvement, and could be made to act either fingly, to draw up one bucket, or double, to let down an empty bucket at the fame time it drew up another loaded with water.

The drawing up of a bucket by a rope and pulley is fo fimple and obvious as to need no explanation. The bucket fhould be of fuch a fize that it will not weigh above twenty-fix pounds, and will therefore contain nearly half a cubic foot of water. For although a man could with eafe raife a much greater weight, yet he would be unable to draw it up fo quickly, or to work at it throughout the day; and what he would gain by the increafed quantity of water, he would lofe in the time which it would require to draw up the bucket, and in the time he would require to reft himfelf from his fatigue. If the rope is conducted horizontally, and the man takes it over his fhoulder and walks along the ground, his force will be applied in a much more effective manner than by fimply hauling the rope over a pulley; and a horfe may be applied in the fame manner with a larger bucket, and there is perhaps no better mode of applying the force of a horfe for a deep well. The bucket fhould not in this cafe weigh above a hundred and twenty pounds, or it muft not contain above two cubic feet to enable the horfe to draw it with that velocity which is moft natural to him.

When a windlafs is employed to wind up the rope, the winch or crank, which is applied to the axis of it, can be made much larger than the radius of the windlafs, and in confequence the power may be increafed fo much that a larger bucket may be drawn, which is fome advantage, becaufe lefs time will be loft in ftopping to fill and empty the bucket, otherwife nothing is gained in drawing up a large bucket, becaufe it muft move flower in proportion to its increafed weight; but in all cafes the length of the handle fhould be about fourteen or fixteen inches, to enable a man to turn it with eafe, and the weight of the bucket muft be fo adapted to the fize of the windlafs, that the power required at the handle will not be above thirty pounds or even twenty-five pounds, if a man is to work continually for fix or eight hours in a day. For example, fuppofe the bucket is about forty-fix pounds weight, and the handle fixteen inches long, then as 46 is to 25, fo is 16 to $8\frac{3}{4}$ nearly; from which

which deduct half the thickness of the rope, and it leaves the proper radius for the roller or windlass. A rope of the proper size for this purpose will be about two inches and a half in circumference, or rather more than three-quarters of an inch in diameter; hence the diameter of the barrel will be 16⅝. If a fly-wheel is applied to the axis, it will be an advantage to equalize the force which the man applies, because some positions of a crank or handle are less favourable than others for the exertion of a man's strength. It is most advantageous to employ two buckets, and as the rope for one unwinds whilst the other winds up, the weight of the two buckets balance each other, and the man has only the weight of the water to draw up.

Bucket-Machines for deep Wells.—When a machine to draw water by buckets is made on a larger scale, the windlass is placed perpendicularly, and levers applied to it at the lower end, which may be actuated either by men, or by horses walking round in a circle on the ground, and drawing or pushing the end of the lever; in this way a powerful machine may be made, and if the depth is very considerable, it is a very good method. Many methods have been proposed to make the buckets fill themselves when at the bottom of the well, and empty when at the top: the best is to suspend the bucket in an iron loop or bow, like the handle of a pail, but this should be made so long, that the pins on which the cask or bucket hangs, shall be but little above the centre of gravity of the bucket when loaded with water; in consequence, when the bucket is drawn up to the top, one edge of it is caught by a hook fixed on the edge of the cistern into which the water is to be delivered, and the bucket still continuing to be drawn up whilst the hook detains one edge, the bucket is thereby overturned, and its contents discharged into the reservoir. It is requisite for this plan, that the bucket be made, by some contrivance, to present itself always in the same direction to the hook, so that it will be seized and overturned thereby: one method is to fix upright pieces of wood or iron in the well on each side of the bucket, and the pivots on which the bucket is poised project on each side beyond the iron loop on which the bucket hangs, and enter into grooves formed in these pieces, so as to be guided in the ascent and descent of the bucket. Another method is to make the rope of the bucket double for some feet immediately above the bucket, that is, the rope divides into two ends, each of which is made fast to the opposite side of the iron loop in which the bucket is suspended: the rope is made to pass through a narrow opening in a piece of plank, which will admit the double rope to pass freely, provided the bucket comes up in the required position; but if it does not, then the forked rope will be acted upon by the sides of this narrow opening in such manner, as to turn the bucket round to the required position.

To make the bucket fill readily at the bottom of the well, a simple valve is made in the bottom, which opens upwards and admits the water, but shuts when the bucket is drawn up out of the water. In the Transactions of the Society of Arts, vol. xii. is a description of a machine by Mr. Russel, in which the bucket, when it is drawn up to the top of the well, acts upon a lever, and causes a moveable trough to run across the well beneath the bucket; and then as the bucket rises higher, a trigger, which belongs to the valve in the bottom of the bucket, is intercepted by a fixed piece of wood, so as to open the valve, and the water runs out of the bucket into the moveable trough which conveys it into the reservoir: when the bucket begins to descend, it allows the levers to return, and the moveable trough retreats from beneath the bucket, and allows it to descend again into the well to bring up a fresh charge. The moveable trough is made to run backwards or forwards over the mouth of the well, by means of wheels or rollers, on which it is supported, and these wheels run upon pieces of wood laid across the well.

Indian Method of drawing Water by a leathern Bucket.—Dr. Roxburgh of Calcutta has given us a description of a method of raising a large quantity of water from a deep well by means of one or two buffaloes or bullocks, which is in common use in many parts of Hindoostan, where the wells are too deep for the lever. A pulley is erected over the well to receive a rope, which the animals draw by walking along an horizontal path in order to elevate a large bucket, and they return towards the well to lower it down: the bucket is made of leather, like a long funnel, extended at the top or mouth by a square frame of wood, or by a hoop, and the lower end terminates in a small open tube, which is flexible, and can be turned up; in which case, if the orifice of the tube is kept as high or higher than the mouth of the bucket, no water can escape through the tube, it is in this condition that the bucket is drawn up full of water: the end of the tube has a cord fastened to it, which is conducted over a roller fixed on the edge of the trough into which it is desired to deliver the water, and which trough must be at least the length of the bucket beneath the great pulley that is fixed over the well. The opposite end of the cord is tied to the great rope near the point where the buffaloes draw, and the cord is of such length as to hold the orifice of the tube rather above the mouth of the bucket, until the tube is drawn up to the roller. When the cord draws the tube over the roller, and leads its end into the trough as the bucket continues to be drawn up, it is raised above the level of the trough, by which means the whole of the water will make its escape through the orifice of the tube into the trough: when the bucket is let down again, the flexible tube returns over the roller, and the cord holds up its orifice above the top of the bucket.

Desaguliers, in the second volume of Experimental Philosophy, describes a very simple contrivance to raise water by a bucket; which is this, to one end of a rope is fixed a large bucket, having a valve in its bottom opening upwards; to the other end of the same rope is fastened a square board, something like the scale-board of a balance, but large enough for a man to stand upright in it; the cord is made to pass over two pulleys, each of about fifteen inches diameter, and fixed in such manner, that as the bucket descends, the scale ascends with equal velocity, and *vice versâ*. The scale is made to run freely between four vertical guide rods, passing through holes at its four corners, and when the bucket is lowered down into the lower water-cistern in order to fill with water, the scale stands nearly level with the horizontal plane of the upper reservoir to which the water is to be raised. When the bucket is full, a man steps into the scale, and his weight, together with that of the frame, exceeding the weight of the vessel and its contained water, will give an ascending motion to the bucket, and causes the valve in its bottom to close. When the bucket is raised to the proper height, a hook which is fixed at the edge of the upper reservoir catches into a hasp at the side of the bucket, and turns it over, to cause it to empty its water into the upper cistern, or into a trough, which conveys it where it is required: at this time the man and the scale have arrived at a platform, which prevents their further descent, and the man must remain in the scale till he finds the bucket above is empty, when he steps from the scale, and runs up a flight of stairs to the place from which he descended: the bucket in the mean while, being somewhat heavier than the scale, descends again to the water, and raises the frame to its original position; thus the work is is continued, the man being at reft during its defcent, and labouring in the afcent.

Defaguliers employed in this kind of work a tavern-drawer, who had been ufed to run up and down ftairs; he weighed 160 pounds, and was defired to go up and down 39 fteps of $6\frac{1}{2}$ inches each (in all about 21 feet) at the fame rate he would go up and down all day. He went up and down twice in a minute, fo that allowing the bucket, with a quarter of a hogfhead of water in it, to weigh 140 pounds, he is able to raife it up through 21 feet twice in a minute, which is equivalent to the whole hogfhead raifed $10\frac{1}{2}$ feet in a minute, and rather exceeds what Defaguliers affigned as a maximum of human exertion; from experiments made with a mercurial pump. He recommends that the man in the fcale fhould weigh one-fifth or one-fixth more than the weight of the water in the bucket, in order to give him a preponderance to bring up the bucket with a proper velocity.

Balance Buckets.—This is an ingenious contrivance for raifing water by the power of a fmall fall of water: fuppofe a wooden lever twenty feet long, poifed upon a centre at five feet from one end, one arm will then be five feet long, and the other fifteen, or three times. At the extremity of the long arm a fmall bucket is fixed, and at the extremity of the fhort arm another bucket, which is rather more than three times as great in capacity: the lever is fo poifed, that it will place itfelf in an horizontal pofition when both the buckets are empty; but fuppofe that in this fituation a fmall fpout of water runs into each bucket, when they become both filled, the larger bucket at the end of the fhort arm will overweigh the fmaller one, becaufe it holds more than three times as much water; in confequence, the larger bucket will defcend and move the lever into a perpendicular fituation, by which means the fmall bucket is raifed fifteen feet above the level of the fpout at which it received the water, whilft the great bucket has defcended five feet beneath its fource of fupply. Both the buckets are fufpended to the ends of the lever on pivots, fo that they can readily be turned over to difcharge their contents; this takes place when the lever arrives near its vertical pofition: the fmall bucket is caught by a hook, and overturned into the elevated trough which is to receive the water, and immediately the lower bucket is emptied by fimilar means. The long end of the lever is now the heavieft, and in confequence the lever returns to its horizontal pofition, in which it remains until the buckets are both full, and then it makes another ftroke. A fimple contrivance is applied to ftop the running of the fpout of water during the time that the lever is in motion, to prevent wafte of the water.

The *lofing and gaining Buckets* is a fimilar machine to the preceding, but admits of raifing the water to a greater height, becaufe chains and wheel-work are employed inftead of a lever. This machine will raife water fufficient to ferve a gentleman's feat, with an overplus for fountains, fifh-ponds, &c. A machine of this kind can be erected wherever there is a fpring affording a fmall fupply of water, and having even fo fmall a fall as ten feet. It is poffible, by this invention, with the lofs of part of the water, to raife the reft, to fupply a houfe, or any place where it is required; but, of courfe, it muft be in a lefs quantity than the fall of water which is to actuate the machine, nearly in the fame proportion as the place to which the water is to be raifed is higher than the fall of the fpring. For example, the fall of one hogfhead through ten feet will raife about one-fixth of a hogfhead to the height of forty feet. This machine had been conceived by Schottus a great many years ago, and he gave a draught of it. It is defcribed in Leopold's Theatrum Machinarum Hydraulicarum, 1720; but it was never put in execution to any good purpofe in England, till Mr. George Greaves, a carpenter, erected an engine upon this principle, about 1730, for fir John Chefter, baronet, at his feat at Chickley, in Buckinghamfhire; a fketch of which is given at *fig.* 13, *Plate Water-Works.* A fmall fpring of water, fupplying four gallons *per* minute, is conveyed feventy-two yards, by a gutter, into a ciftern N, containing about twelve gallons. This water has a defcent to the other ciftern at R, ten feet below X; from the latter, the wafte is conveyed off along H, by a drain or fewer. The defcent of part of the water through this ten feet is the motive force to work the machine. A, B, are two copper pans, or buckets, of unequal weights and fizes, fufpended by chains, which alternately wind off, and on the two multiplying-wheels Y and Z, whereof the wheel Y is fmaller in diameter, and Z larger, in proportion to the different lifts each bucket is defigned to perform. A houfe is built over the well or ciftern, with three floors, for the conveniency of fixing the parts of the engine. On the uppermoft floor is fixed a frame of timber 2 2, in which the moving parts are fupported, as is fhewn, (part being broken off in the figure, to explain the work): acrofs this frame lies an horizontal axis G, three feet and a half long, moving on two gudgeons in braffes. Upon this axis are framed three wheels; firft, the fmall wheel Y, which is two feet diameter, and fhrouded, or made with a raifed rim at each fide: the edge of the wheel is five inches broad, and fhod with iron. Upon the wheel Y is fixed a chain, made very flat and flexible, which, after it has wrapped once round the wheel, is then made double, that it may lie on each fide of the edge part, the double parts having a fufficient opening between them to admit the fingle part, and this prevents fretting or galling, and keeps the chain exactly perpendicular: from the extremity of the double part is hung a long rod of iron, at the bottom of which the great bucket A is fixed. The largeft wheel Z on the axis is fix feet diameter, and one inch and a half broad on the face, which is alfo fhrouded: this wheel is not circular, but fpiraled two inches, both in the fole and in the fhrouds; fo that its radius at the leaft part is two inches lefs than three feet. Upon the large wheel Z is fixed a fmaller chain, to fufpend the bucket B: it is made like the former, and fo arranged, that when the wheel Z has made one revolution from left to right, the fpiral fole will take up a certain length of the chain. After this length, the lower or remaining part of the chain has crofs-bars fixed to it, at equal diftances, which fall upon the edges of the fhrouds into notches plated with iron: by this means, and by the help of the fpiral, this part of the chain is not only prevented from riding upon the other, but helps to equiponderate the increafe of weight of the other chain of the bucket A. A third wheel *r*, three feet ten inches diameter, is fixed on the axis G, between the other two wheels: it is fhrouded like the others, and is fpiraled three-fourths of an inch; it receives a rope, the lower end of which goes about a wheel *d*, of two feet diameter, to which that end is fixed, and on the axis, *d*, of this wheel is another, *t*, one foot diameter, and to this is faftened a rope, which goes down upon the quadrant *a b*, which carries a fliding weight in a box at the extremity of the arm Q; the quadrant *a* moves on the axis *b*, and the rope defcending from the wheel *t*, is guided between iron plates, upon the circumference of the quadrant. The box, at the end of the arm Q, contains a fliding lead weight, to counter-balance the weight of the chains, by keeping an exact equilibrium in every pofition of the machine. Befides the action of the quadrant, the motion is regulated by wheel-work, like that of a jack; thus, upon

 one

one end of the axis G, is a ſtrong iron wheel M, giving motion to a pinion *m*, and by means of a wheel and worm *n* and *o*, to a fly P, which regulates the motion of the engine, and prevents any improper acceleration from the unwinding of the chains. The ſmall bucket B is made of copper, about five gallons in capacity; it has a valve in the bottom, by which the bucket will be filled when it deſcends into the water of the ciſtern N. The bucket is ſuſpended in an iron link, or handle, upon two pivots, ſo that it can be very eaſily turned over upon them. This happens when it is drawn up to F, the edge of the bucket catching a hook which overturns it, and diſcharges the contents into the trough W, at an elevation of thirty feet above X, and whence it is conveyed by pipes wherever it is wanted. The great bucket A is likewiſe made of copper, and contains about fifteen gallons when drawn up to the poſition A: it is filled with water from a valve, or ſluice, in the ſide of the ciſtern N, which is then opened by a bent lever, whereof the end projects, ſo that the bucket will lift it up. In the bottom of the bucket is a ſpindle-valve, which is opened when the bucket has deſcended to R, by the end of its ſpindle reſting on the bottom of the well. Iron rods are fixed vertically to guide both the buckets, which have ears with braſs rollers in them, and incloſe three ſides of each, which is ſquare, and they are thus cauſed to aſcend and deſcend in a perpendicular line, and no other.

The operation of the machine is as follows:—When the buckets are empty, they are ſtopped, as ſhewn in the figure on a level with the ſpring at X, whence they are both filled with water at the ſame time, in the manner juſt deſcribed.

The greater of the two A, being the heavier, when full preponderates, and deſcends ten feet from C and D, and the leſſer B, depending from the ſame axis, is at the ſame time weighed up or raiſed from B to F thirty feet.

Here, by catching the hook F, the ſmall bucket diſcharges its water into the trough W, and thus ſuddenly loſing weight, it lets the great bucket down an inch lower, and the valve in the bottom is opened, ſo as to let out its water, which runs waſte by the drain below at H. The bucket B being then empty, is ſo adjuſted as to overweigh, and deſcending ſteadily as it roſe, betwixt the guiding-rods, it brings or weighs up A to its former level at X, where both being again repleniſhed from the ſpring, they thence proceed as before. And thus will they continue conſtantly moving, (merely by the circumſtantial difference of water and weight, and without any other aſſiſtance than that of ſometimes giving the iron-work a little oil,) ſo long as the materials ſhall laſt, or the ſpring ſupply water.

The ſteadineſs of the motion is, in part, regulated by the fly P, which not only keeps the engine to an equal velocity, but by its running forwards, after the buckets are quite up or down, holds them ſteady till they are completely filled or emptied, and prevents them recoiling back too ſoon. In order to counterbalance the weight of the chains in every poſition, the wheels *r*, *d*, and *t*, are ſo calculated, that during the whole performance up and down, they let the quadrant *a* move no more than one-fourth of a circle; by which contrivance, as more or leſs of the chains which ſuſpend the buckets come to be wound off their reſpective wheels Y and Z, this weight gradually increaſes its action as a counterbalance, and ſo continues the motion equable and eaſy in all its parts. The ſpiraling of the wheels Y and Z help, in ſome meaſure, to regulate the weight of the chains in every poſition, as they act in winding on and off the wheels; but the quadrant *a b*, and lever with the weight Q, complete the equilibrium, by acting with the greateſt force, becauſe the lever is in the horizontal poſition when the chain of the great bucket A is all down, and weighing upon the wheel, the weight Q then acts with its whole weight upon the wheel *t*, as that chain is drawn up, its acting weight is thereby diminiſhed, and the lever of the weight Q is moving down towards its perpendicular, whereby the weight Q diminiſhes equally in its influence on the motion of the wheel *r*, until it hangs perpendicular, and its weight ceaſes to act; but the ſliding-weight then runs down in its box, to keep the rope tight, the ſliding-weight being attached to the end of the rope, and not to the lever. At the firſt return, or re-aſcent of the great bucket, the weight Q is drawn up to a ſhoulder, before any motion is given to the lever of the quadrant; but whilſt the long chain of the ſmall bucket evolves from its wheel Z, the acting-weight of the quadrant is continually increaſing, and at the ſame time the other chain of the great bucket wrapping itſelf upon the wheel Y, its acting weight is decreaſing. The lever of the quadrant riſing higher, brings the line of direction of the weight Q farther from the centre of the quadrant, and ſo lays a greater force or obſtruction to retard the wheel *r*, and continually keeps a counterbalance.

This engine, at a ſlow motion, carries up one bucket full in five minutes; but if the ſpring ran double the quantity, it would go up twice in the ſame time, and an engine of this kind may be made to raiſe one hogſhead *per* minute, or more, if required, the conſumption of water is leſs than what is ſpent by a water-wheel to raiſe an equal quantity of water to the ſame height.

The Endleſs Rope to raiſe Water.—This is a moſt ſimple contrivance, and will raiſe up a ſmall quantity of water from a very conſiderable depth. A ſoft hemp or hair-rope, with the ends ſpliced together, is ſuſpended over a large wheel, which is turned by a handle; the rope muſt hang down into the well, and reach ſome depth into the water, and a ſimilar wheel may be placed beneath the ſurface of the water for the rope to paſs under; but this is not neceſſary when the length of the rope is ſuch, that its own weight will make it apply cloſe to the upper wheel. The upper part of the rope muſt deſcend through a tube, which is fixed in the bottom of the ciſtern, or reſervoir, to prevent the water running down with the rope; the tube is of ſuch ſize as to fit the rope very nearly, but not to cauſe any conſiderable friction. The rope is put in motion by turning the handle of the wheel, and the motion muſt be in ſuch a direction, that the rope where it paſſes through the tube in the ciſtern ſhall deſcend.

The conſequence is, that the water in the well adheres to the rope, and ſurrounds it like a film, or covering of water; but when the rope paſſes over the wheel, ſome of the water is thrown off by the centrifugal force, and falls into the reſervoir, and that part of the water which eſcapes the action of the wheel is ſeparated from the rope by the tube through which the rope paſſes; for it is to be obſerved, that the film of water which ſurrounds the rope is put in motion, whilſt it is in the well, by the lateral adherence of the water to the rope, which motion being continually kept up, is ſufficient to overcome the gravity of the water; but if any body is preſented to the rope, ſo as to reſiſt the motion of the water, without obſtructing the motion of the rope, the water will fly off, and, loſing its motion, will obey the action of gravity, and fall down.

The velocity with which the rope requires to be moved, will depend upon the depth from which the water is to be raiſed. The length of that part of the rope which is immerſed in the water is alſo of ſome conſequence, for it muſt be ſuch, that the rope will act upon the ſtill water which

which immediately furrounds it, until it has put that water in motion with nearly the fame rapidity as the rope, and then fuch portion of water will accompany the rope; but this cannot take place without communicating a flower motion to a much larger quantity of water, which will alfo accompany the rope with a flower motion; but being too far removed from the rope to have its motion accelerated, or even maintained, its velocity will continually decreafe, until it ceafes to afcend, and then it will begin to run back. But this is to be underftood only of that part of the water which is too far diftant from the rope to have its motion fully maintained by the lateral action of that water which is nearer to the rope, and which moves with nearly the fame velocity as the rope. If the rope is examined at the point where it rifes above the furface of the water, it will be found to be furrounded by a column of water which is of a confiderable fize at the bafe, but diminifhes as it rifes upwards, fomewhat in the form of a trumpet, fo that at a few feet in height it is but little larger than the rope. This column of water is compofed of feveral laminæ, each moving with a different velocity: for inftance, the interior part moves nearly as quick as the rope, the water which is more diftant from the rope moves flower, until there muft be a part in which the water remains immoveable, and all the water which is beyond this, and on the outfide of the column, runs downwards, and falls back into the well. On this account, the machine lofes a confiderable part of the power which is applied to it without producing an adequate effect.

This machine was invented by the Seur Vera, in France. A machine was made by him with a wheel three feet diameter, and a hair-rope of half an inch diameter, the well was ninety-five feet deep. A man could turn the wheel fixty times *per* minute, which gives a velocity of five hundred and fixty-five feet *per* minute for the rope. It brought up fix gallons *per* minute, but was fevere labour for one man. When the wheel made fifty turns, and the rope moved four hundred and feventy-one feet *per* minute, the machine ftill raifed a confiderable quantity of water; but if the motion was reduced to thirty turns, or two hundred and eighty-two feet *per* minute, it brought up fcarcely any water. A rope of hair is preferable to hemp, becaufe it is lefs fubject to decay; and when a hemp-rope begins to rot, it communicates a taint to the water.

The *Sucking-Pump* has a valve at the bottom of the barrel, and alfo another valve in the pifton, which is called a bucket, becaufe it brings up the water before it. This pump does not raife water when the bucket is let down, but only when it is drawn up, which is in fome cafes an inconvenience; and another objection is, that it cannot raife water to a greater height than the place where the power is applied, becaufe there muft be an opening for the pump-rod to come out at, and the water would flow out at the fame opening, if it was raifed as high. This inconvenience is remedied by

The *Lift-Pump*, which has a valve in the bucket, the fame as the fucking-pump, but it differs from it in the manner of communicating the force to the pifton or bucket: one way of effecting this is to make the barrel open at the lower end, and the rod from the bucket, inftead of being fixed to the upper fide of the bucket, is fixed to the lower fide, and comes out beneath the furface of the water in which the barrel is immerfed. Rods are jointed to this, and rife up parallel to the barrel, in order to be attached to the lever by which the pump is to be worked: the fixed valve is placed at the top of the barrel above the bucket: this is the old-fafhioned lift-pump.

The *Lift-Pump with a Stuffing-box*, called fometimes a jack-head pump, is exactly the fame as the fucking-pump, except that the top of the barrel is covered by a lid, which has a hole in the centre for the rod to pafs through: the rod is made very fmooth and true, and the hole is fo formed as to contain collars of leather, which fit clofe round the rod, and prevent the efcape of any water by the fide of the rod. The water mounts up a pipe which communicates fideways with the upper part of the barrel.

Another form of lift-pump has been recently introduced, in which the pifton is folid, having no valve in it, and the rod paffes through a ftuffing-box or collar of leather in the top of the barrel, the bottom of the barrel being open. Two pipes are made to communicate fideways with the barrel at the upper part, one of which brings water from the well into the pump when the pifton defcends, and has a valve in it to prevent the return of the water; the other pipe conveys the water away from the barrel when the pifton is drawn upwards, and this is likewife furnifhed with a valve to prevent the return of the water.

One advantage of this kind of pump is, that both valves are fituated in boxes near the top of the barrel, and can be examined and repaired at any time by taking off the doors or covers of the boxes; but in pumps where there is a valve at the bottom of the barrel, it fometimes happens that the valve fails, and requires to be repaired, when the water in the well ftands higher than the cover or door of entry to the valve: in this cafe, fome other means muft be ufed to reduce the water in the well, or elfe the pump muft be drawn up out of its place, which, in large works, is very difficult. Another advantage is, that the apertures of the valves may be made of any required dimenfions to let the water pafs freely through them; but when the water muft come up through a valve in the bucket or pifton, the paffage through the valve muft neceffarily be much fmaller than the barrel, to allow a proper lodgment all round for the valve and alfo for the leathers.

The Force-Pump.—This is made with a folid pifton, like the laft, but the barrel is open at the top, where the pifton-rod comes out. There is a valve at the bottom of the barrel to admit the water into it, and a pipe, which turns fideways out of the barrel at bottom, and has a valve to prevent the water returning into the barrel, to convey the water to whatever place it is to be forced to. The force-pump raifes water only when the pifton is preffed down, whereas the lift-pumps and fucking-pumps raife the water when the buckets are drawn up.

The Lift and Force-Pump of M. De la Hire.—This is the union of the two laft pumps in one, for both thefe pumps work with a folid pifton, and the barrel of the force-pump is open at top, and the barrel of the lift-pump is open at bottom; hence the fame barrel and pifton may be made to ferve for both. This pump throws up water equally when the pifton-rod is drawn up or when it is forced down, and is moft proper for the double-acting fteam-engine. It has the advantage of raifing twice the quantity of water that any of the other pumps will raife, and with the friction of only one pifton; alfo the valves admit of being made of fufficient fize to allow the paffage of the water without any unneceffary refiftance.

Force-Pump with a folid Plunger.—This was invented by fir Samuel Morland, and does not differ from the force-pump laft defcribed, except in the manner of fitting the pifton to the barrel. Inftead of the barrel being bored truly cylindrical withinfide, and the pifton fitted into it fo as to flide up and down, and provided with leathers to make a clofe fitting, the pifton is made of a cylindrical form, and very nearly as large as the hollow barrel into which it defcends, but it does not touch the infide of the barrel. To make the clofe fitting, the outfide furface of the cylindrical pifton, or plunger, as it is called, is made very true and fmooth; and it is furrounded by a collar of leathers fixed at the top of the barrel, fo that no water can leak out of the barrel between the plunger and the leather collars; at the fame time that the plunger can freely move up and down through the collars, and will thereby increafe or diminifh the capacity of the barrel, to produce the fame effect as if the pifton fitted clofe into the barrel.

The principal circumftance to be attended to in this pump is the conftruction of the collar of leathers. To retain thefe leathers in their places, the top of the barrel muft be made with a flaunch, and pierced with holes to receive fcrew-bolts. Upon this flaunch two rings of metal are applied one over the other, with fimilar holes: the internal opening in the loweft ring is exactly the fize of the plunger, and that of the upper one a little larger. Two rings of foft leather are cut out to correfpond with the metal rings, except that the central holes are rather fmaller than the plunger: to prepare the leather, it is foaked in a mixture of oil and tallow for fome hours. One of thefe leather rings is laid on the pump-flaunch, and one of the metal rings placed above it; the plunger is then thruft down through the leather, which turns the inner edge of the leather ring downwards; the other leather ring is then flipped on at the top of the plunger, and the fecond metal ring is put over it, and then the whole are flid down to the metal ring; by this the inner edge of the laft leather ring is turned upwards.

The metal rings and leathers are now fixed on the flaunch by the fcrew-bolts; and thus the leathern rings are ftrongly compreffed between them, and make a clofe joint with the top of the barrel; and as the holes through the leathers are fmaller than the plunger, they grafp the plunger fo clofely that no preffure can force the water through between them. The lower metal ring juft allows the plunger to pafs through it, but without any play, fo that the turned-down edges of the lower leathern ring cannot come up between the plunger and the lower metal ring, but are lodged in a conical enlargement, which is made round the inner edge of the upper part of the barrel; and in like manner the turned-up edges of the upper leather are received in the hole of the upper metal ring, which hole is made larger than the plunger, to leave a fpace all round for thefe edges: it is on thefe trifling circumftances that the great tightnefs of the collar depends. To prevent the leathers from fhrinking by drought, there is ufually a little ciftern formed round the head of the pump, and kept full of water.

This kind of pump is preferable to any other, where the preffure to be overcome is very confiderable. The hydroftatic preffes are conftructed on this principle. See Press.

Piftons or Buckets for Pumps.—A good pifton fhould be as tight as poffible, and fhould have as little friction as is confiftent with this indifpenfible quality. The bucket of the common fucking-pump, when carefully executed, poffeffes thefe properties in a high degree, and is the model for other kinds of pump-buckets, or piftons, in which leather can be employed. This bucket is in the form of a truncated cone, with a hollow through the centre of it, which is half as large as the outfide, at the largeft part; it is generally made of wood not liable to fplit, fuch as elm or beech, but in the beft kind of pumps is made of metal. The fmall or upper end of it is cut away at the fides, fo as to open into the hole through the centre of it, and form an arch, by which it is faftened to the iron rod or fpear of the pump, and within the arch the valve or clack is fituated. The lower end of the conical part may be covered with a hoop of brafs, which fits the barrel of the pump very exactly; the bucket is alfo furrounded with a ring or band of ftrong leather, faftened to the wood with nails, and firmly retained by the brafs hoop which is driven down on the bucket from the upper or the fmaller end of the cone, and binds the leather faft on the wood; but the leather being wider than the brafs, the edge of the leather rifes upwards and furrounds the wood: this part of the leather is made to turn outwards, like a cup or hollow cone, which, at the upper end, is rather larger than the barrel, fo as to fpring againft the infide of the barrel when the bucket is put into it. The leather muft be of uniform thicknefs all round, fo as to fuffer equal compreffion between the wood of the bucket and the working barrel, but this compreffion is very flight, becaufe it is the upper edge of the cup which applies moft clofely to the barrel. The feam or joint of the two ends of the band of leather muft be tapered, and made to overlap and lie very clofe, without increafing the thicknefs, but not fewed or ftitched together, as that would occafion bumps or inequalities, which would fpoil its tightnefs; and no harm can refult from the want of fewing, becaufe the two edges will be fqueezed clofe together by the compreffion in the barrel; nor is it by any means neceffary that this compreffion be great, for it occafions friction, and caufes the leather to wear through very foon at the edge of the bucket, and it alfo wears the infide of the working barrel, which foon becomes enlarged in that part which is continually paffed over by the pifton, while the mouth remains of its original diameter, and then it is impoffible to thruft in a pifton which fhall completely fill the worn part. A very moderate preffure is fufficient for rendering the pump perfectly tight, becaufe the preffure of the water makes the leather cup apply itfelf clofe to the barrel all round, and even adjuft itfelf to all its inequalities. Suppofe it to touch the barrel in a ring of an inch broad all round, this is a trifle, and the friction occafioned by it not worth regarding; yet this fmall furface is fufficient to make the paffage perfectly impervious, even by the preffure of a very high column of incumbent water: for let this preffure be ever fo great, the preffure by which the leather is forced againft the infide of the barrel will always exceed it, becaufe, in addition to the preffure of the water, the leather will always prefs againft the barrel by its own elafticity, the top of the cup of leather being made rather larger than the interior of the barrel.

This method of applying leather piftons is found to be preferable to any other, becaufe if the leather is preffed againft the barrel by any other means than the force of the column of water, the preffure will always be too great or too little.

Pumps which are to raife hot water cannot be leathered, becaufe the leather would fhrivel up; in this cafe, ftrong canvas cloth is fometimes ufed inftead of leather; but as this will not hold water perfectly, fuch pumps are generally packed with hemp, in the fame manner as the pifton of fteam-engines.

Pump without Friction.—When the height to which the water is to be raifed is fmall, a pump may be conftructed in which the pifton does not require to be fitted clofely into the barrel, nor are any leathers required. The barrel of this pump muft be as long as the whole height to which the water is to be raifed, and as much more as the length of the ftroke of the pifton. The pifton is a folid piece of wood, fitted to the barrel as clofely as it can be without actually touching the infide, and may be either fquare or round, but a fquare trunk and a fquare beam of wood are beft, if the pump is made of wood. The pifton muft be as long as the barrel,

barrel, fo that when it is let down it will occupy the whole interior fpace of the barrel, except that fmall fpace which is left between the infide of the barrel and the pifton, to avoid actual contact. The bottom of the barrel has a valve in it which opens upwards, and a pipe proceeds from the lower part to convey away the water to the refervoir into which it is to be raifed by the pump. This pipe is provided with a valve, to prevent the return of any water which has paffed through it, but the greateft elevation of the water in the refervoir muft not be quite fo great as the top of the barrel. When this pump is fixed for work, the lower end of the barrel muft be immerfed in the water of the well at leaft as much as the whole length of the ftroke, fo that the lower end of the pifton will never rife above the furface of the water in the well, and upon this circumftance the action of the pump depends; for when the pifton is drawn up, the water flows through the valve in the bottom by its gravity, and fills the fpace which is left by the drawing up of the pifton; when the pifton defcends, it difplaces from the barrel all this water, and forces it up the fide-pipe into the refervoir. It is true that a fmall portion of water rifes in the fpace between the barrel and the pifton, but this fmall quantity cannot efcape, becaufe the top of the barrel rifes higher than the furface of the water in the refervoir.

Dr. Robinfon, who we believe firft defcribed this pump, obferves that it is free from all the difficulties which are experienced in common pumps, from want of being air-tight. Another is, that the quantity of water raifed is very nearly equal to the power expended; for if there is any want of accuracy in the work, which occafions a diminution of the quantity of water difcharged, it alfo makes an equal diminution in the force which is neceffary for pufhing down the plunger. The doctor mentions a machine, confifting of two fuch pumps, the piftons of which were fufpended from the arms of a long beam or lever, the upper fide of which was formed into a walk, with a rail on each fide. A man ftood on one fide of the centre of the lever, until the pifton of the pump at that end funk to the bottom of its barrel, and of courfe the pifton of the pump on the oppofite fide of the centre was drawn up; he then walked flowly up to the other end of the walk upon the beam or lever, the inclination being about twenty-five degrees at firft, but gradually diminifhed as he went along, and paffed on the oppofite fide of the centre of motion, fo as to change the load of the beam. By this means he made the pifton at the other end go to the bottom of its barrel, and fo on alternately, with the eafieft of all exertions, and what a man is moft fitted for by his ftructure. With this machine a feeble old man, weighing 110 pounds, raifed 7 cubic feet of water $11\frac{1}{2}$ feet high every minute, and continued working eight or ten hours every day. A ftout young man, weighing nearly 135 pounds, raifed $8\frac{1}{3}$ cubic feet to the fame height; and when he carried 30 pounds conveniently flung about him, he raifed $9\frac{1}{4}$ feet to this height, working ten hours a day, without greatly fatiguing himfelf. This exceeds Defaguliers' maximum of a hogfhead of water ten feet high in a minute, in the proportion of 9 to 7 nearly. This pump is limited to very moderate heights, and in fuch fituations it is very effectual.

The *mercurial pump* is a fpecies of lift-pump, in which mercury is employed to make a clofe fitting between the pifton and the barrel, and thus avoid the friction of leathers, and prevent lofs of water.

This pump was originally invented by Mr. Jofhua Hafkins, and was improved by Defaguliers, who defcribed it in the Philofophical Tranfactions for 1722, N° 370. p. 5; and he has alfo given every detail of the conftruction in his Experimental Philofophy, vol. ii. p. 491.

In this pump the barrel is inverted, that is, it is open at the bottom, like the firft lift-pump which we have mentioned; and it has alfo two pipes communicating with the upper end of the barrel, one to bring up the water from the well, and the other to carry it up to the refervoir: each pipe is provided with its valve, to prevent the return of the water. The barrel muft be made of iron, and as thin as is confiftent with the ftrength of the metal. The pifton is a cylindrical plug of wood, fitted to the barrel fo as to fill it, but not to touch the fides. This pifton is fixed perpendicularly in the centre of a hollow cylinder of iron, which is rather larger within than the outfide of the pump-barrel, fo that an annular fpace is left all round between the folid pifton or plug and the infide of the cylinder, into which fpace the pump-barrel can enter, and will fill it very nearly. The annular fpace is then filled with mercury. This compound piece, confifting of the hollow cylinder, with the fmaller folid cylinder within it, forms the pifton; and to this the power which is to work the pump is applied by means of chains, which fufpend it from the fhort arms, fo that if the lever is moved, the pifton will rife up and down. When the pifton is applied in its place, and the inverted pump-barrel is received into the annular fpace between the folid and hollow cylinders, the mercury therein will make a clofe fitting between the folid pifton and the infide of the barrel, fo as to prevent any water paffing between them; and the afcent and defcent of the pifton will produce an alternate contraction and dilatation of the internal capacity of the working barrel, in the fame manner as a folid pifton would do, if it was clofely fitted to the infide of the barrel with leather all round.

As the water exerts a preffure on the mercury, to force it out of the annular fpace in which it is lodged, the depth of the annular fpace and length of the barrel which defcends into it muft be adapted to the height to which the water is intended to be elevated; fo that the column of mercury which it will contain, without raifing the mercury fo high as to run over the edge of the external cylinder, fhall always exceed one-thirteenth part of the height to which the water is to be elevated; the weight of mercury being more than thirteen times the weight of an equal quantity of water.

That there may be lefs mercury ufed, the pump-barrel fhould be made of plate-iron, turned on the outfide, and bored within; the outer cylinder of the pifton fhould be bored, and the inner one turned; and if the work be well performed, eight or ten pounds of mercury will be fufficient, though the bore of the barrel, or diameter of the column of water which is raifed, is fix inches. Lefs than fix pounds of mercury would fuffice, if there were two barrels, in order to keep a conftant ftream. This will very much leffen the expence of mercury, which would otherwife be an objection againft this pump; and by making the inner and outer cylinder of hard wood, as box, or *lignum vitæ*, the expence may ftill be reduced. But if the engine be very large, caft-iron bored will be proper for the outer cylinder, and caft-iron turned on the outfide for the inner cylinder or plug, and hammered iron bored and turned for the middle cylinder.

There is an objection, which feems at firft to take off the intended advantage of this engine, *viz.* that inftead of the friction of the leather of a pifton, when we lift up the pifton to make a ftroke, the refiftance neceffary to make the mercury to rife on the outfide of the barrel in the outer cylinder of of the piston is at least as great as the friction we avoid. Desaguliers says, that resistance is never greater than the weight of a concave cylinder of mercury, whose height is the greatest to which the mercury rises in the said outer cylinder, and the base is the area of the barrel itself. This weight in a pump of 6 inches bore is equal to $57\frac{1}{2}$ pounds, and, therefore, it would appear to be greater than the resistance arising from the friction of a piston. But if it be considered, that in the descent of the piston for sucking, the mercury shifts immediately into the inside of the barrel, rising to the same height therein, and still keeping the same base, the weight of $57\frac{1}{2}$ pounds helps to press down the piston, and facilitates the overcoming of the force of the atmosphere, or suction of the pump; consequently, the weight of the mercury being balanced is no hindrance, whether the pump works with a double or with a single barrel.

There remains only then the hindrance by loss of time, whilst the mercury changes from the outside to the inside of the barrel, at the beginning of any stroke. Desaguliers states this to be one-fifty-second part of the stroke, and that he found the best pumps then in use generally lost near one-fifth of the water that they ought to have given, according to their number of strokes.

Notwithstanding the high terms in which this author and others have spoken of the mercurial pump, it can only be considered as an ingenious suggestion, for the expence of mercury would be too great for the actual application of any such machine in practice; and in respect to friction, it would have a considerable share of resistance in plunging the piston into the mercury, although there would be no actual rubbing of hard substances together. This resistance would arise in the rapid running of the mercury from the inside of the barrel to the outside, and back again, at the beginning of each stroke.

The machine is exceedingly ingenious and refined, and there is no doubt but that its performance will exceed that of any other pump which raises the water to the same height, because there can be no want of tightness in the piston, and friction is in a great measure avoided. But these advantages are but trifling. The expence would be enormous; for with whatever care the cylinders are made, the interval between the inner and outer cylinders must contain a very great quantity of mercury. The middle cylinder must be made of iron-plate, and without any seam, for mercury dissolves every kind of solder. For such reasons, it has never come into use. But although we have professed to describe only the machines in actual use, it would have been unpardonable to have omitted the description of an invention, which is so original and ingenious; and there are some occasions where it may be of use, such as nice experiments for illustrating the theory of hydraulics: it would be the best piston for measuring the pressures of water in pipes, being in fact the same principle as the barometer.

Sector pumps are those in which the piston is made to move upon a centre, like a door upon its hinges. The piston is inclosed within a vessel shaped like the sector of a circle, which forms the body of the pump, and which is divided by the piston into two compartments. The piston is fitted, so that it can move backwards and forwards on its centre of motion, without suffering any water to pass by it; and by this motion it will alternately enlarge or contract the capacities of the two compartments, so as to draw in water through pipes and valves properly situated, and force it out again at other pipes. These kinds of pumps are difficult to construct, and have no advantages over the pumps with straight barrels, except for the engines for extinguishing fire. See that article for a description and figure of Mr. Rowntree's, which is one of the best of this kind.

Rotative Pumps.—As most of the first movers for hydraulic machinery act with a rotative motion, it would be very desirable to have a pump which would at once employ the rotative force to the purpose of raising water. Many schemes have been proposed, and much ingenuity displayed in these inventions; but hitherto no one has been brought to such perfection as to be equal to the pumps with straight barrels. In Ramelli's work, published in 1588, several rotative pumps are described; and Leopold has made a collection of them in his "Theatrum Machinarum Hydraulicarum," vol. i. They are all upon one common principle, *viz.* a hollow cylinder or drum closed on all sides; within this another smaller cylinder is inclosed, and the interior cylinder is placed out of the centre of the hollow cylinder, so that the interior cylinder touches the hollow one at one point of the circumference; but at all other points there is a considerable space between the two. The interior cylinder is provided with four or six valves or leaves, which are united to it by hinges, and, when folded close up to the cylinder, will form a smooth and circular circumference; but if the leaves are opened out, they will reach to the interior surface of the hollow cylinder. When the interior cylinder is turned round by a handle applied to the axis, the valves sweep round within the hollow cylinder, and in this motion perform the office of pistons, because they close up to the internal cylinder, in proportion as they approach towards the point where the internal cylinder touches the hollow cylinder; and the same vanes open out again, after they have passed that point. In this way the spaces between the valves form a number of cavities, which alternately expand and contract in their capacity, and in consequence they will draw up water through a pipe which is inserted into the hollow cylinder, and force it out at another pipe, so as to raise up a continual stream.

The machine is sometimes varied, by making the hollow cylinder of an elliptical form: in other cases, the valves, instead of moving upon hinges, are made to slide in straight lines from the centre of the revolving cylinder; but in either case, the action is the same. The common defect of all these rotatory pumps is, that it is very difficult to pack them so as to be tight, and they have more friction than any other kind of pump.

The *centrifugal pump*, invented by Mr. Erskine, may be called a rotative pump, but it is on a different principle from all other pumps. A perpendicular pipe has another joined to it, in form of the letter T: the lower end of this pipe being immersed in water, and the whole filled with water, it is turned round on the perpendicular stem as an axis; the water contained in the horizontal arms will, by its centrifugal force, fly out, and draw a constant stream of water up through the perpendicular pipe. See *Centrifugal* Pump.

Spiral pump, or *Zurich machine*, is a hollow drum or cylinder turning on a horizontal axis, and partly plunged in a cistern of water, like a very large grind-stone. The interior space of this cylinder or drum is formed into a spiral canal, by a plate coiled up within it, like the main-spring of a watch in its box, only that the spires are situated at a given distance from each other, so as to form a spiral passage of uniform width. (See *fig.* 11. *Plate Water-Works.*) This spiral partition is well joined to the two circular ends of the cylinder, and no water can escape between them. The inner end or central part of the ſpiral paſſage communicates with the axis, which is hollow at one end, and communicates with the vertical pipe which is to convey the water to the elevated reſervoir. The outermoſt turn of the ſpiral paſſage begins to widen at about three-fourths of a circumference from the open end, and this gradual enlargement continues for nearly a ſemicircle; this part being called the horn. The paſſage then widens ſuddenly in form of a ſcoop or ſhovel. The cylinder is ſo ſupported, that this ſcoop may, in the courſe of a rotation, dip ſeveral inches into the water, and take up a certain quantity of water before it emerges again. This quantity is ſufficient to fill the enlarged part called the horn, and is alſo nearly equal in capacity to one turn of the outermoſt uniform ſpiral. The vertical pipe is connected with the axis by a turning joint, ſo as to admit of the rotation of the axis, at the ſame time that it will not allow of the eſcape of any water.

When this cylinder is turned round by a handle applied to the extremity of the axis, a portion of water which the ſcoop takes up at every turn, will continually advance in the ſpiral, until it arrives at the centre; it will then paſs through the hollow in the end of the axle, and will riſe upwards in the vertical pipe; and in the intervals between the periods when the ſcoop dips into the water, the horn will become filled with air, and the ſucceeding portion of water which is taken in will carry the air before it, ſo that the water riſes in the vertical pipe mixed with air. See SCREW.

Dr. Robinſon, in his account of this machine, recommends the riſing pipe to be of ſmall bore; for if the pipe is ſo large as to allow the air to eſcape freely upwards through the water, the machine will raiſe the water to a certain height, proportioned to the number of turns of the ſpiral, and to their diameter; but if the pipe be narrow, ſo that the air cannot riſe freely, it will riſe in the pipe almoſt as ſlowly as the water. By this circumſtance, the water mixed with the air becomes of a leſs ſpecific gravity, as it were, and can be raiſed to a much greater height than it could be raiſed by the mere preſſure of the columns of water and air in the different turns of the ſpiral. This is effected with hardly any augmentation of the power, but if the air, after being compreſſed, is ſuffered to eſcape, all the force exerted to compreſs it will be loſt. The entrance into the riſing pipe ſhould be no wider than the laſt part of the ſpiral; and it would be adviſeable to divide it into four channels by a thin partition, and then to make the riſing pipe very wide, and to put into it a number of ſlender rods, which would divide it into ſeveral ſlender channels, that would ſerve completely to entangle the air among the water. This procedure will greatly increaſe the height to which the heterogeneous column may be carried.

Another Form of the Spiral Pump.—When the main pipe is very high, the former conſtruction will require either an enormous diameter of the drum, or many ſpiral turns of a very narrow pipe. In ſuch caſes, it will be much better to make the ſpiral in the form of a cork-ſcrew, than of a flat form like a watch-ſpring; or, the pipe which forms the ſpiral may be wrapped round the fruſtum of a cone.

We regret that we have had no opportunity of making experiments upon a machine of this kind, as its principles of action, though treated of by many authors, are not deſcribed in a ſatisfactory manner in any works which we have read.

The *chain pump* is an effective means of raiſing water, and with the advantage of a continuous motion. It is generally made with a ſquare or round barrel, placed in a perpendicular poſition. The chain is furniſhed with ſeveral piſtons of the ſame figure as the barrel, which are fixed at ſmall diſtances aſunder upon the links of the chain. The ends of the chain are united together, and it is extended between two wheels, one fixed at the upper end of the barrel, and the other at the lower end; but ſometimes only the wheel at the top is uſed. Theſe wheels have forks fixed on the circumference, which are ſo contrived as to receive one half of each of the flat piſtons in the intervals between the forks, whilſt the forks take hold of the links of the chain, and draw them up, when the wheel is turned round by means of a handle applied to the axis. The piſtons on the chain are made accurately to fill the ſection of the barrel, at the lower part near the water, and alſo for a few feet upwards; but above this, the barrel is made larger, ſo that the piſtons riſe up free: indeed, the upper part of the barrel is only to contain the water which is brought up by the piſtons, and may, therefore, be ſquare, or of any other figure. The lower end of the barrel is immerſed in water, and the chain being cauſed to circulate by turning the wheel, each piſton, as it enters into the lower or bored part of the barrel, will bring up water before it in the barrel; which water will riſe in the upper part of the barrel, till it runs over the top; and as the piſtons ſucceed each other in a regular ſucceſſion, they produce a conſtant ſtream. Chain pumps are chiefly uſed in ſhips, where they are worked by the force of men turning winches. (See PUMP.) In other ſituations they are moved by horſes, and ſometimes by the impulſe of a ſtream of water. They are ſo contrived, that by the continual folding in of the piſtons, when they enter into the bottom of the barrel, ſtones, dirt, or whatever comes in the way, may be cleared off. On this account they are often uſed to drain ponds and ſewers, or to remove foul water, when no other pump could be employed.

The greateſt diſadvantage in the chain pump is the friction of the chain, and of the piſtons, which is greater than in other pumps; becauſe ſeveral piſtons are moving in the barrel at the ſame time, and alſo becauſe the piſtons do not admit of the application of the cup-leathers, which we have deſcribed. The edges of the cups would fold up when they enter into the barrel, and get between the edge of the piſton and the barrel. The piſtons are, therefore, made with a thick piece of leather, which is placed between two round plates, which form the piſton or ſaucer, as it is called; the leather is cut round to the ſize of the barrel, ſo that the edge of the leather may be applied to the inſide of the barrel. In this way, its tightneſs muſt depend wholly upon the force with which the leather is ſqueezed into the barrel, and it occaſions great friction to make the piſtons ſufficiently tight.

Another variety of the chain pump is an endleſs rope, with ſtuffed cuſhions faſtened upon it at regular intervals. By means of two wheels or drums, the rope is made to circulate, and the cuſhions are drawn up in ſucceſſion through the barrel, and each one carries ſome water before it.

The chain pump is found to raiſe a greater quantity of water to the ſame height, when the barrel is placed in an inclined poſition, than when vertical. M. Belidor recommends the barrel to be placed at an angle of 24 degrees with the horizon, and the diſtance between the piſtons to be equal to their diameter. The reaſon of this advantage is, that an inclined pump acts with leſs friction, becauſe the piſtons need not be ſo exactly fitted, but they will, by their weight alone, apply cloſely to the bottom or loweſt ſide of the inclined barrel; whereas the piſtons of the vertical pump muſt exactly fill the barrel, or the water will leak down from one to the next in a conſtant ſtream.

Bellows-Pump.—A pair of leathern bellows may be employed as a pump, if a ſuction-pipe is applied to the lower valve, and another pipe to the nozzle, with a valve to prevent

prevent the water returning into the bellows after it has been driven out by clofing the bellows. This kind of pump has been frequently propofed, and the advantages of difpenfing with barrels and piftons loudly infifted upon; but the refiftance of the leather in folding, and the lofs of water by leakage, and above all the want of durability, will always prevent the adoption of fuch pumps.

The Pump with a Diaphragm of Leather, which does not flide in the Barrel.—This is very nearly allied to the bellows-pump. The beft form for conftructing it is fully defcribed in our article SHIP'*s Pump*, where the invention is attributed to Benjamin Martin; but we find the fame thing was long before applied by Meffrs. Goffet and De la Deuille, in France. (See Belidor's Arch. Hydraulique, vol. ii. p. 120.) This is a good pump, but is not durable, becaufe the conftant ftrain on the leather will caufe it to crack.

Sucking-Pump, which gives out a continual Stream.—Mr. Smeaton applied the following fimple and effectual expedient to make a fingle fucking-pump deliver the water equally in the defcent of the bucket as in its afcent. The pump-rod was enlarged, by furrounding it with a cylinder of wood at the part where it rofe above the furface of the water contained in the ciftern at the top of the pump. This cylinder of wood was of fuch diameter, that its fection was equal to half the area of the pump-barrel at the place where the bucket worked. When the bucket was drawn up, and raifed water into the ciftern at top of the pump, the wood cylinder, which was attached to the pump-rod, rofe up out of the water in the ciftern, and thereby made place in the ciftern for one-half of the water which was brought up by the bucket, and in confequence only one-half of the water ran out at the fpout of the ciftern; but when the bucket moved downwards, in order to fetch another ftroke, this cylinder of wood difplaced from the ciftern half as much water as the pump brought up in the former inftance, and confequently an equal quantity of water was given out at the fpout in either cafe.

If the pump is worked by the force of a man working a fimple lever, then he will make the down-ftroke of the bucket in lefs time than the up-ftroke, and in this cafe the area of the cylinder fhould be made lefs than half the area of the barrel of the pump. It muft be obferved, that this contrivance is only a remedy for the unequal efflux of water from the fucking-pump, and that the power required to work the pump is ftill left unequal in the up-ftroke and down-ftroke, becaufe it is only in raifing up the bucket that the water is drawn from the well below; and that water which runs out at the fpout when the bucket defcends, is drawn from the ciftern at the top of the pump, and not from the well. When the pump is worked by a man with a lever, this inequality of the refiftance is advantageous, becaufe a man can exert his force moft conveniently when he depreffes the end of the lever to draw up the bucket; alfo, in a fingle-acting fteam-engine, the principal power is exerted to draw up the bucket.

In machines worked by wind, water, or horfes, the moving force is uniform, and the refiftance muft, by fome means, be made uniform alfo, or the machine will move by fudden ftarts. A fufficient weight may be applied to the oppofite end of the lever to counterbalance one-half of the force neceffary to draw up the bucket; this weight will tend to diminifh the force of drawing up the bucket, and when the bucket defcends, and the machine would otherwife have nothing to do, it will have to raife up the weight ready to aid it in the fucceeding ftroke. Or a fly-wheel may be applied: but a ftill better method is to employ two pumps to act alternately, by which means the refiftance is continual, and the efflux of water alfo. When two fucking-pumps are employed, they may be combined together, by making them both draw from a common fuction-pipe, and both may be made to lift the water into the fame ciftern. Or two or three force-pumps may be combined together, as is defcribed in the article PUMP, in order to produce a continuous ftream.

Air-Veffel for equalizing the Difcharge of Water from Pumps.—This is the moft perfect contrivance for effecting that purpofe. It is a clofe veffel of any figure, which will contain air, and is made to communicate with the pipe which conveys the water away from the pump. This communication muft be made at the lower part of the air-veffel, fo that the water will have free ingrefs and egrefs from it. The air in this veffel will be compreffed into a fmaller fpace, in proportion to the column of water which the pump has to raife; and by its elafticity endeavouring continually to regain its former fpace, it will act as a fpring to equalize all fudden motions of the water through the pipe; for in any pump which acts by a barrel and pifton, the water will be propelled by ftarts; and even if two or three barrels are combined together fo as to produce a continual efflux of water, fuch efflux will not be perfectly equal during all the periods of the motion.

The evil of this may appear trifling and fo it would be merely with refpect to the difcharge of the water; but it muft be confidered that the mafs of water contained in a long pipe is very great, and that it requires a very confiderable force to put this mafs in motion with that velocity with which it muft flow through the pipe. Now if the operation of a pump is by ftarts, the mafs of water in the main-pipe will remain at reft, preffing on the valve during the time that the pifton is withdrawn from the bottom of the working barrel. In this cafe, the force neceffary to put the water in motion muft be expended at every ftroke, becaufe if the column comes to reft only for an inftant, it muft be put in motion again before the operation can be refumed: this is a heavy additional load upon the firft mover, and has another more ferious evil in ftraining the pipe and all parts of the machinery; becaufe the column of water in the pipe, after it ftops, runs back for a fmall fpace until the valve fhuts; and it makes juft as great a concuffion or fhock when its motion is fuddenly ftopped by the fhutting of the valve, as any other folid body would do which was of the fame weight, and moved with the fame velocity. In large fteam-engines, the fhock occafioned by the fhutting of the valve is exceedingly violent, unlefs an air-veffel is applied. In that cafe, if the pump urges the water with a fudden motion, the air in the veffel will yield, and admit the water into the veffel in far lefs time than the whole column of water could be urged into motion; but as the air will become compreffed by more force than the column of water in the pipe, the elafticity of the air will force the water from the veffel and up the pipe with a regular motion, and this will continue until the air has regained fo much fpace that its elafticity is only juft fufficient to balance the column of water in the pipe.

The air-veffel fhould be placed as near the pump as poffible, that it may produce an equable motion of the water in the whole length of pipe. The air-veffel is of confiderable advantage when a column of water of great length is to be raifed by a fingle-acting pump. If the pifton of the pump at one end of the pipe is put at once into motion, even with a moderate velocity, the ftrain on the pipe would be very great before the column of water could be put in motion. But the air-veffel tends to make the motion along the main-pipe lefs defultory, and therefore diminifhes thofe ftrains which would really take place in the pipe. It acts like the ſprings of a travelling carriage, whoſe jolts are incomparably leſs than thoſe of a cart, and by this means really enables a given force to propel a greater quantity of water in the ſame time.

The ſtream produced by the aſſiſtance of an air-veſſel is almoſt perfectly equable, and as much water runs out during the returning of the piſton as during its active ſtroke; but it muſt not be imagined that it therefore doubles the quantity of water. No more water can run out than what is ſent forwards by the piſton during its effective ſtroke. The continued ſtream is produced only by retaining part of this water in the air-veſſel during the ſtroke of the piſton, and by providing a propelling force to act during the piſton's return; but it cannot enable the moving force of the piſton to produce an increaſed effect: for the compreſſion which is produced in the air-veſſel, more than what is neceſſary for merely balancing the quieſcent column of water, reacts on the piſton to reſiſt its compreſſion juſt as much as the addition of a column of water would do, the height of ſuch column being ſufficient to produce the required velocity of the efflux.

Machines for working Pumps.—The beſt method of working pumps from a firſt mover which acts with a rotative motion, is by means of cranks; and if two or more pumps are to be actuated by the ſame machine, the cranks for them ſhould be placed at regular intervals round the centre, ſo as to produce a continual action.

It has been obſerved, in our article STEAM-*Engine*, that the reciprocating motion obtained by a crank is very unequal, even when the rotative motion of the crank is quite uniform. This renders the motion of the piſton in the barrel of the pump irregular, for at the top and bottom of the barrel the motion of the piſton is very ſlow, but when the piſton is at the middle of the barrel the piſton moves quickly. This property is a great advantage in working pumps, becauſe it puts the column of water in motion with a leſs ſudden ſhock; but it has been very generally miſtaken and conſidered as a defect, and many ingenious contrivances have been propoſed, by means of racks and pinions, to give an uniform motion to the piſton-rods of pumps. Theſe have never ſucceeded in practice, and have always been laid aſide.

The attempts of mechanicians to correct this unequal motion of the piſton-rod are miſplaced; for if it could be done it would greatly injure the performance of the pump. As this is a favourite ſpeculation, and new attempts to perfect it are conſtantly making, we think it right to ſhew the reaſon of their failure.

Suppoſe the firſt mover to move uniformly with a rotatory motion, and that the machinery is ſo conſtructed, that the piſton-rod will be moved up and down with a regular motion, or that the velocity of the piſton ſhall be at all times the ſame, whether it is at the top or bottom, or in the middle of its courſe. In this caſe, at every reciprocation, the column of water in the main pipe muſt be ſuddenly urged into motion from a ſtate of reſt, and the machine could not perform one ſtroke, if the velocity of the firſt mover did not ſlacken a little, or if the different parts of the machine did not yield by bending or compreſſion. Theſe ſtrains would be ſo ſudden and violent, that no ſtrength of materials could withſtand the violence of the ſhocks at every reciprocation of the motion. This would be chiefly experienced in great works which are put in motion by a water-wheel, or ſome other equal power, exerted on a large maſs of matter, of which the machine conſiſts. The water-wheel, being of great weight, moves with ſteadineſs or uniformity; and when an additional reſiſtance is oppoſed to it by the beginning of a new ſtroke of the piſton, its quantity of motion is but little affected by this addition, and it proceeds with very little loſs of motion. The machine muſt therefore yield a little by bending and compreſſion, or it muſt break to pieces, which is the common event.

A crank is free from this inconvenience, becauſe it accelerates the piſton gradually, and brings it gradually to reſt, while the water-wheel moves round with almoſt perfect uniformity. It has been ſtated as an inconvenience of this ſlow motion of the piſton at the beginning of its ſtroke, that the valves do not ſhut with rapidity, ſo that ſome water gets back through them; but this is a miſtake, becauſe the valves always fall by their own weight as ſoon as the water ceaſes to flow upwards through them. Now when the piſton begins to move with its ſlow motion towards the end of the ſtroke, leſs water is cauſed to flow through the valves, and in conſequence they cloſe gradually, and will be fully ſhut by the time that the piſton becomes motionleſs, and before it begins to return. This is ſhewn in the large machines, ſuch as that of London-bridge, where the pumps are worked by cranks, and the valves cloſe imperceptibly; but in a ſteam-engine of the ſame power, the ſhock occaſioned by the ſhutting of the valves is exceedingly violent. In ſhort, by a judicious application of the crank and a fly-wheel, or an air-veſſel, and by employing two or three barrels to the pump, the evils of the reciprocating motion of pumps may be completely remedied, and on this account we conſider, that if a rotatory pump could be brought to perfection, it would have no ſuperiority over an accurate pump with a ſtraight barrel.

Mr. Smeaton's proportions for a two-horſe pump machine for raiſing water are as follow: horſe-track thirty feet diameter; great cog-wheel nineteen feet diameter, with 144 cogs; this gave motion to a trundle of ſeventeen ſtaves, fixed upon an horizontal axis, which carried a caſt-iron fly-wheel of ten feet diameter, and the rim three inches by three inches. On the extremity of the horizontal axis was a crank of a foot and a half in length, which, by means of a connecting-rod, gave motion to one end of a working beam or lever of ſeventeen feet long, which was poiſed on a centre in the middle of its length, and at the oppoſite end was an arched ſector for the chain, by which the pump-rod was ſuſpended. The pump was a ſucking-pump, ſix inches diameter in the barrel, and the length of the ſtroke was three feet. A weight was applied to the end of the beam over the crank, which was ſufficient to balance one-half of the column of water in the pump. In this machine, when the horſes walked two miles and a half *per* hour, they made two turns and one-third *per* minute. The trundle and fly-wheel made twenty turns *per* minute; the pump made the ſame number of effective ſtrokes, and raiſed upwards of a hundred barrels ale meaſure *per* hour. By the counter balance and the fly-wheel, the reſiſtance to the horſes was rendered perfectly uniform.

The *Pump Machine at Blenheim*, which was erected by Mr. Alderſea for the duke of Marlborough, is thus deſcribed by Mr. Ferguſon in his lectures. The water-wheel is underſhot, and is turned by the fall of the water running down an inclined plane, and ſtriking the floats of the wheel. The extremity of the pivot or gudgeon is formed into any number of cranks; for inſtance ſix, that is, three at each end of the axis, more or leſs, according to the force of the fall of water, and the height to which the water is intended to be raiſed by the engine. As the water-wheel turns round, theſe cranks move as many levers up and down, by the iron connecting-rods. Theſe levers alternately raiſe and depreſs the piſtons of the forcing-pumps by other iron rods, which are attached to the oppoſite ends of the levers, and as one is raiſed the oppoſite piſton is depreſſed. Pipes go from all theſe pumps, to convey the water which they draw up (to a ſmall height) into a cloſe ciſtern or box, from which

the

the main-pipe proceeds, the water is forced into this ciftern by the defcent of the piftons. And each pipe, going from its refpective pump into the ciftern, has a valve to cover its end in the ciftern, which valves will hinder the return of the water by the pipes; and, therefore, when the ciftern is once full, each pifton upon its defcent will force the water (conveyed into the ciftern by a former ftroke) up the main-pipe, to the height to which the engine is intended to raife it; which height depends upon the quantity to be raifed and the power that turns the wheel. When the power upon the wheel is leffened by any defect of the quantity of water turning it, a proportionable number of the pumps may be laid afide, by difengaging their rods from the vibrating levers.

When fuch a machine is placed in a ftream that runs upon a fmall declivity, the motion of the levers, and action of the pumps, will be but flow; fince the wheel muft go once round for each ftroke of the pumps. But when there is a large body of flow running water, a cog or fpur-wheel may be placed upon each fide of the water-wheel, upon its axis, to turn a trundle upon each fide; the cranks being formed upon the axis of the trundle. And by proportioning the cog-wheels to the trundles, the motion of the pumps may be made quicker, according to the quantity and ftrength of the water upon the firft wheel; which may be as great as the workman pleafes, according to the length and breadth of the float-boards of the wheel. In this manner the engine for raifing water at London-bridge is conftructed; which we fhall now proceed to defcribe.

The original engine at London-bridge was put up by Mr. Sorocold towards the beginning of the laft century: it deferves notice on account of a contrivance for raifing and falling the water-wheel, to accommodate it to the different heights of the water: this was the invention of Mr. Hadley, who put up the firft of that kind at Worcefter, for which he obtained a patent.

Mr. Beighton has thus defcribed this machine in the Philofophical Tranfactions. The wheels of the London-bridge water-works are placed under the arches of the bridge, and moved by the common ftream of the tide-water of the river. The following are the particulars of the largeft wheel.

The axle-tree of the water-wheel is nineteen feet long, and three feet in diameter, in which are four fets of arms, eight in each fet; thefe arms fupport four circular rings or felloes, twenty feet in diameter, to which are attached the float-boards, fourteen feet long and eighteen inches deep, being about twenty-fix in number. The wheel lies with its two gudgeons, or centre-pins, upon braffes in two great levers, which are placed in an horizontal pofition, and therefore fupport the weight of the wheel. The wheel is, by thefe levers, made to rife and fall with the tide in the following manner. The levers are fixteen feet long; thus, from the fulcrum of each lever, to where the gudgeon of the water-wheel bears on it, fix feet; and from thence to the extremity ten feet. At the extremity is a fector or arch of a circle defcribed from the fulcrum of the lever, and to the bottom of this arch is fixed a ftrong triple chain, made after the fafhion of a watch-chain; but the links are arched to a circle of one foot diameter, having notches, or teeth, to take hold of the leaves of a pinion of caft-iron, ten inches diameter, with eight teeth in it moving on an axis, which is fixed up over the arch at a confiderable height, and the chain goes up to the pinion and turns over it. The other loofe end of this chain has a large weight hanging at it, to help to counterpoife the great weight of the water-wheel, and prevent the chain from fliding on the pinion. On the fame axis as the pinion is fixed a cog-wheel, fix feet diameter, with forty-eight cogs. To this is applied a trundle, or pinion, of fix rounds, or teeth; and upon the fame axis is fixed a fecond cog-wheel, of fifty-one cogs; laftly, this is turned by a trundle of fix rounds, on whofe axis is a winch or windlafs. The other lever is provided with a fimilar chain and wheel-work, and the axis of the laft-mentioned trundle is prolonged until the two winches nearly meet, fo that one man, with the two windlaffes, raifes or lets down the wheel, as there is occafion to dip always equally into the water.

By means of this machine, the ftrength of an ordinary man will raife about fifty ton weight, which much exceeds the weight of the water-wheel.

Near each end of the great axis of the water-wheel, a cog-wheel is fixed, eight feet diameter, and forty-four cogs, working into a trundle, of four feet and a half diameter, and twenty rounds, whofe axis or fpindle is of caft-iron four inches in diameter, lying in braffes at each end, fupported by ftrong timber framing.

And becaufe the fulcrums of the levers above defcribed are in the line of the axis of the trundle, in what fituation foever the water-wheel is raifed or let down, the great cog-wheel is always equidiftant from the trundle, and works or geers truly therewith.

A quadruple crank of caft-iron is attached to the end of the axis of the trundle, the metal being fix inches fquare, each of the necks being diftant one foot from the centre of motion; the gudgeons of the cranks are fuftained in braffes at each end in two headftocks faftened down by caps. One end of this crank is placed clofe abutting to the end of the axis of the trundle, which at that end is fix inches diameter, and having a flit in the end, the end of the crank terminates in the fame manner, and an iron wedge is put, one half into the flit in the end of the axis, and the other half into the flit in the end of the crank, by means of which the axis turns the crank about with it.

The four necks of the crank have each an iron fpear, or rod, jointed to them, and alfo jointed at the upper end to the refpective libra, or lever, within nine feet of the centre of the lever. Thefe levers are twenty-four feet long, moving on centres in the middle of their length, and fupported by the frame; at each end of each lever is jointed a rod, which defcends into the pump-barrel, and has the forcer faftened to it. Each end of the four levers works a quadruple forcing-pump, confifting of four caft-iron barrels or cylinders four feet three-quarters long, feven inches bore above, and nine inches below, where the valves lie; the four barrels are faftened by fcrewed flanches over four holes in a hollow trunk of caft-iron, having four valves in it juft over thefe holes, at the joining on of the bottom of the barrels, and at one end of the hollow trunk is a fucking-pipe and grate, going into the water, which fupplies all the four pumps alternately, when they fuck or draw up water.

To carry away the water which they force out, there proceeds from the lower part of each pump-barrel, a neck turning upward arch-wife, whofe upper part is caft with a flanch to fcrew up to the under fide of another fquare trunk, which receives the necks of all the four barrels; which necks have bores of feven inches diameter, and over the holes in the trunk, communicating with them, are placed four valves at the joinings or flanches. The fquare forcing-trunk is caft with four boffes, or protuberances, ftanding out againft the valves, to give room for their opening and fhutting; and on the upper fide of the trunk are four holes ftopped with plugs, to take out on occafion, to cleanfe the valves. One end of this trunk is ftopped by a large plug, and to the other the iron-pipes are joined by flanches, through

through which the water is forced up a hundred and twenty feet, or to any height or place required.

See a drawing of a triple forcing-pump of this fame kind, in our article PUMP.

Befides this four-barrelled pump, there is fuch another placed at the other ends of the libræ, or levers; but to avoid confufion, we fpoke only of one quadruple pump, as the other is juft the fame; but its rods and forcers being at the oppofite ends of the levers, the barrels draw and force alternately.

At the other end of the water-wheel is placed all the fame fort of work as at the end already defcribed; *viz.* the great cog-wheel and the trundle, fixed upon the fpindle or axis, which is united, as before-mentioned, with the axis of the quadruple crank.

Alfo the four rods from thefe cranks, to work the four horizontal levers, each of which has a forcer at both ends, to ferve the four barrels of a quadruple pump at each end of the levers; fo that one fingle wheel works fixteen pumps, *viz.* two quadruple engines at each end of the axis.

Mr. Beighton, who has defcribed the ftructure and operation of this engine, (fee Phil. Tranf. abr. vol. vi. p. 358.) has thus calculated the quantity of water raifed by it in a given time.

In the firft arch next the city there is one wheel with double work of fixteen forcers. In the third arch, one wheel with double work at one end, and fingle at the other, having twelve forcers. A fecond wheel in the middle having eight forcers. A third wheel with fixteen; fo that there are in all fifty-two forcers. One revolution of a wheel produces in every forcer $2\frac{1}{5}$ ftrokes; fo that one turn of the four wheels makes 114 ftrokes, taking all the barrels into account. When the river acts with moft advantage, the wheels go fix times round in a minute, and but $4\frac{1}{2}$ at middle tide; hence the number of ftrokes in a minute is 684; and as the ftroke is two feet and a half in a feven-inch bore, it raifes four ale gallons; and all raife *per* minute 2736 ale gallons; *i. e.* 164160 gallons or 3420 hogfheads *per* hour, ale meafure, to the height of 120 feet. Such is the utmoft quantity they can raife, fuppofing that there were no imperfections or lofs at all; but Mr. Beighton infers, from experiments performed on engines whofe parts were large and excellently conftructed, that they will lofe one-fifth and fometimes one-fourth of the calculated quantity.

Mr. Beighton obferves, that, though thefe water-works may juftly be efteemed as good as any in Europe, yet fome things might be altered much for the better. If, he fays, inftead of fixteen forcers, they worked only eight, the ftroke might be five feet in each forcer, which would draw much more water with the fame power in the wheel; becaufe much water is loft by the too frequent opening and fhutting of the valves; and that the bores that carry off the water from the forcers are too fmall; and that they fhould be near nine inches in diameter. This objection Dr. Defaguliers fays is of no force, unlefs the velocity of the piftons was very great; but here the velocity of the water paffing through the bores is much lefs than two feet in a fecond. This laft writer obferves, that a triple crank diftributes the power better than a quadruple one. He adds, that forcers made with thin leather tanned, of about the thicknefs of the upper leather of a countryman's fhoe, would be much better than thofe of the ftiff leather commonly ufed.

In order to calculate the power which the above water-wheel exerts, we muft find the weight which it raifes, and the fpace through which it is raifed in any given time.

The weight of the column of water, in any one of the pumps, is found thus: Diameter feven inches fquared = 49 circular inches area. Now one cylindrical inch, a foot high, weighs .34 pounds avoirdupois, and therefore 49 fuch cylinders muft weigh $16\frac{2}{3}$ pounds; but the column is 120 feet high, and therefore $120 \times 16\frac{2}{3} = 1999$ pounds weight. This column of water is raifed $2\frac{1}{2}$ feet at every ftroke, now each pump makes $2\frac{1}{5}$ effective ftrokes for every turn of the wheel, or taking the wheel at fix turns *per* minute, each pump makes 13.2 ftrokes *per* minute. Multiply this by $2\frac{1}{2}$ feet, and we find the motion given to each column of water is near 33 feet in a minute, and the weight of it 1999 pounds.

But the wheel which we have defcribed actuates 16 fuch columns, and therefore the total weight will be 31984 lbs. raifed 33 feet in a minute. This is equal to 1055571 lbs. raifed one foot high *per* minute.

What is called a horfe-power, in fteam-engines, is 33000 pounds raifed one foot high *per* minute, and we find this contained near thirty-two times in the above quantity, fo that this fingle machine exerts thirty-two horfe-power. But as the above horfe-power is $1\frac{1}{2}$ times what horfes can do for conftant work, it would take forty-nine horfes to do as much work as this wheel, and they would not be able to work more than eight hours every day, but the water-wheel works five or fix hours each tide.

We fhall afterwards give a fimilar calculation of the machine at Marly, in France, in the fame terms, fo as to admit of a direct comparifon, and from this it will appear, that the old machine at London-bridge, which was erected not long after the machine at Marly, is three times as powerful as any one of the water-wheels at Marly.

The above ftatement of the wheel making fix turns *per* minute is taken from Mr. Beighton's account, who alfo ftates the velocity of the water at 685 feet *per* minute, and the velocity of the wheel 310 feet *per* minute, or as 1 to 2.2.

In 1763 Mr. Smeaton found, by an average of the fix years preceding, that the engine above defcribed had made 3025 ftrokes in each pump at every tide, taking an average of all the circumftances of high and low tides. This is only 1375 turns for the water-wheel, or 4033 ale hogfheads every twelve hours; and hence the produce falls very fhort of the calculation of fix turns *per* minute; but this does not affect the power of the machine during the fhort time when it is working at that rate.

In 1762, when the two middle arches of London-bridge were thrown into one by the removal of the pier, the water way of the river was fo much increafed, that the water-wheels did not perform fo much as they did before, the daily produce being reduced to 2716 hogfheads. In confequence, the city granted to the Water-works Company the ufe of the fifth arch, for which Mr. Smeaton planned a larger machine than any of the others: it was erected in 1767, and which we fhall now defcribe.

We fuppofe it underftood, that London-bridge is not built with ftone down the bottom of the river, but according to an ancient method of driving piles into the bottom of the river, and cutting off the tops level with the loweft water line, upon thefe the ftone-piers of the bridge are erected; but as the original piles were fubject to decay, and admitted of no renewal, it became neceffary to furround them with gravel and chalk; and to retain the chalk, cafings of piles, called ftarlings, are driven in all round the piers. Thefe diminifh the fpace between the arches, fo as to occafion a very rapid current of the water in running through them, becaufe the water-paffage bears only a fmall proportion of the artificial folids, thus placed in the way of the current, and this reduces nearly all the arches to fluices as it were. Of the twenty arches in this bridge, fix are devoted

devoted to the water-machines, that is, five on the London ſide, and one on the Southwark ſide.

Mr. Smeaton's great Engine at the fifth Arch of London Bridge.—This machine is repreſented in perſpective, in *Plate* II. WATER-WORKS, *Machines for raiſing Water.* The view being taken from beneath the arch of the bridge, B B repreſents the ſtarling of the fourth pier of the bridge, compoſed of a vaſt body of piles driven into the bed of the river, and the interſtices filled up with chalk and gravel. Upon the heads of theſe piles, a ſet of horizontal beams are laid in the manner of joiſts, and all is made level by chalk and gravel.

The fifth pier C C is made in the ſame manner. The water-wheel F F G G is made of ſuch a breadth as to fill the ſpace between the two ſtarlings as exactly as poſſible, without touching; and the bearings for the gudgeons of its axis are ſupported upon head-ſtocks E E, which reſt upon the ſtarlings. The water-wheel has four circular rings F F F F, each ſuſtained by ſix arms mortiſed into the axis; each ring has twenty-four ſtarts mortiſed into it, and to theſe are nailed the float-boards *f f*, upon which the water acts to turn the wheel round.

Upon each end of the main axis is fixed a large wooden wheel H H, round which caſt-iron rings of cogs are fixed in ſegments. Theſe cog-wheels turn two trundles, which give motion to the forcing-pumps, which are ſix in number, *viz.* one three-barrelled pump on each ſide of the water-wheel; but only one of the engines or triple pumps is ſhewn in the figure, for as the other is exactly the ſame, it is ſufficient to deſcribe one. The axis on which the trundle I is fixed is of caſt-iron; it is connected with a triple crank, one arm of which is marked *b*, and two others are hidden behind the frame: *g h i* are ſtrong iron rods, joined to the cranks at their lower ends, and to the ends of the great levers or regulators K L M at the upper ends.

The regulators are poiſed on centres in the middle of their length, and have arches *k l m* at the other ends, which are ſtruck from the centres of motion, upon which arches the chains are laid, to give motion to the piſton-rods of the pumps N.

By the motion of the water ſtriking the float-boards, the water-wheel is made to revolve on its axis, and the large cog-wheel H with it. This turns the trundle I and the triple cranks *b c*, which, being arranged round the axis at equal intervals, elevate and depreſs the crank-rods *g h i* and regulators K L M ſucceſſively, and give to the pump-rods and piſtons a vertical motion.

The joints of the crank-rods *g h i* are made to ſcrew together round the crank-neck with braſs between; by this means they work very pleaſantly, and when worn can be ſcrewed up tight again that they may have no ſhake. The crank-rods are each made in two lengths, each of which has a flanch at the end, and they join at *n* in the middle of the rod: the flanches are held together by three ſcrews, ſo as they may be taken apart occaſionally without difficulty, when the pump-forcers are to be drawn out of the barrels to new leather them.

The joints at the end of the beam or levers are made with braſſes, and ſcrews to adjuſt them; and ſo are the centres or fulcrums of the levers.

The levers or regulators are admirably well deſigned to be ſtrong, with but little timber; they are formed of two pieces of timber, between which the caſt-iron axis on which they turn are placed; and then the ends of theſe pieces are bent to touch, and are kept together by hoops and ſcrew-bolts, ſo as to make cloſe joints. At the ends, ſeveral ſmall ſquare pieces of wood are interpoſed croſs ways in theſe joints at the ends of the lever, being let into both timbers; by theſe, when they are firmly bound together, the two pieces of timber are prevented from ſliding end ways upon each other, ſo as they form an excellent truſs-beam, for it cannot bend or yield without ſtretching one timber and compreſſing the other.

The pump-rods are attached to the arches at the ends of the beams by four iron chains each, as is ſhewn in *fig.* 2. The rod has a croſs-piece *p* fixed on the top of it, to which the two outſide chains are attached, and the lower ends of the ſame chains are faſtened at the lower end of the arch.

Theſe chains act to pull down the piſton-rods; the other two chains which return or raiſe the rods are faſtened to the top of the arch, and to the rods at the lower ends, as ſhewn in the figure.

The pumps are forcing-pumps, and raiſe the water when the piſtons are depreſſed: the lower piece of the triple pump is a ſquare iron-pipe or trunk, ſcrewed faſt down upon the groundſells of the engine-frame; this is called the ſuction-piece: it has a flanch at each end, to one of which a lid is ſcrewed, and the other joins it to the ſuction-pipe R, which brings up the water from the river. On the top of the trunk, the three barrels N are ſcrewed, each having a valve in the joint, which allows water to enter into the barrel, but prevents its return. From the bottom part of each barrel proceeds a crooked pipe *q*, which communicates with another ſquare trunk S, called the forcing-piece, having valves at the joint, to prevent any water from getting back into the barrels. On the top of the trunk over each valve is a round hole, over which a lid is ſcrewed, but can be removed to clean or repair the valves when neceſſary. Similar lids are ſcrewed on over openings into the ſuction-trunk, at the back towards the cranks. At the ends of the forcing-trunk S are flanches, one of which receives a lid like the lower trunk, and the other flanch joins to the pipe *s*, which conveys the water away from the pumps.

The piſtons or buckets of the pumps are ſolid, that is, without valves in them; and their action is as follows:

When the piſton of any of the barrels is drawn up, it makes a vacuum in that barrel; and the preſſure of the atmoſphere on the ſurface of the water from which the ſuction-pipe R draws, raiſes the valve at the bottom of that barrel, and fills it with water. At the deſcent of the piſton, the lower valve ſhuts, and the water contained in the barrel can find no paſſage but through the valve in the forcing-trunk S; and when the piſton is drawn up again this valve cloſes, and the lower one opens to give a freſh ſupply of water to the barrel. By the poſition of the triple cranks, it always happens that one or other of the barrels is forcing the water into the force-pipes; and as the ſtrokes of the other ſet of pumps at the other end of the water-wheel are contrived to be intermediate or alternating to theſe, a conſtant ſucceſſion is kept up.

The main-pipe *s* is continued to the ſhore, to convey the water into the ſtreets. A wooden ciſtern T is placed over the pumps to hold water, and keep a conſtant ſupply of it above the piſtons to prevent leakage. The whole engine is ſurrounded by a ſtrong timber fence, which guards it from the injuries it might receive from veſſels or floating ice, ſtriking it at high water, when the water riſes above the level of the ſtarlings nearly to the axis of the water-wheel. On the tops of theſe piles, a large ſtage is built, to ſerve as a road from the ſhore to the engine, and the underſide of it ſupports the main-pipes, which convey the water aſhore. There are alſo other ſtages in different parts of the machine, to ſupport workmen when repairing it; theſe prevent the whole engine from being ſeen from the bridge at one view, and for

for this reafon they are omitted in the drawing, which is in fome degree imaginary, as it reprefents the engine detached.

This machine is more fimple than the preceding, as it performs more work by fix pumps of ten inches bore and $4\frac{1}{2}$ feet ftroke than the other by fixteen pumps of feven inches bore and $2\frac{1}{2}$ feet ftroke, and therefore with much lefs lofs of power by friction; and as the cranks only work in one direction, they work much more pleafantly than when there are pumps at both ends of each lever, becaufe in that cafe the ftrain on the cranks, connecting-rods, and the fulcrums of the levers, in fact on all the joints, is alternately in different directions, and if there is any fhake or loofenefs in the joints, it produces jerks and irregularities. By ufing three barrels and triple cranks, the fupply of water, forced into the main-pipe, is more equable than when four are ufed, though not perfectly fo. The perpendicular motion produced by the arches and chains, is a great advantage in making the barrels wear equally.

In order to enable this engine to work as long as poffible in each tide, and after the velocity of the motive water is abated, it is contrived to adjuft the refiftance to the diminifhed power. This is done in the moft fimple manner by a fmall cock and pipe in the chamber of each pump-barrel; juft above the fuction-valve from this cock, a rod of communication rifes up to the ftage to turn it by, and this cock being opened will admit air into the barrel when the pifton is drawn up, fo that the water of the river will not be drawn up into that barrel; and in confequence, it will become inactive, and the wheel will be relieved from the load of working it. In this way, the load of the engine is adapted to the power of the tide at its different periods; but when all the three barrels are thus relieved by opening the air-cocks, the motion of that engine becomes a ufelefs loud friction of the piftons and movements; and to relieve this, the fhaft or axis of connection between the axis of the trundle and the triple crank, is provided with the means of difuniting or uniting them whilft in motion, fo that one engine will ftand ftill whilft the other is at work.

The principal dimenfions of this machine are as follow: —The water-wheel is thirty-two feet diameter, meafuring to the outfide of the float-boards; the length of the float-boards fifteen feet and a half, and their breadth four feet and a half; the number of float-boards twenty-four. At each end of the axis is fixed a cog-wheel, fourteen feet diameter, with eighty cogs: each of thefe turns a trundle of twenty-three ftaves, fixed on the axis of the cranks, which are triple; that is, three cranks are formed fide by fide on the fame axis, and bent in different directions, fo as to produce a continual action. Each crank actuates a lever or working beam eighteen feet long, which is poifed on a fulcrum in the middle, and gives motion to the pump-rods by an arch-head and iron chains. The pump-barrels are ten inches diameter, and the piftons make ftrokes of four feet and a half long; they are forcing-pumps, and three barrels are combined together, to throw the water into one main pipe, which conveys the water into the town; the higheft elevation to which the water is ever lifted is a hundred and twenty feet. The cranks, beams, and pumps, at each fide of the wheel, are exactly fimilar, fo that the wheel actuates fix pumps.

This machine was erected, under Mr. Smeaton's directions, in 1767, and worked conftantly for fifty years, when the timber-work becoming decayed, it was rebuilt in 1817, with caft-iron inftead of wood, and has been lately fet to work. The principal proportions of Mr. Smeaton's defign have been preferved, but the great levers have been fuppreffed, and the cranks are placed over the fame pumps as the former.

Mr. Smeaton's Pump Machine at Stratford Water-works.—This is fo like the laft, that we fhall only give the principal dimenfions, as an example of the beft proportions for a machine with a breaft-wheel, the laft being underfhot. The water-wheel was fixteen feet diameter and eight feet wide; upon its axis was a cog-wheel of eleven feet and a half diameter, with feventy-eight cogs, which turned a cog-wheel of five feet one inch diameter, with thirty-five cogs. This was fixed upon the axis of the cranks, which were three in number, and by means of three beams gave motion to three forcing-pumps nine inches diameter and two feet and a half length of ftroke, lift of the water 84 feet. In addition to the pair of cog-wheels juft mentioned, there was another pair, of different proportions, fixed clofe to the fides of the others, and by a fimple contrivance either pair could be brought into action, and the other pair would then be difengaged. The fecond wheel, which was fixed in the axis of the water-wheel, was nine feet eight inches diameter, with fixty-fix cogs, and the wheel on the axis of the cranks which belonged to it had forty-feven cogs. The intention of thefe two fets of wheels was to adapt the water-wheel to work equally well when it was flooded and impeded in its motion, as when the water was low; for when the quick motion was in ufe, the cranks made 15.6 revolutions *per* minute, whilft the water-wheel made feven revolutions. But when the flow motion was in ufe, the cranks would make $15.\frac{1}{2}$ revolutions *per* minute, whilft the water-wheel made eleven. This machine is feven horfes' power.

The *Pump Machine at Marly*, near Paris, being fo much celebrated on account of its magnitude and the multiplicity of its parts, we fhall be expected here to give fome account of it, which we have taken from Belidor, and we fhall fubjoin a few remarks upon its conftruction, from which it will appear we do not recommend it as a model.

This machine is fituated between Marly and the village La Chauffée. In that place the river Seine is penned up partly by the machine and partly by a dam, which keeps up the water; but in order that the navigation may not be interrupted, a canal has been cut, two leagues above Marly, for the paffage of boats and barges. There has been erected, about thirty-five fathoms from the machine, a contrivance, called an *ice-breaker*, to prevent floating pieces of ice or timber, which come down the ftream, from damaging the machine, and the better to fecure the pen-ftocks, and the channels in which the water-wheels move. There is a grate of timber to ftop whatever may come through the ice-breaker.

The water is raifed to its deftined height by the force of fourteen underfhot water-wheels, which work the pumps at three different ftages: firft, one fet of pumps to lift the water from the river, to a refervoir placed up the hill two hundred and thirteen yards from the river, and at the elevation of a hundred and fixty Englifh feet above the level of the Seine. The power of the wheels is conveyed alfo to this place by chains, in order to work a fecond fet of pumps, which force the water to the fecond refervoir, a hundred and eighty-fix feet higher, and therefore three hundred and forty-fix feet above the river, and fix hundred and ninety yards diftant. At this fpot is a third fet of pumps, to throw up the water from the latter to the fummit of a tower a hundred and eighty-nine feet higher, and at a diftance of one thoufand three hundred and thirty yards from the river up the mountain. The whole elevation is rather more than five hundred and thirty-five feet above the river. From the ciftern in the tower the water is conveyed, by an immenfe aqueduct, to the gardens of Marly.

The breadth of the machine comprehends fourteen water-courfes,

courfes, each fhut by a fluice or pen-ftock, which can be raifed and depreffed by racks, and in each of thefe courfes an underfhot wheel is placed. The fourteen wheels are difpofed in three lines acrofs the river. In the firft line, which is up the ftream, there are feven wheels, in the fecond line fix, and only one in the third.

The wheels are thirty feet diameter, and five feet wide, and they are all nearly the fame as follow: the ends of the axle of each wheel go beyond their bearing pieces, and are bent into cranks, which make levers of two feet; the crank which is towards the mountain gives motion to a beam or lever, which carries four piftons or forcers at each end, to work in the barrels of as many forcing-pumps, which as the wheel works alternately fuck up the water of the river, and drive it up into the firft ciftern. The other crank at the oppofite end of the axle gives motion to the chains, which go up the hill, to work the pumps in the two elevated cifterns.

Each of the fix wheels on the firft line is conftructed in this manner, to give motion by one of its cranks to an engine, confifting of eight forcing-pumps combined together. The engine is actuated by a lever or beam, from each end of which a fquare piece of wood is fufpended, that carries and directs four piftons of forcing-pumps; the beam of the engine is put in motion from the crank of the wheel by a beam or leader, which is connected with the crank of the wheel at one end, and with one arm of a regulator or bent lever, whilft the other arm of this regulator is united by another leader to the extremity of the beam of the engine, which beam is thus made to vibrate up and down and work the pumps.

Of the fix wheels we have juft mentioned, there are five which, by their oppofite cranks, give motion to the pumps in the elevated ciftern of the firft lift. This is effected by means of one vertical beam or lever, and two horizontal levers, which are bent, and actuate the chains that communicate the motion; the three levers are only to change the direction of the motion of the crank into a proper direction to go up the hill. The fixth wheel, which is the firft towards the dam, gives motion to a long chain that goes up the hill to work the pumps of the upper ciftern. The feventh wheel of the firft line is exclufively applied to move a chain, which goes to the firft ciftern, by both its cranks.

The fix wheels of the fecond line are like the five wheels in the firft row, *i. e.* one of the cranks of each works an engine of eight pumps, and the other a chain that goes to the upper ciftern.

Laftly, the fingle water-wheel, which is on the third line by each of its cranks, works an engine of eight forcing-pumps fixed in the river, and of itfelf fupplies one conduit-pipe of eight inches and a half bore.

There are then eight engines in the river, and reckoning all the chains which go up the hill, they are thirteen in number, including the chains that come from the fixth and feventh wheels of the firft line: thefe thirteen chains afcend the hill all together, and are fufpended at regular intervals of twenty feet by levers, to bear them up from touching the ground, which by moving on their centre admit of the working of the chains. Each chain is double, that is, there is a fecond chain, which is connected to the oppofite ends of the fufpending levers, and each chain ferves to draw the other chain back again after it has made its ftroke. Five of thefe double chains are employed to actuate levers, which work thirty inverted lift-pumps fituated in a ciftern at the firft lift, and which drive the water through two pipes of eight and a half inches bore up to the upper lift. The other eight double chains go ftraight on to the upper ciftern.

The feven chains of the wheels of the firft line, in going along, work alfo eight fucking-pumps, placed a little below the ciftern of the firft lift, becaufe in that place the water of a confiderable fpring is brought by an aqueduct, and thefe fame chains take up that water a fecond time by forty-nine pumps, which are fituated in a feparate ciftern, at the firft lift, on a level with the firft ciftern, and force it into the upper refervoir, through two conduit-pipes of eight and a half inches diameter, and three others of fix and a half inches diameter.

The water raifed by the feventy-nine pumps in thefe two cifterns at the firft lift, difcharges itfelf into a great refervoir at the fecond lift, and thence by two conduit-pipes of a foot diameter each, it runs into refervoirs of communication, and is diftributed into the feveral wells or little pump-cifterns of the upper ciftern, which all together contain eighty-two inverted lift-pumps; thefe force the water through fix conduit-pipes of eight inches and a half diameter up into the ciftern, in the tower which anfwers to the aqueduct. Thefe eighty-two lift-pumps are worked by the eight great chains before mentioned, that go ftraight to the upper ciftern, without moving any pumps by the way; and the fame chains work fixteen fucking-pumps behind the upper ciftern, to bring back into the refervoir of the fame ciftern the water which leaks out of the fix iron pipes that go to the tower.

To fum up all the pumps of this intricate machine:

1. The eight engines in the river contain fixty-four pumps, which fuck and force the water 160 feet up five iron pipes of eight and a half inches bore, and 213 yards long, up to the firft lift.

2. The two cifterns at the firft lift contain feventy-nine lifting-pumps, which raife the water 186 feet, through four pipes of eight and a half inches bore, and three pipes of fix and a half bore, and 477 yards up to the fecond lift.

3. The cifterns at the fecond lift contain eighty-two lifting-pumps, which raife the water 189 feet through fix pipes of eight and a half inches bore, diftance 640 yards: In all 225 forcing-pumps, which lift 535 feet and 1330 yards diftance. To this muft be added eight fucking-pumps in the river called feeders, which raife water into the cifterns at the top of the forcing-pumps, to keep water in the pumps, and prevent leakage; alfo the eight others which are below the midway ciftern; and laftly, the fixteen fucking-pumps, which we mentioned as placed behind the upper ciftern, fo that the machine has in all 257 pumps.

The bafin of the tower, which receives the water raifed from the river, and fupplies the aqueduct, is 1330 yards diftant from the river, and 535 feet above the level: the water having run along a ftone aqueduct, which is raifed upon thirty-fix arches, is feparated into different conduits, which lead it to immenfe refervoirs at Marly, and formerly conveyed it alfo to Verfailles and Trianon.

Such is the mechanifm of the machine of Marly. Its mean produce in Belidor's time was from 3000 to 4000 Englifh cubic feet of water *per* hour: he fays mean produce, becaufe under certain favourable circumftances it has formerly raifed more than 8484 cubic feet *per* hour. But during inundations, or when the Seine is frozen, when the water is very low, or when any repairs are making, the machine ftops in a great meafure, if not entirely.

The annual expences of the machine have been ftated formerly at 3300*l.* fterling, or 9*l. per* day, including the falaries of thofe who fuperintend it, and the wages of the workmen employed, together with repairs, neceffary articles, &c. This makes about one farthing for every eleven cubic

cubic feet. Or, taking into the account the intereſt of 333,000*l.*, the original expenſe of erection, which is five times as great as the annual expenſe, 11 cubic feet, which is 67 gallons, will coſt three half-pence, or at the rate of a farthing for 11 gallons.

This is the account of it given by Belidor in his ſecond volume.

Rannequin, the inventor, was an ingenious practical mechanic, but no mathematician or philoſopher. In ſeveral poſitions, the moving forces act unneceſſarily obliquely, which occaſions a great loſs of power, and renders the machine leſs effectual. A great proportion of the whole moving power of ſome of the water-wheels is employed in giving a reciprocating motion to the ſets of rods and chains, which extend from the wheels to the ciſtern, nearly two-fifths of a mile diſtant, where they work a ſet of pumps.

As this machine is continually quoted as the moſt powerful of all machines, we will compare its power with ſome of the large ſteam-engines in England. The quantity of water is $(8484 \div 60 =)$ 141 cubic feet *per* minute $\times$ by 535 feet, the height to which it is raiſed, $=$ 75649 cubic feet *per* minute lifted one foot high. Divide this by 528 cubic feet, which is the quantity that can be lifted one foot *per* minute, by what is called a horſe-power in ſteam-engines $=$ 143 horſe-power; but as the machine acts by 14 water-wheels, each one will be ſcarcely $10\frac{1}{7}$ horſe-power. The horſe-power is one-third greater than the average of horſes, and we therefore eſtimate that 215 horſes working together, would do as much work as this machine ever did, or 15 horſes to each wheel; but as the horſes could only work eight hours *per* day, three ſets muſt be kept to continue conſtantly.

M. Montgolfier informs us that the ſupply of water to the wheels is 138000 cubic feet *per* minute, and the fall is $4\frac{1}{2}$ feet; this gives a power $8\frac{3}{4}$ times as great as the effect produced. Montgolfier found $22\frac{1}{3}$ times when he tried it.

The whole work is now in a very ruinous ſtate, and many projects have been formed for a reſtoration of the machine on better principles.

It is probable Rannequin thought his moving force would not be ſufficient to raiſe the water to the height of 535 feet at once; and this is agreeable to the practice of more modern engineers.

If the machinery was conſtructed in caſt iron, in the ſame manner as ſteam-engines are now made, the force of one crank would be more than ſufficient to raiſe a cylinder of water of that altitude, and above eight inches in diameter, without any complication; but the pipes would require very great ſtrength. This is proved by a machine that has been lately erected at Marly, in place of one of the old water-wheels.

Even according to the original conſtruction, the water might be raiſed in one jet to the ſecond reſervoir. This appears from two experiments, one made in 1738, and the other in 1775. In the firſt, M. Camus endeavoured to make the water riſe in one jet to the tower; his attempt was not attended with ſucceſs, but he made the water riſe to the foot of the tower, which is conſiderably higher than the ſecond reſervoir. During this experiment the machine was ſo much ſtrained, that it was found neceſſary to ſecure ſome parts of it with chains.

The object of the ſecond trial, made in 1775, was to raiſe the water at once to the ſecond lift, 346 feet. It did aſcend thither at different times, and in great plenty, but the pipes were exceedingly ſtrained at the bottom, ſo that ſeveral of them burſt, and it was neceſſary to ſuſpend and recommence the experiment ſeveral times. This aroſe from a fault which might eaſily have been remedied; *viz.* from the age of the tubes and their want of ſtrength; therefore it reſults from this trial, that the chains which proceed from the river to the firſt lift might be ſuppreſſed, together with the firſt well itſelf: and this perhaps is all that is to be expected without a complete change in the machinery.

Rules for calculating the Dimenſions of Pumps.—The quantity of water delivered by any pump will be in the joint proportion of the ſurface or baſe of the piſton and its velocity; for this meaſures the capacity of that part of the working barrel which the piſton paſſes through; and the ſame is true of ſector pumps, or rotative pumps: but as pumps with ſtraight cylindrical barrels are the only kind in general uſe, it will be ſufficient to give the rule for calculating the content of a cylinder, which is ſimply to multiply the area of the baſe by the length; thus, take the diameter of the barrel in inches, and the length of the ſtroke in feet.

Square the diameter in inches, and divide by 183.3: multiply this by the length of the ſtroke in feet, and it gives the content of the cylinder in cubic feet.

Example.—How many cubic feet of water will be raiſed in an hour by a pump $8\frac{1}{2}$ inches diameter, and $3\frac{1}{2}$ feet ſtroke, which makes 18 ſtrokes *per* minute?

Diameter 8.5 inches $\times$ 8.5 $=$ 72.25 circular inches: divide it by 183.3, which is the number of circular inches in a ſquare foot, and it gives .394 ſquare feet for the area of the barrel $\times$ 3.5 feet in length $=$ 1.379 cubic feet; the content of the barrel $\times$ 18 ſtrokes *per* minute $=$ 24.822 cubic feet of water raiſed *per* minute $\times$ 60 minutes $=$ 1489 cubic feet *per* hour.

If it is required to know the quantity which a pump will raiſe in ale gallons, it is obtained by the following rule: take the diameter of the barrel in inches, and the length of the ſtroke in feet.

Square the diameter in inches; multiply by the length in feet, and divide by 30.

This ſhould give the content of the barrel in ale gallons of 282 cubic inches each; but the rule is not perfectly correct, for it aſſumes the gallon to be $282\frac{3}{4}$.

Example of the ſame Pump as above.—The ſquare of the diameter is 72.25 $\times$ 3.5 feet in length $=$ 252.875 $\div$ 30 $=$ 8.429 ale gallons for the content of the barrel. The true meaſure in this caſe is 8.45 gallons, which is very near.

To find the force requiſite to work any pump, take the diameter of the barrel in inches, and the perpendicular height of the column of water in feet.

Square the diameter in inches; multiply by .34 decimal, and multiply by the height of the column in feet.

This gives the force in pounds avoirdupois. It is uſual to add one-fifth to this weight, on account of friction and reſiſtance.

Example.—Suppoſe the above pump lifts the water 64 feet in the whole, what force will it take to draw up the piſton?

The ſquare of the diameter is 72.25 $\times$ .34lbs. $=$ 24.565 lbs., which is the weight of one foot high of the column $\times$ 64 feet $=$ 1572 lbs., the weight of the whole column. Add $\frac{1}{5}$th of this, *viz.* 314 lbs. $=$ 1886 lbs. the weight required to draw up the piſton and give it a proper velocity.

In conſtructing pumps, care muſt be taken to avoid all unneceſſary contractions in the valves or pipes which convey the water. If the water-way is too ſmall, the water will be be greatly resisted in its passage through such contractions; and this is called by the workmen wire-drawing the water.

The velocity of the water in the conduit-pipe, and in its passage through every valve, will be greater or less than the velocity of the piston, in the same proportion that the area of the piston or working barrel is greater or less than the area of the passage of the valve. For whatever quantity of water passes through any section of the working barrel in a second, the same quantity must go through any one of the passages: this enables us to modify the velocity of the water as we please, and we can increase it to any degree at the place of delivery, by diminishing the aperture through which it passes, provided we apply sufficient force to the piston. This is the case in the engine for extinguishing fires; but no such increase of velocity must be suffered in pumps which are required to raise the greatest quantity of water with a given power; because the power required to force the water with a great velocity is very considerable, and the velocity so obtained adds nothing to the mechanical effect which is produced. The resistance arises from a two-fold cause; *viz.* the friction of the water against the sides of the passage, and still more from the resistance which water opposes to any sudden change of figure; for though water is a perfect fluid, and will readily accommodate itself to any change of figure by its own gravity, yet, it requires some time to make such change; and if we force it to change its figure in less time than it naturally would, it requires mechanical power to do so, just the same as to compress a mass of clay, or other soft and non-elastic body.

In practice, the velocity with which the piston of the pump moves, determines the size of the smallest passage through which the water can pass without unnecessary resistance. Few pumps move with a greater velocity than 80 or 100 feet *per* minute; and we think the area of the narrowest passages and pipes should bear such a proportion to the area of the barrel, that the water will never be urged with a greater velocity than three feet *per* second, or 180 feet *per* minute, if the power required to move the pump is an object. In general, this will be accomplished by making the area of the smallest opening equal to half the area of the barrel; or if the diameter of the barrel is divided into 10 parts, the diameter of the least opening should be 7 of those parts. If the pump moves slower, then the passages may bear a smaller proportion. The pumps which have solid pistons are preferable, because the valves can be made of any size which is desired; but when a valve is made in the piston, its size is necessarily limited to less than we have recommended.

Estimate of the Strength of Men to raise Water.—Various authors have stated the mean force of a man so widely different, that the student is perplexed which to choose. The following table contains several of these statements, which we have reduced to one common denomination; *viz.* the number of pounds avoirdupois, or the number of cubic feet of water which a man can raise up in one minute to the height of one foot.

Authors.	Pounds Avoirdupois raised one Foot *per* Minute.	Cubic Feet of Water raised one Foot *per* Minute.	Duration of the Work.

Emerson - - - -	6300	100.8	For 10 hours.
Dr. Robinson - - -	5031	80.5	A feeble old man, working 8 or 10 hours *per* day, a pump without friction.
	6648	106.4	A young man weighing 135 lbs.: 10 hours *per* day.
Average of all these - - -	4098	65.5	
True standard - - -	3750	60.	Working 10 hours *per* day.

It is not difficult to account for these great differences, when we consider how the muscular force varies in different individuals, and also the power of enduring fatigue. The only means of ascertaining the mean force of a man is to take the sum total of the work executed by a number of men acting for a great length of time. This was repeatedly done by Mr. Smeaton, on a very large scale, and with so very little variation, that we can very confidently recommend engineers to calculate a man's force at 60 cubic feet, or 3750 lbs., raised one foot *per* minute: as this is just one cubic foot *per* second, it will easily be fixed in the memory. Desaguliers' estimate of one hogshead raised ten feet high *per* minute, is very frequently used, and is 5500 lbs. raised one foot *per* minute, but it is too great for a mean; and Desaguliers himself called it the maximum, which no machine can exceed.

When a machine is to be turned by the force of a man turning a winch or handle, the handle ought not to be longer than from 12 to 16 inches; nor should it be calculated to make more than 30 turns *per* minute; and when moving with this velocity, it should not require a greater force than $16\frac{3}{4}$ lbs. pressure upon the handle; or a man will not be able to move it without greater fatigue than he can endure for a day's work. If the handle is required to move slower, flower, for inftance 20 turns *per* minute, then the load may be increafed in proportion; *viz.* to 25½ lbs., and this will be lefs fatiguing.

The Force of Horfes to raife Water.—This we find as varioufly ftated by different authors as the force of men.

Authors.	Pounds Avoirdupois raifed one Foot *per* Minute.	Cubic Feet of Water raifed one Foot *per* Minute.	Duration of the Work.
Hachette's eftimate that a horfe is equal to 7 men	9406	150.5	Working 9 hours *per* day.
Fenwick	13200	211.2	
Gregory	18480	295.6	
More	21120	337.9	
Watt	20000	320.0	
Smeaton's 2 horfe machine, with an Archimedes' fcrew	20104	321.6	Working 9 hours *per* day, light work.
Smeaton's 4 horfe machine to work a flafh-wheel	20418	326.7	Working 8 hours *per* day.
Smeaton's ftandard	22916	366.6	
Defaguliers' eftimate that a horfe is equal to 5 men	27500	440.0	
Smeaton's experiment on drawing coals with 2 horfes	27720	443.0	Working 4½ hours *per* day, 4 horfes were kept in order to work for 9 hours *per* day.
Meffrs. Boulton and Watt's horfe-power in fteam-engines	32000 33000	512.0 528.0	The ftrongeft horfes, fuch as are ufed in London, cannot work at this rate throughout the day.
True ftandard	22000	352	Working 8 hours *per* day, nearly equal to 6 men.

In this, as in the former inftance, we feel inclined to give the preference to Mr. Smeaton's eftimate, both from his fuperior experience and accuracy, and alfo becaufe by his MS. papers, we are informed of the particulars of his experiments. He found, from examining the accounts of a colliery, that each horfe drew 27720 pounds one foot *per* minute; but as they could only continue to work at that rate for 4½ hours *per* day, Mr. Smeaton fixed his ftandard at 250 hogfheads *per* hour raifed ten feet, which is equal to 22,916 pounds, raifed one foot high. Still we find in two of his machines, of which we have already given the particulars, the performance fell rather fhort: we have, therefore, chofen to recommend 352 cubic feet of water, or 22,000 pounds *per* minute raifed one foot high, as a ftandard for a horfe's force, when he works 8 hours *per* day, and moves with a velocity of 2½ miles *per* hour. This is fettled by univerfal confent as the moft proper pace for a horfe to walk; and he will in that cafe draw juft 100 pounds, which is an eafy number to remember.

The eftimate of Defaguliers we confider as the maximum of a horfe's power; for the horfe-power of Meffrs. Boulton and Watt is only ufed as a meafure of the force of their *fteam-engines*. See that article.

In applying horfes to work machines, the circular tract in which they walk fhould be as large as poffible, that the horfes may turn round in the circle with little inconvenience. Few cafes will admit of a walk of more than 30 feet diameter; and in proportion as this is diminifhed, the horfe lofes fome of his power. No horfe-walk fhould be made of lefs than 20 feet diameter, if he is required to act with any confiderable force. When this fize cannot be obtained, we are of opinion that the horfe would work to a greater advantage by walking within a large perpendicular wheel, like thofe wheels ufed for cranes.

It muft be remembered, that the horfe fhould always move with a velocity of 2½ miles *per* hour, or 220 feet *per* minute; and, therefore, the number of turns which he will make in a minute muft be proportioned to the fize of the track in which he works.

Diameter of the Horfe's Track.	Circumference.	Number of Turns *per* Minute, when the Horfe walks 2½ Miles *per* Hour.
30 feet.	94 feet.	2.34
28	88	2.5
26	81.5	2.7
24	75.2	2.9
22	69	3.17
20	62.6	3.5

The machine which is to raife the water fhould be fo connected with the principal wheel which the horfe turns, that it will move with the proper velocity, when the horfe-wheel turns at the rate above fpecified. The velocity proper for moft machines is mentioned in the defcription of each.

Water-Wheels applied to raife Water.—The circumference of a water-wheel will work to the greateft advantage, when it moves with a velocity of from 3 to 4 feet *per* fecond, or from 180 to 240 feet *per* minute. A very proper velocity for a water-wheel is to make it the fame as the horfes, by the above table; and we have, therefore, added the velocities for fmaller diameters.

Diameter.	Circumference.	Turns *per* Minute.
18 feet.	56.4 feet.	3.9
16	50	4.4
14	44	5
12	37.5	5.86
10	31.4	7

Few machines, with pumps worked by a water-wheel, will raiſe more water to a given height in any timo, than amounts to one-third the mechanical effect of the quantity of water employed to work it; that is, conſidering the differences of the heights to which the water is raiſed, and the height of the fall, and reducing them both to an equality, the quantity of water raiſed will never exceed half of the quantity which falls. The other half is loſt in friction and leakage, and in overcoming the *inertiæ* of the parts of the machine.

Preſſure engines are thoſe machines which give motion to the piſton of a pump, by the force of a column of water acting in a cylinder or barrel, ſimilar to that of the pump. (See the article PRESSURE-*Engine*.) It was omitted in that article, that M. Belidor invented a machine, which may be conſidered as the firſt which was perfect, and was indeed the model for that made by Mr. Smeaton. See Architecture Hydraulique, vol. ii. p. 240.

M. Baillet made obſervations upon ſeveral machines of this kind in the mines of Hungary, from which it appears that the mechanical effect produced, is only four-tenths of the mechanical effect of the firſt power.

Height of the Fall of Water to work the Machine.	Diameter of the Piſtons.	Quantity of Water expended in 24 Hours.	Height to which the Water is raiſed.	Quantity of Water raiſed in 24 Hours.	Ratio of the Effect, and the Cauſe.

The French metre is equal to 3.281 Engliſh feet, and the cubic metre is 35.3198 cubic feet Engliſh.

Power of the largeſt Steam-Engines to raiſe Water.—The moſt powerful machine in exiſtence is the ſteam-engine, on Mr. Watt's principle, called Stoddart's engine, at the United Mine in Cornwall. Three other engines of equal dimenſions are employed to drain the mine, but only this one is loaded ſo as to exert its utmoſt force. The ſteam cylinder is 63 inches diameter, and acts double; that is, it operates to raiſe water equally in the aſcent or deſcent of the piſton. The weight of water in the pumps is 82,000 pounds, and with this load it makes $6\frac{1}{2}$ double ſtrokes *per* minute of $7\frac{3}{4}$ feet each; or, it gives to the load $100\frac{3}{4}$ feet motion *per* minute.

Multiply 82,000 pounds by $100\frac{3}{4}$ feet, and it gives 8,261,500 pounds *per* minute lifted one foot high: divide this by 33,000 pounds, which is called the horſe-power, and it gives $250\frac{1}{3}$ horſe-power for the acting force of the engine. Again, divide 8,261,500 pounds by $62\frac{1}{2}$ pounds, the weight of a cubic foot of water, and we find this engine is capable of raiſing 132,184 cubic feet of water *per* minute to a height of one foot. This is not one of the beſt engines with reſpect to fuel, and it burns $31\frac{1}{2}$ pounds of coal to raiſe this quantity.

The whole power employed to drain the United Mine is as follows:

		Horſe-Power.
Stoddart's engine, 63 inch cylinder, double acting		$250\frac{1}{3}$
William's engine, 65 inch cylinder,	do.	200
Sim's engine, 63 inch cylinder,	do.	185
Poldorey's engine, 63 inch cylinder,	do.	196
Total	-	$831\frac{1}{3}$

Here we have a ſingle machine of nearly double the power of the famous machine at Marly, which is in fact compoſed of fourteen machines, working in concert for a common object; and ſo do the four engines in the mine, which amount to $831\frac{1}{3}$ horſe-power, without reckoning the engines employed to draw up the ore.

The engines at ſeveral other mines in Cornwall are of immenſe power. We will ſtate two.

The mine called Wheal Alfred has four engines: a 63 inch double engine, which is lightly loaded, and only exerts 80 horſe-power; a ſingle acting engine of 66 inch, and 60 horſe-power; and two others of 64 and 60 inch, equal to 51 and 54 horſe-power:—in the whole, 245 horſe-power to drain one mine.

The Dolcoath mine has three engines: a double engine of 63 inch cylinder, and 132 horſe-power; a ſingle engine of 63 inch, and 45 horſe-power; and a ſmaller ſingle engine of 20 horſe-power:—in all, 197 horſe-power to drain the mine.

It will be obſerved above, that the power of the different engines is not in proportion to the dimenſions of the cylinders: this is becauſe the preſſure upon each ſquare inch of the piſton varies in different engines from 7 to 20 pounds. But cuſtom has eſtabliſhed, that certain ſizes of cylinders will be equal to a certain number of horſes' power, as is ſhewn by the following table.

The ſteam in the boiler is ſuppoſed to be kept within the limits of from 2 to 4 lbs. preſſure on each ſquare inch more than the atmoſphere; and in that caſe the cylinders of the diameters marked in the Table will have very nearly the powers aſſigned to them.

A TABLE of the Dimenſions of the Cylinders of Mr. Watt's Steam-Engines, either Double or Single, ſhewing their different Powers, either to raiſe Water by Pumps, or to turn Machinery by Cranks and Fly-Wheels.

Nominal Horſe-Power.		Dimenſions of the Piſton.			Effective Preſſure or Load on the Piſton.		Velocity of the Motion with which the Load is raiſed. This Table is formed from obfervations of a great number of engines of different powers, and making the intermediate fizes to correfpond to the fame law of increafe. Thus, a twenty-horfe engine is always made with a cylinder of 24 inches diameter, which is allowing 22.6 fquare inches of the pifton's furface for each horfe-power; but larger engines have a lefs allowance; an eighty-horfe engine has 19.8 fquare inches to each horfe-power, and fmall engines have a much greater allowance; a ten-horfe engine having $24\frac{1}{2}$, and a one-horfe, 28 fquare inches. This difference is to compenfate for the numerous difadvantages which always attend fmall machines.

The proper length of the ftroke for different engines is not at all fettled. Mr. Watt's firft engines were made much longer than this Table, but of late years they have been made fhorter, and without any adequate reafon which we can perceive; for it muft be an advantage to a machine to make as few reciprocations as is confiftent with a practicable length of cylinder. Thefe differences in the length of ftroke do not affect the calculation of powers, becaufe if the length of the ftroke is altered, the number *per* minute is alfo changed, and the velocity of the pifton is the fame; at leaft it will be always nearly the fame as the Table for thofe engines which work a crank and fly-wheel. But it muft be obferved that thefe engines move with a greater celerity than the engines for pumping water, becaufe it is neceffary to accumulate a confiderable velocity in the fly-wheel, or it muft be immenfely heavy if the pifton was to move fo flowly as the pumping engine generally does.

It is ufual with engine-makers to calculate the velocity of the piftons of engines at 220 feet *per* minute; but we have rarely found them to come up to this in practice, and have therefore calculated them at lefs. In the Table, the preffure upon each fquare inch of the furface of the fteam-pifton is in proportion to the velocities there marked; and if the velocities are found lefs than the Table, as is the cafe with engines for pumping, then the load upon each inch of the pifton muft be increafed in proportion, or elfe the power of the engine will be different, although the cylinder remains the fame.

For inftance, the engine at the Birmingham canal, mentioned in the article STEAM-*Engine*, had a twenty-inch cylinder; and being a fingle engine, fhould, by our Table, be rather more than feven horfes power. How does this agree? The weight raifed *per* hour to one foot high was calculated, in the article STEAM-*Engine*, at 13,961,805 lbs.; which divided by 60 gives 232.697 lbs. *per* minute: divide this by 33,000, the horfe-power, and we have a feven-horfe power; fo far it agrees with the Table. But the preffure on each fquare inch of the pifton was 11.7 lbs., and the Table fays the preffure fhould be 7.1 lbs. This difference is reconciled by the differences of the velocities; for the pifton of the Birmingham engine moved $63\frac{1}{4}$ feet *per* minute, and the velocity in our Table for a fingle engine is 98 feet: now as 11.7 lbs. is to 7.1 lbs., fo is 98 feet to $59\frac{1}{2}$ feet, inftead of $63\frac{1}{4}$; the difference is very fmall, and may be thus accounted for. The Birmingham engine, although feven horfes power, had only a twenty-inch cylinder, yet, according to our Table, it fhould be 20.6; its pifton therefore required to move rather quicker, in order to make an equal produce. Thus, the area of a twenty-inch cylinder is 314 fquare inches; and of a cylinder 20.6 diameter, it is 332 fquare inches: now as 314 fquare inches is to 332 fquare inches, fo is $59\frac{1}{2}$ feet *per* minute to 63 feet *per* minute, inftead of $63\frac{1}{4}$, which the engine actually moved.

The allowance for fuel in this Table is as fmall as it will ever be found to be in actual practice; the confumption of fuel is not in direct proportion to the power of the engine, becaufe fmall engines lofe more heat, and have more friction in proportion than large ones, and the reciprocations of the motion are more frequent. We have taken the effect of the twenty-horfe engine at twenty millions of pounds of water *per* minute, raifed one foot with each bufhel of coals weighing 84 lbs.; this makes the confumption of fuch an engine very near two bufhels *per* hour; an eight-horfe burns one bufhel. We have alfo taken the performance of the engine of 100 horfes at 30 millions, and made all the intermediate fizes by a regular law of increafe; the refult agrees fo well with feveral engines which we have obferved, that we confidered the Table as very correct. The quantities of coal are the fmalleft; fcarcely any engines will do with lefs fuel when they are working with their full load; but many engines will require more. Engines will be conftantly found which are of the dimenfions marked in our Table, and are called fo many horfe-power, although they are working with either a greater or leffer power than the Table expreffes; in fuch cafes, allowance of fuel muft be altered in proportion.

We have now gone through the defcription of thofe machines for raifing water which are actuated by the mechanical force of animals, or water or fteam acting externally by means of levers and other connecting mechanifm; but there are fome machines in which a current or a column of water is made to operate within clofe veffels, and raife water to a confiderable height: thefe are the Chremnitz fountain, the fypho interruptus, and the hydraulic ram. Thefe are moft admirable machines, particularly the laft, becaufe they are fo fimple, and having fcarcely any moving parts, are not liable to decay and injury; and they do not wafte the motive power in unneceffary friction and refiftance.

The original fteam-engines of the marquis of Worcefter and Savery, which are all of this clafs, are fully defcribed under the article STEAM-*Engine*. The wafte of fuel in thefe engines is fo great, that they fall very far below other engines. We have mentioned the engine made by Mr. Kier, which by a calculation will be found to raife only $2\frac{3}{4}$ millions of pounds of water one foot high with each bufhel of coals, and the power of the engine is $2\frac{3}{4}$ horfes. An engine of the fame kind, of five horfes power, which Mr. Smeaton calculated raifed $5\frac{1}{3}$ millions, end this is perhaps the utmoft of this kind of engines. Another engine of $2\frac{3}{4}$ horfe-power, raifed $5\frac{1}{4}$ millions. The beft engine on Newcomen's principle will raife 10 millions; Mr. Watt's 30 millions; and Mr. Woolf's 50 millions. From this ftatement, it is clear that the expence of fuel in Savery's engines is fo great as to counterbalance any advantages arifing from their fimplicity.

The Chremnitz Machine.—In this a column of water, defcending from an elevated refervoir, is made to raife up another column of water from a confiderable depth, and air is introduced as the medium for communicating the preffure of the motive column to that column which is to be raifed. This machine is not a new invention; its principle is fully defcribed in the Italian book, "Le Machine," by Brancas of Rome, 1629. A machine at Chremnitz, in Hungary, is fo celebrated as to have given a name to this invention from its fize, and the moft extraordinary formation of ice and fnow by the working of it, befides that it is the only one of the kind which had been applied to large works. An account was given to the Royal Academy at Paris by their correfpondent M. Jars, which is inferted in their memoirs for the year 1768; and Dr. Wolfe has alfo defcribed it. The machine was executed by father Hell, a profeffor of aftronomy at Vienna, in the year 1755; it is ufed to raife the water in a fhaft named Amalie, in the mines at Schremnitz, or Chremnitz, in Hungary: *fig.* 14. *Plate Water-*

ter-works, is a ſketch of this machine, in which the pipes are not drawn in the proportion of their lengths, but are contracted to the ſpace of the deſign. O is a wooden trough, placed in the middle of the mountain, 143 feet above the place, K, where the water drains off; this water is conveyed from the mines above it, and the fall of the water from this reſervoir works the machine. There is alſo another trough higher up the mountain, *viz.* 260 feet above the place of delivery K, into which rain-water is conveyed for the purpoſe of working the machine with 260 feet fall, when a ſupply can be obtained therefrom; but when this ſupply fails, the machine is worked by the ciſtern O with 143 feet fall. T is an iron-pipe deſcending from the reſervoir, to convey the water to an air-veſſel of copper, A, placed at the foot of the mountain near the place of delivery. The water from the reſervoir O, or from the more elevated reſervoir, flows through the deſcending pipe T, whenever the cock H is opened: the pipe T deſcends very nearly to the bottom of the veſſel A A, as ſhewn by the dotted lines X, with the intention that the air included in the veſſel ſhall be compreſſed when the water enters, and forced through the tube L M into a lower veſſel, B, which is ſimilar to A, but only of half the capacity; it is placed at the bottom of the lower mine, which is to be drained at 104 feet below the delivery K, and veſſel A; this lower veſſel receives the waters collected in this mine from the trough D, through the pipe Q and cock C, and by the force of the compreſſed air introduced into B by the pipe M from the upper veſſel; the water contained in B is expelled through the pipe S, which deſcends to the bottom of the veſſel B, and is diſcharged at F.

The wooden trough D is the termination of a trough or channel from another engine, which raiſes the water from a yet greater depth; K is a pipe with a cock for diſcharging the water out of the veſſel A, when the operation is over, in order to fill it again with air ready to repeat it, for which purpoſe the ſmall pipe I is likewiſe opened to admit air; the cock L tranſmits and diſcharges air from the upper veſſel A into the lower veſſel, through the pipe M. The little pipe E, and its turncock, muſt be opened to let out the air from the veſſel B, and it muſt remain open whilſt B is filling, by the water from the trough D, through the pipe C Q, and it is at the orifice of the little pipe E that ſnow and ice are generated. A valve is placed at the lower ends of the pipe F S, to prevent the water from eſcaping out of the pipe F S, after it has been raiſed, and whilſt the veſſel B is filling with freſh water.

The operation is performed thus: two men are placed at the veſſels A and B to open and ſhut the cocks; ſuppoſe all the cocks ſhut, and the reſervoir O, at 143 feet high, is always full; the pipe T H is alſo full as far as the cock H; the reſervoir D is kept conſtantly full of water from the mine, which is to be drained by raiſing the water from D to F, 104 feet; for this purpoſe, it muſt firſt be admitted into the veſſel B: the cock C is therefore opened, and the water flows into B, the air being at the ſame time ſuffered to eſcape from that veſſel by opening the cock E. The veſſel B is known to be full by the emiſſion of water at E, at which inſtant both the cocks C and E are to be cloſed. The machine is now prepared for the operation, which is began by opening the cocks H and L; the deſcending water from the reſervoir O enters the veſſel A, and compreſſes the included air till its elaſtic force becomes equal to the preſſure of the column of water D F, and then the air deſcends through the pipe M, and enters the lower veſſel B, where it preſſes on the ſurface of the water contained in the veſſel, and forces that water to aſcend through S to F, which opens into the adit, through which the water is diſcharged from the mine. This water being raiſed, the lower veſſel B is become filled with condenſed air in place of the water, and the upper veſſel A is become filled with water in place of the air. The cocks H and L are then ſhut, and K and I are opened; the cock K ſuffers the water contained in A to flow off, and I accelerates the diſcharge, by admitting the external air into the veſſel A; and both theſe cocks are cloſed again as ſoon as the evacuation of the upper veſſel is completed. During this laſt operation another man below opens the cock E, by which the condenſed air included in the veſſel B iſſues with great force through E; he then opens C, and the water from D again fills the veſſel B, as at firſt; this being done, he cloſes C and E.

The apparatus is now charged again ready for action, and by opening H and L the above operation will be repeated; *viz.* the contents of B will be forced up to F, and thus the engine may be kept continually at work as long as the two reſervoirs O at the top, and D at the bottom, are kept ſupplied.

The dimenſions of the principal parts, as given by father Hell, are as follow, in Hungarian meaſure:

The diameter of the upper veſſel A $32\frac{1}{2}$ inches; its height 60 inches; the thickneſs of the copper $1\frac{1}{4}$ inches.

The iron-pipe T is 260 feet; from H, to the moſt elevated reſervoir above O, it is $4\frac{1}{2}$ inches bore; and the thickneſs of the metal is $1\frac{1}{4}$ inches.

The lower reſervoir O 143 feet above H.

The pipe F S, 104 feet long, $3\frac{1}{2}$ inches bore.

The air-pipe L M is formed narrower towards the bottom; at its upper end it is two inches bore, and at its lower end 1 inch; thickneſs of the metal $1\frac{1}{4}$ inches.

The Chremnitz foot is to the Paris foot, as 1538 to 1440; the pound, as 106 to 92. The Paris foot to the Engliſh, as 32 to 30.

A cubic foot of water of the mine weighs 72 lbs.

The upper veſſel A contains $57\frac{1}{2}$ cubic feet, and the lower veſſel B $27\frac{1}{2}$.

Twenty-five cubic feet are raiſed at every operation, and ſometimes $31\frac{1}{2}$ feet, as the water deſcends from the upper or lower reſervoirs at O, the duration of the operation being different; for when the upper ciſtern O is uſed at 260 feet of elevation, 20 or 21 draughts are made in an hour; but when the lower ciſtern is uſed at 143 feet elevation, only 17 or 18 draughts *per* hour.

Each of theſe veſſels is caſt in three pieces, which are joined by flanches and ſcrews, with a ring of lead and another of leather placed between each to ſecure the joint, and prevent the tranſmiſſion of any fluid. M. Jars obſerves that the pipes would have been better if connected by flanches, in the manner ſhewn by the figure; but the real practice is to drive the ends of the pipes into hollow cylinders of dry wood, bound with iron hoops; theſe anſwer tolerably well, and are of conſiderable durability.

The moveable plugs of the cocks, C, E, K, are ſcrewed in their places by caps or covers faſtened down with ſcrews.

The produce of water raiſed by this machine is thus eſtimated by Dr. Wolfe:

If the veſſel A were completely emptied after each operation, the expence of water, when the fall of 260 feet is uſed, would be 1178.25 cubic feet in an hour, deſcending 206 feet; and the effect, or the water raiſed, would be 563.75 cubic feet to a height of 104 feet; or, when the fall of 143 feet is uſed, the expence *per* hour would be 1006.25 cubic feet, and the effect 481.25. But as it is not neceſſary that the veſſel A ſhould be much more than half emptied, the expence of water will be nearly equal to, or will not much exceed the quantity raiſed.

It

It ſhould follow, from experiments on the nature of air, that the column F D is counterpoiſed by the compreſſed air in the inverſe ratio of 104 to 32: hence the volume of air contained in the veſſel A and the pipe L M, equal to $58\frac{1}{2}$ cubic feet, muſt be reduced to 18 cubic feet, before the elaſticity will be equal to the preſſure of the column C F 104 feet; but by increaſing the compreſſion a little more, the water in B will be made to flow out through F.

If, at the moment the veſſel A is full of water, the cock H be ſhut, the water will continue to flow through F, until the air occupies a ſpace of 18 cubic feet in the veſſel B, and in the pipe L M; the elaſticity of the air will then be in equilibrio with the column F D, and the efflux of the water through F will ceaſe. In this manner, not above 17 cubic feet of water are evacuated at each draught, and $10\frac{1}{2}$ cubic feet are conſtantly left in the veſſel B.

But if the cock H is not ſhut the very moment that the veſſel A is full, the water in A will follow the air through L M, and, before it gets to the veſſel B, will raiſe one cubic foot more out of that veſſel. After the water from A enters into the veſſel B, the diſcharge at F will not be the water of B, but the water of A deſcending and aſcending again by a uſeleſs circuit, until H be ſhut; which being done, the water will continue to flow at F, until the remainder of $10\frac{1}{2}$ cubic feet is expelled from B by the air contained in it. The moment when the water from A has deſcended into the lower veſſel B may eaſily be known, by the velocity of the efflux at F becoming ſuddenly three times greater.

That this is actually the caſe is proved, becauſe ſometimes $31\frac{1}{2}$ cubic feet are diſcharged; which quantity exceeds the capacity of the veſſel B by more than 4 cubic feet.

This inconvenience might eaſily have been prevented, by giving to the pipe S a diameter of 18 inches; for then there would have remained only the juſt ſpace of 18 cubic feet for the compreſſed air.

The height of the column T to the loweſt of the two reſervoirs at O is 143 feet, which, taken upon the diameter of the veſſel A as a baſe, is equal to the weight of $822\frac{1}{4}$ cubic feet, and would compreſs the air into a fourth; or, when the water is deſcending into the lower veſſel B, into a ſeventh part of its natural ſpace, provided it were equally reſiſted at F. The veſſel A becomes filled at a mean in 8 ſeconds; and in twice that ſpace of time, 17 cubic feet are evacuated through F.

The power of the column of 260 feet from the moſt elevated reſervoir, acting within the veſſel A, is equivalent to the weight of 1495 cubic feet of water. It can raiſe a greater quantity, if the veſſel B be ſo conſtructed as to allow no more than a juſt ſpace to the compreſſed air. If the veſſel A were filled in 4 ſeconds, then 17 cubic feet of water would be diſcharged through F in twice that time, and the air would be reduced into an eighth, and, during the deſcent of the water of the veſſel A into the lower veſſel B, into an eleventh part of its bulk. But this makes no alteration as to the quantity of the effect; and when water ceaſes to flow out at F, there will always remain $10\frac{1}{2}$ cubic feet of water in the veſſel B.

Two men are required to attend it, but it would be very eaſy to connect the levers of the cocks above and below, ſo as to require only one man to work the whole ſet; and indeed there would be little difficulty in making the machine work itſelf ſafely, without any attendant, except to ſet it off at firſt, or ſtop it when requiſite. The machinery for this purpoſe has been propoſed by Mr. Boſwell. See Nicholſon's Journal, 4to. iv. 117.

From what has been ſaid, it is evident that this machine, though it anſwers the author's intention, is ſo deficient as to the effect the ſame fall of water might produce, as to bear ſcarce any proportion; and there is a defect in the principle of the machine, *viz.* that the air will require a conſiderable ſhare of the power to compreſs it, and this air muſt be ſuffered to eſcape, before the veſſels can be refilled to repeat the action; in conſequence, all the power taken to compreſs the air is loſt, and expands itſelf in forcing out a ſtrong blaſt of air at the diſcharging cock, without producing any uſeful effect. Notwithſtanding this defect, the cheapneſs and eaſe of conſtruction, and the little wear and tear, together with the facility with which it may be made to work and ſtop for very ſhort periods of time, are powerful recommendations of this machine, in ſuch places as afford the requiſite fall of ſuperior water, and do not require a higher ſingle lift than 15 or 20 fathoms.

A curious phenomenon has been obſerved in this machine, when it is near the end of its operation, that is, when nearly the whole of the water has been raiſed out of the lower veſſel B, and the cock E be opened to give vent to the compreſſed air, and before the cock L is ſhut, ſo that the air is followed up by the water, then if a hat or miner's bonnet be preſented to the aperture E, the aqueous vapours diſperſed through the compreſſed air, and perhaps alſo, ſays M. Jars, part of thoſe of the external air are condenſed in the bonnet in the form of very white and compact ice, very much reſembling hail, and not eaſily ſeparated from the bonnet. It ſoon melts, which is not to be wondered at, as the temperature of the place itſelf is not cold. Meſſrs. Du Hamel and Jars remained in Hungary from January to July 1758, and obſerved the ſame phenomenon at all ſeaſons; but as they had no thermometer, they could not make a number of experiments, which might have been of value in the inveſtigation of the ſubject.

It is obſerved that the air iſſues out with ſuch impetuoſity, that the workman could not hold the bonnet at the diſtance of a few inches from the aperture, as he does in this experiment, if he were not ſupported behind. The ice is much more compact, if the cock be only in part opened.

When the cock at which the air is diſcharged is opened, it ruſhes out with prodigious violence, and the drops of water are changed into hail or lumps of ice. It is a ſight uſually ſhewn to ſtrangers, who are deſired to hold their hats, to receive the blaſts of air: the ice comes out with ſuch violence as frequently to pierce the hat like a piſtol bullet. This rapid congelation is a remarkable inſtance of the general fact, that air, by ſuddenly expanding, generates cold; its capacity for heat being increaſed.

The formation of the ice and ſnow, when the condenſed air ruſhes out of this machine, has been explained in a different way in almoſt every ſyſtem of philoſophy. It appears to us to be a neceſſary conſequence of the condenſed air, on ruſhing out into the open air.

The air of the atmoſphere, and the water when taken into the machine, are nearly of the ſame temperature; and it may be conſidered that each cubic foot of water and of air contains ſome certain quantity of heat or caloric; but they will readily impart a portion of this heat to any body containing a leſs degree than themſelves, or they will abſorb or take up heat from any body containing a greater proportion of heat than themſelves, in conſequence of that property of heat, by which it will diſtribute itſelf equally among all bodies which are in contact with each other. By the action of the machine, the air is compreſſed into one-third of the ſpace it before occupied, and the ſhare of heat contained in that air is likewiſe concentrated or thrown into a third of the ſpace, and in conſequence becomes more intenſe. Some part of the

the heat will, therefore, be communicated to the ſurrounding water, until the heat diſtributes itſelf again between the water and the condenſed air, ſo that they come to the ſame temperature. In this ſtate, if the air is ſuffered to ruſh out of the veſſel, it will ſuddenly expand and recover its former volume, and it muſt alſo recover its former ſhare of caloric, which it can only do by abſtracting heat from the ſurrounding air, or from any ſubſtance with which it comes in contact: hence the coldneſs of the blaſt of air. In reſpect to the formation of ſnow and ice, it muſt be conſidered that the air of damp places always contains a conſiderable portion of water in a ſtate of vapour, and the air in this machine will have taken up more than the ordinary ſhare, in conſequence of being in contact with the water. When the air expands itſelf, the heat being ſuddenly abſtracted from this watery vapour, it becomes fluid, and accumulates in drops like rain; which drops, by a farther abſtraction of heat, become ſolid like ſnow or hail.

An inſtrument which is in common uſe to produce fire, by the ſudden compreſſion of air, ſhews the reverſe of this action: it is a ſyringe fitted with a piſton, which is air-tight; at the bottom of the barrel a ſmall piece of tinder is placed. Now, if the piſton is very violently and ſuddenly forced down to the bottom of the barrel, and the piſton is then withdrawn, the tinder will be found on fire. The heat contained in the air which fills the barrel is ſo concentrated at the ſame time with the air, as to produce actual fire. If the piſton is forced ſlowly down, the air will be condenſed to an equal degree, but no fire will be produced, becauſe the heat has time to eſcape through the metal of the barrel, before it arrives at any conſiderable degree of concentration. We conſider that in all caſes when air (and perhaps other elaſtic fluids) is compreſſed into a ſmaller ſpace, part of the heat it before contained will be given out to the ſurrounding matter; or if it is ſuffered to expand to fill a larger ſpace, it will abſorb or take up heat from the ſurrounding matter.

A larger Machine at Chremnitz.—This does not differ from the original machine, ſo as to require a minute deſcription; but as this machine is not employed in England, and we think it might be uſeful in many caſes in mining diſtricts, we ſhall give the proportions and calculations of a larger machine, as a model for engineers.

	Feet.
Height of the ſource above the place of delivery or fall of water, which is to work the machine: deſcending pipe 4 inches bore	136
Depth from which the water is to be raiſed out of the pit to the place of delivery: aſcending pipe 4 inches bore	96

	Cubic Feet.
Upper veſſel a copper cylinder 5 feet diameter, and 8½ feet high; metal 2 inches thick; the deſcending pipe goes to within 4 inches of the bottom: contents	170
The lower veſſel a braſs cylinder 4 feet diameter, and 6½ feet high; metal 2 inches thick; the aſcending-pipe goes within 3 inches of the bottom: capacity	83
Air-pipe which communicates between the two veſſels, 2 inches bore, and 96 feet in length	

To underſtand the action of this machine clearly:—Suppoſe that the lower cylinder is charged with water, and the upper cylinder with air ready for action; when the water from the ſource is admitted into the upper cylinder, if no iſſue was given to the contained air, the water would enter into the veſſel, until the air was compreſſed into one-fifth of its bulk by the column of 136 feet high; for a column of 34 feet nearly balances the ordinary elaſticity of the air. But when there is an iſſue given to the air through the air-pipe, it will drive the compreſſed air along this pipe, and it will expel water from the lower cylinder.

When all the air is expelled from the upper cylinder, there will be 34 cubic feet of water expelled from the lower cylinder. Now if the aſcending pipe had been carried up more than 136 feet above the lower level, inſtead of 96 feet, then the water would have riſen 136 feet high in that pipe, by the intervention of the elaſtic air, before it was in equilibrio with the water in the deſcending pipe; but no more water would have been expelled from the lower cylinder than what would fill this pipe.

But the aſcending pipe being only 96 feet high, the water will be thrown out at the top of it with a conſiderable velocity. Were it not for the great obſtructions which the water and air muſt meet with in their paſſage along the pipes, it would iſſue from the mouth of the aſcending pipe with a velocity of more than 50 feet *per* ſecond. It iſſues, however, much more ſlowly.

When the upper cylinder is become filled with water, the ſupply is ſtopped; but the lower cylinder ſtill contains 34 cubic feet of compreſſed air of ſufficient elaſticity to balance the water in a diſcharging-pipe 136 feet high, whereas the aſcending-pipe is only 96 feet. Therefore the water will continue to flow at the mouth of the aſcending-pipe till the compreſſed air is ſo far expanded as to balance only 96 feet of water, that is, until it occupies one-fourth of its ordinary bulk, or one-fourth of the capacity of the upper cylinder, *viz.* 42½ cubic feet. Therefore 42½ cubic feet of water will be expelled, and then the efflux will ceaſe, leaving the lower cylinder about one-half full of water.

When the diſcharging-cock of the upper veſſel is opened the water iſſues with great violence, being preſſed by the condenſed air returning from the lower cylinder. It therefore iſſues with the ſum of its own weight, and of this compreſſion. Theſe gradually decreaſe together, by the efflux of the water and the expanſion of the air; and this efflux ſtops before all the water in the upper veſſel has flowed out, becauſe there are only 42½ feet of the lower cylinder occupied by air. This quantity of water nearly will therefore remain in the upper cylinder. The workman knows this, becauſe the diſcharged water from the upper veſſel is received firſt of all into a veſſel containing three-fourths of the capacity of the upper cylinder, which ſerves as a meaſure; when this is filled, the attendant opens the cock which admits the water into the lower veſſel, by a long rod which goes down the ſhaft: this allows the water of the mine to fill the lower cylinder, and the air returns into the upper cylinder through the air-pipe, and permits the remaining water to run out of it; and when the attendant finds no more water will come out, every thing is brought to its firſt condition.

The above account of the procedure in working this engine, ſhews that the efflux at the mouth of the aſcending-pipe becomes very ſlow near the end. On this account, it is found convenient not to wait for the complete diſcharge, but to cut off the ſupply when about 30 cubic feet of water have been diſcharged, and more work is done in this way.

A gentleman of great accuracy and knowledge of theſe ſubjects, took the trouble of noticing particularly the performance of the machine. He obſerved that each ſtroke, as it may be called, took up about three minutes and one-eighth, and that 32 cubic feet of water were diſcharged, and 66 cubic feet were expended.

The expence therefore is 66 cubic feet of water falling

136

136 feet, and the performance is 32 cubic feet raifed 96 feet, and they are in the proportion of 66×136 to 32×96, *viz.* 8976 to 3072, that is the power employed is to the effect produced, as 2.9 to 1. The quantity raifed, *viz.* 32 cubic feet, divided by the time $3\frac{1}{8}$ minutes, gives very nearly 10 cubic feet *per* minute, and multiplied by the height raifed 96 feet = 960 cubic feet raifed 1 foot high. Divide this by 528 cubic feet, which is the horfe-power, and it gives 1.8. The machine is not therefore equal in effective power to a fteam-engine of two-horfe power, but the power employed is juft equal to five-horfe power.

When we confider the great obftruction which water meets with in its paffage through long pipes, we find we may gain fome advantage by increafing the bore of the defcending-pipe of fupply. The quantity of water which defcends through this is 66 cubic feet in $3\frac{1}{4}$ minutes, or very nearly 30 cubic feet *per* minute; the area of the four-inch bore is 12.5 fquare inches, and therefore 11.5 fuch areas would make a fquare foot. Multiply 30 cubic feet by 11.5, and we have 345 feet, which is the velocity with which the water muft defcend in the pipe. This is much too great, and it would be an improvement if the pipe was increafed to fix inches bore, and the velocity would then be only 151 feet *per* minute. The performance of the machine would then be greatly increafed, we think as much as one-third; it is true that it would expend more water, but not in the fame proportion; for part of the deficiency of this machine arifes from the needlefs velocity of the water in the pipe, as well as from the violent efflux of the water by the condenfed air, as we have before mentioned.

The difcharging-pipe ought to be 110 feet high inftead of 96, and would not give fenfibly lefs water. It muft be confidered if the original expence of this fimple machine would not be lefs than a water-mill which would raife 10 cubic feet of water, 96 feet high, in a minute; the repairs of it would be fmall when compared with a mill. And, laftly, let it be noticed, that fuch a machine can be ufed where no mill whatever can be put in motion.

A fmall ftream of water, which would not move any kind of wheel, will raife one-third of its own quantity to the fame height, working as faft as it is fupplied.

From its fimplicity, we think the HUNGARIAN *Machine* (which fee) eminently deferves the attention of mathematicians and engineers, to bring it to its utmoft perfection, and into general ufe. There are many fituations where this kind of machine may be very ufeful. Thus where the tide rifes 17 feet, it may be ufed for compreffing air into feven-eighths of its bulk, and a pipe leading from a very large veffel inverted in the tide-water may be ufed for raifing water from another veffel of one-eighth of its capacity, 15 feet high; or if this veffel has only one-tenth of the capacity of the larger one fet in the tide-way, two pipes may be led from it, one into the fmall veffel, and the other into an equal veffel, 16 feet higher, which receives the water from the firft. Thus one-fixteenth of the water may be raifed 34 feet, and a fmaller quantity to a ftill greater height, and this with a kind of power that can hardly be applied any other way.

Sipho Interruptus to raife Water by Suction.—This machine is the reverfe of the Chremnitz machine in its action, for the power of a defcending column of water, running out of a clofe veffel, caufes a vacuum therein; and another column of water is fucked up into the veffel, or rather forced up by the preffure of the atmofphere to fill the vacuous fpace. This machine is fully defcribed by Leopold, in his Theatrum Machinarum Hydraulicarum, vol. i. It is provided with apparatus to open and fhut the cocks. It would be difficult to explain this machine without feveral figures, and we have therefore preferred to defcribe a machine of the fame kind invented by Mr. Goodwin; he calls it a machine that will raife a body of water to any height not exceeding the height of that column which will counterbalance the preffure of the atmofphere, (fay 30 feet) and acts by the defcent of part of the fame body of water through a fomewhat greater height, aided by the preffure of the atmofphere.

Let A, *fig.* 10, *Plate Water-works*, be a fpherical veffel of copper or other metal, about 18 inches diameter; B, another fphere, about two feet fix inches in diameter; C, a refervoir kept conftantly fupplied with water, part of which is to be raifed up to E, by the power of another part defcending to a confiderable depth beneath the refervoir C. D is a glafs cap, about fix inches long, fixed on the top of the upper veffel A, for the purpofe of feeing when the water begins to fill and has filled it; E is the upper refervoir into which the water of the refervoir C is to be elevated, and the contents of the upper veffel A is to be emptied; 1 is a pipe about half an inch in diameter, joined into the top of the lower veffel B, and rifing upwards to within about an inch of the top of the glafs cap D of the upper veffel; 2 is a pipe of the fame diameter, and a few feet longer than 1, 1, joined to the bottom of the lower veffel B, and defcending downwards in a perpendicular or inclined direction, to a rather greater diftance beneath C than the upper veffel A is elevated above C; 3 is a pipe one inch and a half in diameter, joined to the bottom of the upper veffel A, and paffing upwards through the bottom to within two inches of the top of the glafs cap D; 4, 4, is a pipe of about half an inch diameter, joined to the top of the veffel B, it paffes through the bottom of the refervoir C, and rifes above the furface of the water therein; 5 is a pipe of the fame diameter, fixed to the top of the veffel B, and terminating in and fixed to the bottom of the refervoir C; *a* is a pipe or fpout of the fame diameter, fixed into the bottom of the upper veffel A, to convey the water into the refervoir E; 7 is a trumpet mouth-pipe fixed to the bottom of the pipe 3, and extending downwards beneath the water to within about an inch of the bottom of the refervoir C; *a*, *b*, *c*, and *d*, are cocks fixed to the pipes. The veffels, pipes, cocks, and joints, muft all be air-tight.

In order to raife water from the lower refervoir C into the upper refervoir E, all the cocks being fhut proceed thus: open the cocks *b* and *c*, in order to fill the lower veffel B, and when B is filled, fhut the cocks *b* and *c*, and open the cock *d*. The water will then begin to run from the fphere B by its gravity, and by means of its communication with the upper fphere A, through the pipe 1, will draw off the air therefrom to fupply the fpace left in the lower veffel B, by the running out of the water the air in A is thus rarefied. The atmofpheric air at the fame time preffing on the water in the refervoir C, will caufe it to rife through the trumpet-mouth 7 of the pipe 3, and by falling over the top of the pipe 3 at D, it will fill the upper fphere A. When A is full, which may be feen through the glafs cap D, fhut the cock *d*, and open the three cocks *a*, *b*, and *c*, the cock and pipe *b* will allow the atmofpheric air to return into the veffel, and fill both with air, by which means the water contained in the veffel A will run into the elevated refervoir E, and B will be replenifhed for another operation. Then fhut the cocks *a*, *b*, and *c*, and open the cock *d*, and it will repeat the operation of raifing the water into A.

If it be required to raife any body of water from refervoir C into refervoir E, by means of the defcent of a body of fome other water from the veffel B, a communication muft be made into B, independently of the pipe 5, and

 cock

cock *c*; *viz.* through a pipe-cock leading from another refervoir, as is reprefented by the dotted lines communicating with B near the pipe and cock 5; the action is the fame as before; but the cock with the dotted lines is to be ufed in lieu of pipe 5, and cock *c*. By this means, if the water which is employed to work the machine is foul or tainted, it will have no communication with the water which it raifes. This machine has the fame defect as the Chremnitz machine; *viz.* that the power which is expanded in rarefying the air is greater than the quantity of water raifed, and the difference is loft when the cock in the lower veffel is opened, and the air rufhes in.

A different Form of the Siphon Machine.—Mr. Goodwin's engine is formed upon a very elegant principle, and operates by the affiftance of only a fmall quantity of water. It may be made in various forms, either to raife the fluid above the defcending column, or from below it to a level with the bottom, and the height may be doubled or trebled by proportionally increafing the defcending mafs, and raifing feveral columns of water from different elevations at the fame time, by combining two or more of the fimple machines together, as is fhewn in *fig.* 8. *Plate Water-works.*

C, as in the former figure, reprefents the refervoir or fource of water which is to work the machine; B reprefents the loweft of the two veffels which contain the rifing and defcending bodies of water; and the fmall fquare near *fig.* 8. reprefents the upper veffel A, *fig.* 10. Thefe veffels are fpherical in the original drawing, but to leffen the lofs of fpace in defcent, they are here made flat and cylindrical; E is the higher ciftern of the original figure, into which the water is to be raifed; 2, 3, and 4, are the pipes arranged in the fame manner as the former machine; F, a veffel the fame as A, with tubes 3 and 6: it communicates with the veffel B by a pipe, and is intended to raife water out of the ciftern E into a higher and additional ciftern G.

The veffels E, F, and G, form a fecond machine, which has the fame parts and properties as the former, except that the lower veffel B is common to both, and ferves as the lower veffel to exhauft and drive up the water both to A and to F; 2 is an enlarged tube like the original drawing, through which the water defcends to produce the action; 5 is a hole in the top of B, inftead of a tube. This hole, and the tubes 2, 4, and 6, muft be provided with valves inftead of cocks, which muft be kept clofe by weights or fprings, (while the water is rifing) except the valve to tube 2, which muft be open. The tubes 3, 3, may alfo have valves to fupport the raifed columns.

Operation.—Fill the cifterns C and E with water, and let the lower ciftern be conftantly fupplied; open the valves of the tubes 4, 5, 6, 6, and clofe the valve of the defcending-tube 2, the veffel B then becomes filled through the hole 5. Now clofe the valves of the tubes 4, 5, and 6, and open the valve of the tube 2, the water will then begin to defcend out of B, and will exhauft the air from A and F, juft as in the firft-mentioned machine; the preffure of the atmofphere on the furface of the water C, will raife one body of water out of C into A, and out of E into F; when B is nearly empty, or when A and F are full, open the tubes 4, 5, 6, 6, and clofe 2, then B will be filled a fecond time, and the veffels A and F will empty themfelves into their refpective cifterns E and G: thus the reciprocations continue without interruption.

Another body of water may be raifed out of G into a higher ciftern by additional apparatus, and by proportionally increafing the dimenfions of the veffel B and the tube 2. The dotted lines reprefent the apparatus for raifing water below the bottom of the tube 2, to be ufed inftead of thofe above the ciftern C.

This arrangement of the engine is of great utility in many cafes; and in fituations where this machine can be erected, it may be of confiderable ufe for raifing water out of mines for draining pieces of land, or elevating the water employed in domeftic purpofes.

Comparifon of different Preffure-Engines.—In Mr. Nicholfon's Journal, 8vo. vol. i. Mr. Bofwell has given a plan for conftructing Mr. Goodwin's engine on a large fcale, to operate without attendance of any perfon, to open and fhut the cocks, and another method of caufing the Chremnitz machine to raife water above the level of the prime refervoir; and he makes the following comparative view of the advantages of both kinds of engines and their powers.

It will be found that the powers and capabilities of thefe machines are nearly fimilar. 1ft, In both the greater the height of the original fall of water from the fource to the difcharge, and the greater the quantity of water which it can fupply in a given time, the greater quantity can be raifed by either of thefe engines in a given time. 2dly, Both engines can be conftructed fo as to raife water above the original level, and from below, to the furface, or from a pit. 3dly, By a fucceffive number of refervoirs, both engines can be brought to raife water to any height, but as they will raife a fmaller quantity as the height is increafed, the quantity wanted in a given time, and the expence of conftruction, will limit the extent of their elevation. 4thly, In both engines the diftance of one refervoir from another muft always be lefs than that of the original fall: the circumftances in which thefe engines differ arife from the difference in their manner of action. 5thly, The Chremnitz engine operates by caufing a fall of water to comprefs the air, which reacting on other water, forces it to rife in a pipe to a certain height. The fyphon engine acts by caufing a fall of water to rarefy a certain quantity of air, in whofe fpace the preffure of the atmofphere forces a quantity of water when permitted. 6thly, Hence in the Chremnitz engine the preffure acting from within outwards tends to burft the veffels ufed in the ftructure, and to open and extend any fiffures which may chance to be in them. 7thly, In the fyphon engine, the preffure acting from without inwards, clofes all the parts of which it is compofed more together. 8thly, The Chremnitz engine will always raife water of a height nearly equal to that of the original fall from one refervoir to another, fuppofing the original fall of any height whatfoever as 100 feet. The fyphon engine will not raife water by one refervoir fo high as thirty feet in any cafe whatfoever, as there cannot be a complete vacuum formed by it in the air-chamber, but only an approximation to one.

From this comparifon, it will follow that wherever the original fall of water is lefs than thirty-two feet, the fyphon engine will be much preferable to the Chremnitz, as from the feventh article of the comparifon it may be made of the cheapeft materials, fuch as ftrong wooden cafks and wooden pipes, whereas the Chremnitz engine from the fixth article muft be made of the ftrongeft, and of courfe the moft coftly materials, as metal, and that of confiderable thicknefs; but wherever the original fall exceeds the height of thirty feet confiderably, and it is required to raife the water to nearly the fame height, then the Chremnitz engine appears to be preferable, as, in all probability, the fewer number of parts which it will require in this cafe will more than compenfate for its coft in materials.

When it is required to raife water to a height much greater than that of the original fall above the firft level, or from a greater depth, either from the original fall being fhort, or the

the required height being great, it is better to employ an engine in which the preſſure of the water is made to act by a piſton in an apparatus ſimilar to that of a ſteam-engine. (See our article PRESSURE *Engine.*) When neither the ſyphon engine nor the Chremnitz can be uſed without a number of reſervoirs, then the piſton preſſure-engine ought to be preferred, but this will much depend on the number of reſervoirs; for perhaps one or two in addition to the Chremnitz might coſt leſs than boring the cylinder of the piſton-engine perfect, and conſtructing its additional machinery. For merely raiſing water the powers of each are nearly equal, depending entirely on the height of the original fall of water.

It would be a great advantage of the piſton-preſſure engine if a fall of water could be applied to it without any waſte, to work mills or machinery for any purpoſe; this would be of very great conſequence when the fall of water is of conſiderable height, and the ſtream or ſupply ſmall. We have mentioned the advantage in this engine to have its action made elaſtic, by the addition of an air-chamber, on the ſame principle as that uſed in engines for extinguiſhing conflagrations. Mr. Boſwell ſuggeſts that this might be effected by making the piſton hollow, and of a larger ſize, to contain air for this purpoſe, as the air's elaſticity would then act both on the upper and lower preſſure of the water.

Machine for raiſing Water by the lateral Communication, from the Motion of a Stream of Water running through a conical Tube.—This machine operates by ſuction, or more properly by the preſſure of the atmoſphere, and is in ſome reſpects ſimilar to the ſyphon machine. (See *fig.* 9. *Plate Water-works.*) A A repreſents a reſervoir of water kept conſtantly full, at the ſame time that the conical ſpout, B, is running full under a conſiderable preſſure; D, a ſpherical copper veſſel, with a tube, C, joined into its bottom, and riſing up within to ſome height above the centre of the ſphere; E, another tube joined to the bottom of the ſphere D, and terminating near its top; the lower part of this tube is bent, and the extremity of it is introduced into the ſmaller apertures of the conical tube B; F, a ſpout or tube to empty the veſſel D, when it is filled with water which has been raiſed up out of the reſervoir A; G, a ſmall tube paſſing through the ſpout F, and riſing to near the top of the ſphere, D, for the admiſſion of air to quicken the deſcent of water out of that veſſel. Both theſe tubes are cloſed at their lower ends by a leather valve at the end of the lever L, which lever is fixed upon the turning plug of a cock in the tube E, and has a weight upon one end, in order that the other end may bear the valve up againſt the openings of the tubes F, G, with a conſiderable force, and alſo to ſupport the weight of the ſmall bucket I, which is ſuſpended from the lever by a wire (at leaſt when the bucket is empty); H is a ſmall ciſtern to be filled with water from the reſervoir A, in the ſame time that the water is raiſed up into D; this muſt be done by regulating the cock, *k*, upon the pipe which ſupplies the ciſtern with water. The ciſtern H is provided with a ſyphon, which will begin running as ſoon as the veſſel is full of water, and will ſoon empty it. The ſmall bucket I, which is ſuſpended from the lever L, is alſo furniſhed with a ſyphon-tube, which will begin to run and empty the bucket whenever it is quite full, but not before.

The operation of the engine will be as follows:—The reſervoir A being kept conſtantly full of water, and the conical tube B completely filled at its wider end by the water which runs out of A, the force of the lateral motion of the fluid will be increaſed by the conical form of the tube B, and will act upon the end of the tube E to draw air out of the ſame, ſo as to rarefy the air in the veſſel D; and the preſſure of the atmoſphere upon the ſurface of the water in the reſervoir A, will cauſe part of that water to riſe up the pipe C, to run over its top and fill the ſphere D; it will then deſcend through E, and join the ſtream of water which flows out at B. When the veſſel D is full of water, if the valve at the ſpout F is opened, the water will run out.

In order to open the valve the cock *k* is regulated, that the ciſtern H will be filled ſoon after D is full, and the ſyphon of this ciſtern beginning to empty the water it fills the bucket I, which then overbalances the weight upon the lever L, and opens the ſpout F, and air-pipe G, and at the ſame time cloſes the cock in E; the column of water in the deſcending pipe C immediately deſcends into the reſervoir, and if the ſmall tube G be full of water it will be emptied by the deſcent of that column, and will admit air into D ſo as to allow the water to flow out at F into the elevated reſervoir. The ſyphon in the ciſtern H is regulated ſo that the ciſtern and the veſſel D will be empty of water about the ſame time, and the bucket I by its ſyphon will become empty ſoon after: the weight upon the lever L will then cloſe the ſpout F, and open the paſſage through E, when all the parts will ſtand as at firſt ready for a repetition of the operation of the lateral action of the ſtream, by which the water is raiſed up into D as before.

If the water ſhould deſcend through E before F and G are opened, it will render the cock in E more tight. To quicken the reciprocation of the engine, and increaſe the quantity of raiſed water, a valve may be made to ſupport the column of water in the ſuction-pipe; this valve may be placed in a cheſt at the bottom of the pipe.

The deſcending branch of the ſyphon in the higher veſſel H ſhould be made of conſiderable length, to prevent a conſtant dripping, and make the reciprocation end at once; the ſyphon of the bucket I ſhould fall as large in bore as the other, in order that the weight on L may preponderate quickly, and cloſe the valve immediately.

The inventor entertains no doubt reſpecting the operation of a machine of this kind, and that a column of water may be raiſed to any height not exceeding thirty feet by proportionally increaſing the preſſure of water in the reſervoir, and the dimenſions of the conical tube.

In many ſituations, however, the requiſite quantity of water for this purpoſe cannot be had, and others may not admit of ſufficient deſcent.

Where the ſtream has a conſiderable deſcent, the water may be raiſed by a number of lifts inſtead of one, by combining as many machines. Suppoſe three reſervoirs each with its conical tube or ſpout through which the water runs from one to the other; alſo three exhauſting veſſels each with its elevated ciſtern into which the raiſed water is to be delivered; and the ſuction-pipe of each veſſel draws its water from the elevated ciſtern of the veſſel below it. From each exhauſting veſſel a pipe is conveyed to the conical ſpout of one of the three reſervoirs, and the lateral motion of the ſtream paſſing through the ſpouts of the three reſervoirs will act upon all three engines at once.

In like manner, when there is plenty of water, but not convenience for a deep reſervoir, ſeveral conical ſpouts may be fixed to different parts of the reſervoir, and all upon the ſame level. Each machine muſt be provided with a lever and weight to work its own valves, but they may be all opened at the ſame time by the deſcent of one veſſel connected with all the levers, or each may have its reſpective bucket and ſyphons.

This kind of machinery, by altering the poſition of the rarefying tubes, may be made to raiſe water from a depth below the ſtream equally as well as to a height above it; and

in

in fituations where there is plenty of water and convenience for a refervoir a lower body of water may be conveyed into a ftream above by the help of a fingle tube, one end of which is placed in the water to be raifed, and the other muft be introduced into the fmaller aperture of the conical tube adapted to the refervoir; a conftant ftream will then rife, fo long as water below can fupply the tube.

Mr. Whitehurft's Machine for raifing Water by its Momentum.—Fig. 7, Plate Water-works, is a reprefentation of the firft machine on this principle, which was executed in the year 1772, by the ingenious Mr. John Whitehurft, at Oulton in Chefhire, at the feat of Mr. Egerton, for the fervice of a brew-houfe and other offices, and which purpofe it was found to anfwer effectually. This firft form of the momentum machine would be a ufeful application in many fimilar fituations. The circumftances attending this waterwork are as follow: A reprefents the fpring, or original refervoir, which fupplies the water, the upper furface coincides with the horizontal line B C, and the bottom of the refervoir K, into which the water is to be raifed; D is the mainpipe, one inch and a half in diameter, and nearly two hundred yards in length; E, a branch-pipe, of the fame dimenfions, for the fervice of the kitchen-offices. It is to be obferved, that the kitchen-offices are fituated at leaft eighteen or twenty feet below the furface of the refervoir A; and that the cock F is about fixteen feet below it. G reprefents a valve-box, and g the valve within it; H is an air-veffel, and O, O, are the two ends of the main-pipe, inferted into the air-veffel H, and bending downwards, fo that in effect the pipes communicate with the loweft part of the veffel, and the air cannot efcape when the water is forced into it, but it muft be compreffed by the column of water; W is the furface of the water in the air-veffel. It is well known from theory that, when water is difcharged from an aperture, under a preffure of fixteen feet perpendicular height, it will move at the rate of thirty-two feet in a fecond; the velocity of the water from the cock F will be nearly as much, making fome allowance for friction and refiftance; and although the aperture of the cock F is not equal to the diameter of the pipe D, yet the velocity of the water contained in the pipe will be very confiderable; confequently when the cock is opened a column of water two hundred yards in length is put into motion, and if it is fuddenly ftopped by the fhutting-cock F, its momentous force will open the valve g, and condenfe the air in veffel H; this action will be repeated as often as water is drawn from F. It is needlefs to fay in what degree the air is thus condenfed in the inftance before us; but it will be fufficient to obferve, that it was fo much condenfed as to force the water up into the refervoir K, and even to burft the veffel H, in a few months after it was firft conftructed, although it was apparently very firm, being made of fheet-lead, about nine or ten pounds weight to a fquare foot. Whence it is reafonable to infer that the momentous force is much fuperior to the fimple preffure of the column in the refervoir K, above the level line C B, and therefore equal to a greater refiftance (if required) than a preffure of four or five feet perpendicular height. It may be neceffary farther to obferve, that the confumption of the water in the kitchen-offices is very confiderable, becaufe water is frequently drawing from morning till night all the days of the year.

From this account which is publifhed in the Philofophical Tranfactions for 1775, it is clear that Mr. Whitehurft was fully aware of the power of the momentum of running water, and though he applied it only to raife water to a fmall height, he knew it might be carried to a greater extent.

Montgolfier's Hydraulic Ram.—We have given the account of Mr. Whitehurft's machine, becaufe it fhews the firft origin of a moft valuable invention, which was afterwards practifed in France by M. Montgolfier, the inventor of the firft balloon with heated air. Mr. Boulton took a patent in England for Montgolfier's machine in 1797; he afterwards called his machine *belier hydraulique*, that is, hydraulic ram, becaufe of the fhock which the water makes when its motion is fuddenly ftopped. In his publication in the Journal des Mines, vol. xiii. he fays, "This invention is not originally from England, but belongs entirely to France; I declare that I am the fole inventor, and that the idea was not furnifhed to me by any perfon. It is true that one of my friends, with my confent, fent to Meffrs. Watt and Boulton copies of feveral drawings of this machine with a detailed memoir on its applications. Thefe are faithfully copied in the patent taken out by Mr. Boulton in England, dated December 13, 1797, as that gentleman has avowed." We do not wifh to detract from the merit of M. Montgolfier, as we believe that Whitehurft's machine was unknown to him, but we muft ftate the hydraulic ram an Englifh invention. To have an idea of this invention, it is proper to ftate its phyfical principle of action, which is as follows.

When water is running with a rapid current through a pipe or clofe channel, if the end at which the water iffues be fuddenly ftopped, the water (by its acquired motion, momentum, or impetus,) will act upon the fides or circumference of the pipe, and endeavour to efcape with a force proportioned to its quantity and velocity. If the materials of the pipe are ftrong enough to refift that impetus, the water may be made to iffue with violence and velocity, at any aperture which is opened in or near the clofe end of the pipe; therefore if an afcending pipe be joined to that aperture, a portion of water will afcend in it. The machine being provided with proper valves, to prevent the return of the water fo elevated, the operation may be repeated in a conftant fucceffion, and will form a kind of perpetual pump.

The fame effect will be produced by a different arrangement of this apparatus, *viz.* a pipe open at both ends, with a valve and afcending-pipe, fuch has as been defcribed. Let this be fo attached to fome kind of machinery, that it can be fwiftly moved along, in the direction of its length, through ftanding water; then, upon clofing the hinder part of the pipe fuddenly, a portion of water will be forced up in the afcending-pipe, in the fame manner as in the former cafe, and for the fame reafon, becaufe the water will be relatively in motion with refpect to the pipe.

The fame principle may be readily extended to raife water by fuction from a lower level than that on which the machine is placed, and this by either of the means abovementioned. Suppofe a fuction-pipe, which communicates with water at a lower level, be joined to the main-pipe through which the water flows, and that the junction is near that end of the pipe where the water enters into it. Suppofe alfo that the water has acquired a rapid motion through the pipe, either by the current of water running through the pipe, or by the pipe moving through the water; then let the mouth or end at which the water enters be fuddenly fhut by the machinery, and the water by its momentum will continue its motion relatively to the pipe, and will tend to exhauft the content of the pipe. This action will draw or fuck up water through the afcending-pipe from the lower level, fo as to fill up the vacuity in the main-pipe, occafioned when the water therein perfeveres in its previous motion.

The

The firft aud moft fimple hydraulic ram is fhewn in fection at *fig*. 4. (*Plate Water-works*); here C C reprefents the main-pipe, or body of the ram, through which the ftream of current water is conducted; D, the afcending-pipe provided with a valve of exit at A, to allow the paffage of the water which is raifed, but to prevent its return; B is a ftop-valve to clofe the end of the main-pipe; E is a balance-weight fixed upon the lever G, which communicates with another, K, attached to the axis of the ftop-valve B; this weight tends to open the valve at the proper time. The main-pipe is to be fituated in a current or ftream of water, either produced by the natural current or declivity of a river or other ftream, or by penning up the water by a dam or weir, and inferting the end of the main-pipe through the dam, fo as to obtain the greateft fall of water which the natural circumftances will admit of. To put the machine in action, let the ftop-valve be opened to the pofition fhewn in the figure, the water will run through the main-pipe C, until it acquires a certain velocity which will be proportioned to the height of the fall of water which produces the current of water. The action of the current upon the ftop-valve B, in its reclined pofition, will increafe until it is fufficient to overcome the weight E, and then it will fhut the ftop-valve. The water being now fuddenly ftopped, and confined in the pipe C, by its impetus or momentum, will exert a confiderable force within the pipe, which will open the other valve A, and a portion of the water will rife up the afcending-pipe D. The force of the momentum being expended in raifing this water, the water in the main-pipe will immediately recover the equilibrium, and the clofing of the valve A will prevent the return of the water which is raifed in the afcending-pipe. The weight E now defcends, and opens the ftop-valve B, and the water in the main-pipe refumes its motion until its velocity is fufficient to clofe the valve A again, and the operation of raifing the water is again repeated.

This water gradually rifes in the afcending-pipe until it reaches its fummit, and then a quantity will iffue from it at every ftroke into a proper refervoir R. The quantity will be more or lefs, according as the height to which it is raifed, and to the velocity of the current, and the fize of the apparatus. In this defcription, we have taken no notice of the action of the air-veffel J, at the bottom of the afcending-pipe D, although its ufe is very important to the practicability of the contrivance; for where the water is to be raifed to any confiderable height, the pipes, although formed of the beft materials that can be procured, will be in danger of rupture from the great concuffion of the water when fuddenly checked; hence the rifing of the water would be limited to the height of a few feet, or the pipes muft be made of an extraordinary thicknefs, difregarding expence.

This danger of burfting the pipes is to be regarded in every cafe of applying this invention to practice; but it will be prevented, or very much diminifhed, by introducing an air-veffel I. The water from the main-pipe enters at every ftroke through the exit-valve A, and compreffes the air in the veffel J, which again, by its expanfion or elafticity, acts upon the water, (which is prevented from returning to the pipe C by the fhutting of the exit-valve,) and therefore rifes through the afcending-pipe, and by repeated ftrokes acquires the defired height.

The dimenfions of the air-veffel, as well as its form and pofition, and whether it is affixed to the main-pipe laterally or above, are in a great meafure arbitrary; but its contents of air ought not to be much lefs than ten times the quantity of water to be raifed through the afcending-pipe at each ftroke, and if very much larger ftill the better, the principal boundary being expence.

The regulation of the ftop-valve B, is a principal point in the conftruction of thefe machines. It may be opened and fhut by the current, as has been defcribed, in a very fimple manner, by adapting the valve to move upon an axle or hinge, and affifting it to open at the proper time by a weight attached to a lever fixed to its axis at the proper angle. The valve fhould be prevented from opening to fuch a degree, that the action of the current of water could not fhut it. This muft be done by fome fixed refiftance behind the valves, as fhewn at B, *fig*. 3, or by any other convenient means.

It is neceffary to adjuft the weight by experiment, fo as to open the valve at the right time, according to circumftances, which may be done either by fliding the weight nearer to, or farther from, the centre of motion, or by increafing or diminifhing the weight itfelf. The inconvenience of this method is, that the weight being generally under water, it is troublefome to adjuft it; therefore the mechanifm fhewn in *fig*. 4. is better adapted to the ftop-valve. The weight E is fitted upon a lever connected with a fpindle, to which another arm or lever G is alfo fixed, and that is connected by rod *a*, with the arm K fixed to the valve.

The rod may be prolonged to any neceffary length, and the weight and its mechanifm may be always placed above water, fo as to be eafily come at for adjuftment. Valves of this kind may be hinged either upon their lower or upper edge, or upon one of the perpendicular fides as a common door, as convenience requires, and the mechanifm is connected accordingly.

When it is required to open the ftop-valve fo completely that the current of water in the main-pipe cannot act upon it, to fhut it, a fmall ftream of water is led from the head, which fupplies the main-pipe, or from fome other fource into a pipe or trough, which is furnifhed with a cock to regulate the quantity. This pipe or trough pours its water into the bucket G, *fig*. 5, which caufes the bucket to preponderate, and by means of the lever *b c*, fixed to its axle, and the rod *c d* attached to it, it fhuts the ftop-valve B, by the connection of the lever *d e* attached to it. The bucket then empties its water, and the pendulous weight E, as foon as the recoil of the water in the main-pipe takes place, preponderating in its turn, opens the valve, and reftores the bucket to its place. In this contrivance, by opening the cocks of fupply more or lefs, and by adapting the capacity of the buckets in proportion to the weight E, the number of ftrokes to be made in any given time is regulated.

The ftop-valve may be conftructed in a circular form, and, inftead of being hinged upon one fide, may be fixed upon a fpindle in its centre, which flides in a focket, fimilar to what are called button-valves ufed in pump-work, and at the proper time is opened by mechanifm fimilar to the former; or, in place of the weight, a fpring may be employed.

In conftructing large machines, where the fhock, from fhutting the ftop-valve, might endanger the derangement of the machine, other kinds of ftop-valves will be preferable to thofe before defcribed.

A very good form of valve is that which opens in two leaves, like the gates of a canal-lock. The leaves may fhut one upon another in the middle, or may fhut upon an upright bar placed there. They are opened by the fame kind of mechanifm as we have defcribed before, only there muft be two connecting-rods, one to each leaf of the valve; and thefe being united together, will caufe them to fhut both together. The aperture for this valve is of a rectangular form.

A valve in two leaves, fuch as is called a butterfly-valve, may alfo be hinged in the middle of the opening, but would too much obftruct the water-way. When the main pipe is of a large diameter, (for inftance, two feet or upwards,) the ftop-valve may be made in three, four, or more leaves connected together by mechanifm, fimilar to Venetian window-blinds.

Another kind of valve is poifed upon an axis, like a common fire-ftove chimney damper; the axis does not pafs through its centre, but divides it into two unequal fegments. The valve is not opened fo far as to ftand in the line of the current of water, but, when opened, ftands inclined to that current; fo that the larger fegment being placed towards the ftream, the latter may by its action fhut it at the proper time. It is opened by mechanifm fimilar to the former. Another kind of valve is a fpherical ball of porcelain, which is fitted into a feat.

When the machine is made ufe of in an open river, which does not admit of having its water penned up by a weir or dam-head, the main pipe ought to be laid fo as to be covered by the low waters of the river; and it ought to be parallel to the furface of the river, fo as to have the greateft poffible declivity that can be obtained in the length of the main pipe: its mouth or receiving end fhould be fhaped like that of a trumpet or bell. In all cafes whatfoever, the valves ought to be completely under the furface of the water, in the lower refervoir.

Performance of the hydraulic Ram, (fee RAM).—M. Montgolfier, in his publication, fays, that a belier hydraulique, executed with care, is capable of rendering three-fourths of the force which is employed to move it, that is, the product of the weight of water raifed, multiplied by the height to which it is raifed, will be equal to three-fourths of the product of the weight of water which works the machine, multiplied by the height of the fall. Commonly it yields fix-tenths, but he would only engage to furnifh half. Thus, if the water was to be raifed 100 feet by a fall of 5 feet, he would engage to make a machine which fhould deliver at 100 feet a fortieth part of the whole quantity which fell. He recommends particularly that the machine fhould be fixed in the moft folid manner, by mafonry or timber, fo that the fhock of the water can produce no motion of the machine, becaufe all fuch motion will deduct confiderably from the quantity of water raifed. It is ftated that the machine will make from 20 to 120 ftrokes *per* minute.

The dimenfions of an hydraulic ram at the bleaching works of M. Turquet, near Senlis, in France, when reduced to Englifh meafure, are as follow: diameter of the body of the ram 8 inches, fall of the water 3 feet 4 inches, height to which the water is raifed 15 feet 1 inch. In three minutes this machine made 100 ftrokes, which expended 67 cubic feet of water, and raifed $9\frac{1}{4}$ cubic feet: hence, 67 cubic feet $\times$ $3\frac{1}{3}$ feet $=$ 223, and $9\frac{1}{4}$ cubic feet $\times$ $15\frac{1}{12}$ feet $=$ 140. Now $\frac{140}{223}$ is equal to $\frac{63}{100}$ths, fo that the effect produced is above fix-tenths of the power applied. In another experiment it was found to be 64-hundredths. This machine raifed a quantity of water equal to 6.2 inches of water (pouces de fontanier), for 269 litres which are nearly equal to 280 pints, in three minutes; and the pouce de fontanier is a meafure of running water equal to 14 pints (French) *per* minute, or 796.37 cubic inches, Englifh. This machine working 24 hours will raife 134400 pints (French), or 4512 cubic feet Englifh, of water to a height of 15 feet 1 inch. The water raifed by this machine is equal to $\frac{3}{4}$ the power of a man, according to our ftandard.

M. Montgolfier recommends the pipe or body of the ram to be of an equal diameter through the whole length; and all internal irregularities are to be avoided, becaufe they diminifh the velocity of the water: the ftrength of the pipe fhould be at leaft equal to fuftain a column of twice the height to which it is intended to raife the water.

He fays, that he executed one with a fall of 10 feet, which compreffed the air in an air-veffel to an equal degree with 40 atmofpheres, which, taking the preffure of the atmofphere equal to 33 feet of water, makes the preffure equal a column of water 1320 feet in height.

Improved hydraulic Ram.—M. Montgolfier, the fon of the inventor, has recently obtained a patent in England for an improved hydraulic ram, in which, by attention to fome minute particulars in the conftruction, he is enabled to make the length of the tube much lefs than in the former machines; and he has even obtained a refult equal to 84 *per cent.* of the power employed.

One of thefe improvements is the addition of a fmall fnifting-valve, which, at each movement, ferves to introduce a fmall quantity of air into the head of the ram, from whence it is driven by the next movement into the air-veffel, which would otherwife become filled with water, if the air, abforbed by the contact of the water under a ftrong preffure, were not continually replaced by fome fuch means.

Alfo, in the interior of the head of the ram is an annular fpace, furrounding the frame of the ftop-valve: this contains a fmall volume of air, which cannot be forced into the air-veffel, but which, at each movement, is compreffed by and receives the firft effort of the moving water. This he calls the air-matrafs, and by means of it, the fhutting of the ftop-valve makes lefs noife, the pipe is not ftrained, and all the operations take place with fo much eafe, that the machine is lefs fhaken, and lefs frequently out of repair. The following is a defcription of the new machine.

That end of the pipe or body of the ram which receives the water of the refervoir is formed like a trumpet-mouth, that the water may flow more readily into the pipe; and the length of the pipe muft be regulated according to the height of the fall of water, which is to produce the current through it. The pipe is compofed of feveral pieces or lengths fcrewed together by flanches, or other fimilar means; but it is in the end piece, which is called the head of the ram, that the moving parts of the machine are placed.

The extremity of the pipe or head of the ram is a hollow fphere, the diameter of which is nearly twice as great as the bore of this pipe: the upper part of the fpherical end is flattened, fo as to reduce it to a fegment of a fphere, with a flat circular furface on the top or upper fide, in the centre of which furface is a large circular opening to receive and hold the feat of the ftop-valves, at which the water iffues; but when the valve is clofed, it prevents the water from iffuing.

When the valve opens, it defcends perpendicularly into the hollow fphere, and leaves a free paffage through the opening. Its motion is guided between three or four perpendicular ftems, which have hooks formed at the lower ends to retain or fupport the valve when opened; and thefe ftems are fixed by fcrews, fo that they can be regulated to allow the valve to defcend more or lefs, and open a greater or lefs paffage for the water. The valve is made of metal, and hollow, for it has a flat circular plate of metal, with a hollow cup or difh of metal attached to its lower furface:

this

this at the fame time renders the valve lighter in the water, and gives it a convex furface on the lower fide, which, when the valve is opened, correfponds in curvature with the interior concave furface of the fpherical end of the head of the ram. The feat of the valve is compofed of a fhort cylinder or pipe, of which the opening is much greater than the tranfverfe fection of the body of the ram. This fhort cylinder is fcrewed by its flanch into the opening in the upper furface of the head of the ram. This flanch of the feat is fo formed as to have an inverted cup round the upper part of the fhort cylinder, that is, a circular channel or annular fpace within the head of the ram, which will contain air, and from which the air cannot efcape when the water compreffes. The air in this channel is called the air-matrafs.

The fnifting-valve is at the end of a fmall pipe, which leads from the annular fpace or matrafs to the open air. The fnifting-valve opens inwards, in order to admit the air to enter into the matrafs; but to prevent its return, there is another fmall valve in the fame pipe, which opens outwards: the office of this is to admit a certain quantity of air into the matrafs, and then to fhut and prevent any farther entrance.

On the outfide of the feat of the ftop-valve that is over the aperture in the head of the ram, where the water iffues, another ftop-valve is applied, which is fimilar to the internal valve before mentioned, but fhuts down on the outfide of the feat. Its ufe will be hereafter explained.

The upper part of the pipe or head of the ram is made flat at the part near the end where it enlarges to a fphere; and this flat furface on the top of the pipe has feveral narrow openings acrofs it, which are covered by as many flap-valves of leather, to allow water to pafs out from the main pipe, but to prevent its return. And on each fide of the head of the ram, at the part oppofite to thefe flap-valves, is a hollow enlargement, in form of a fegment of a horizontal circle; and the two enlargements taken together form a circular bafon, through the centre of which the pipe of the ram paffes; but, as before ftated, the pipe, inftead of being circular, is flat at top at that part, to form the feats for the flap-valves. This circular bafon is covered by a cylindrical air-veffel, fcrewed down by means of a flanch at the edge, fo that the circular bafon forms the bottom of the fpace in the air-veffel; the flap-valves being covered by the air-veffel are therefore within the veffel.

In confequence of this arrangement, all the water which iffues from the body of the ram through the flap-valves will flow off on each fide, and be received in the bafon; but as the circular bafon or bottom of the air-veffel is divided into two parts, by the pipe of the ram which paffes through it, there is a paffage communicating from one of the enlargements to the other; for which purpofe, it curves down and defcends beneath the pipe of the ram; and the afcending pipe that carries away the water which the machine raifes, proceeds either from this curved paffage or from fome other part of the bafon, fo that it may receive the water which has paffed from the body of the ram through the flap-valves and the air-veffel into the bafon, at each fide of the pipe.

The action of this hydraulic ram is nearly the fame as the preceding. Suppofe the pipe or body of the ram is full of water, if the internal ftop-valve is opened, the water from the refervoir will flow through the body of the ram, and iffue through the opening at the end, it will lift up the external ftop-valve and efcape; but the current having continued until the water has acquired a certain velocity, the force of the current buoys up the internal valve, and clofes the paffage. The motion of the water contained in the ram will thus be fuddenly arrefted, and by its *vis inertiæ*, or moving force, will exert a fudden preffure againft the ftop-valve, and againft all the interior parts of the ram. The fmall quantity of air contained in the fpace around the interior ftop-valve, which is called the air-matrafs, is compreffed into a fmaller fpace, and, by its elafticity, takes off the violence of the fhock or blow which would otherwife be produced. This preffure opens the flap-valves on the top of the pipe, which are within the air-veffel, and a portion of the water will be driven into the air-veffel, which is fuppofed to be full of air, compreffed or condenfed, till its elafticity equals the preffure of the column of water which is to be raifed up the afcending pipe by the action of the machine.

The water which is forced into the air-veffel caufes the air therein to be condenfed, and to exert a greater degree of elafticity, until it will exceed the preffure of the column of water in the afcending-pipe; by degrees this air will therefore force through the faid pipe all the water which was injected through the flap-valves, and caufe that quantity of water to iffue from the upper extremity of that pipe.

The moving force, or *vis inertiæ* of the mafs of water, which was in motion in the body of the ram, having expended itfelf by forcing a portion of water into the air-veffel, and making a ftill greater compreffion of the contained air, a recoil of the water in the body will take place with a flight motion from the valve towards the open end of the body; this arifes from the reaction or elafticity of the air contained in the air-matrafs, and alfo of the metal of which the tube is compofed.

The flap-valves within the air-veffel fhut, and prevent the return of the water which has been forced into the air-veffel. This recoil of the water in the body towards the open end caufes a flight afpiration within the whole body of the ram, and the external ftop-valve defcends by its weight, and prevents the water with which it is covered from entering through it; but the air paffes through the fmall pipe, leading from the open air to the annular fpace or air-matrafs, and opens the fnifting-valve, and a fmall quantity of air is fucked into the matrafs; but this is a very fmall quantity, becaufe the external air-valve clofes as foon as the air flows with a rapid current through the pipe and fnifting-valve.

During the recoil, the internal ftop-valve having nothing to fuftain falls by its weight, and opens the paffage; and as foon as the force of the recoil has expended itfelf in acting againft the column of water contained in the refervoir at the open end of the body, the water begins again to flow through the body in its original direction, and repeats the action before defcribed.

It fhuts the internal ftop-valve when it has acquired the intended velocity, and being thus ftopped, the efflux of the *vis inertiæ* condenfes the air-matrafs, and opening the flap-valves, forces a quantity of water into the air-veffel, from which the reaction of the contained air will drive it up the afcending-pipe.

The *vis inertiæ* of the moving column of water being thus expended, the recoil commences by the reaction of the air in the matrafs, the flap-valves fhut, and the external ftop-valve likewife; the afpiration produced by the recoil draws fome air through the fnifting-valve, and it joins the air in the matrafs. The internal ftop-valve falls open by its weight and opens the paffage, fo that the water in the pipe can refume its motion when the recoil has exhaufted itfelf.

The fmall quantity of air which is drawn into the machine through the air-valve, at each afpiration, caufes an accumulation of air in the matrafs; and when the afpiration of the recoil takes place, a fmall quantity of this air paffes from the annular fpace, and proceeds along the pipe till it arrives beneath the flap-valve, and lodging in the fmall fpace beneath thefe valves, it will be forced into the air-veffel at the next ftroke, by which means the air-veffel is always kept filled with air.

The following are the dimenfions of a machine which is calculated to raife water up the tube to 100 feet above the furface of the water in the refervoir, when the fall by which it is worked is five feet, that is, where the level of the water in the refervoir is five feet above the lower level; and the length of the pipe from the open end to where the water is difcharged is to be twenty feet long, and fix inches in diameter.

Such a machine may be expected to expend about feventy cubic feet *per* minute to work it, and to raife up about two and one-third cubic feet *per* minute; but thefe quantities cannot be exactly ftated, becaufe they depend upon the care and accuracy with which the machine is conftructed. Under different circumftances, having a greater or lefs fall or quantity or water, the dimenfion of the machine muft be calculated accordingly.

The improvements in this laft form of the hydraulic ram are,

Firft, that by conftructing the head of the ram with the upper fide of the pipe flat, and applying the flap-valves immediately upon the top, there is very little fpace to contain dead water, that is, water which will be motionlefs when the current takes place in the pipe; and by dividing the fingle valve of the original machine into feveral fmall and narrow valves, they open and fhut more fuddenly, and with lefs lofs of water.

Secondly, in making the bafon on each fide of the pipe, which bafon is on a lower level than the flap-valves. By this means the water will flow off from the flap-valve on each fide, and at the inftant when the machine performs its ftroke, and forces water through the faid valves into the air-veffel, the valves will not be covered, or at leaft very flightly covered by water; confequently, when thofe valves open, and the water is forced into the air-veffel, it has only the compreffed air to oppofe it, which from its elafticity allows the water to enter with more facility than if it was refifted by a column of water refting upon the valves; not that there is any lefs hydroftatic preffure upon the valves, becaufe it is the air which bears upon them, inftead of the water, but there is a lefs mafs of matter to be put in motion by the water which enters into the air-veffel: for it has only the matter contained in the valves themfelves to put in motion.

Thirdly, in applying the external ftop-valve, the ufe of which is to prevent the water returning into the ram when the recoil takes place, and having this provifion, a greater quantity of air can be employed in the matrafs than could otherwife conveniently be done; this renders the fhock which takes place when the ftop-valve is fhut lefs fudden. We have examined feveral of thefe machines made in France by the inventor, and can with confidence recommend them to engineers as the very beft machine, and the moft fimple for raifing water when there is a natural fall. The laft improvements, as they enable us to fhorten the length of the body of the ram to nearly one-third, without reducing the performance, are very important.

The hydraulic ram is adapted to give motion to the hydroftatic preffes, which are in common ufe under the name of Bramah's preffes. For this purpofe, it is only neceffary to apply the afcending-pipe to the cylinder of the hydraulic prefs, and at each ftroke of the ram a fmall quantity of water will be forced or injected into the cylinder of the prefs, and will thus produce the afcent of the pifton of the prefs in the fame manner as is now performed by the fmall injection-pump worked by the force of men. But by the application of the hydraulic ram to that purpofe, the prefs can be worked in any fituation where there is a fmall fall of water, and the ram may be fet in motion whenever the prefs is wanted.

An *Hydraulic Ram*, or *Momentum Machine acting by Suction*, is fhewn at *figs.* 2 and 3. *Plate Water-works.* This is applicable in cafes where the water to be raifed is below the level of the main-pipe, and is to be difcharged at that level; a cafe which frequently occurs in the drainage of marfhy lands, where the action of the current of water, in an embanked river, or other ftream or fource of water on a higher level, can be employed; or this method can be applied in raifing water out of the holds of fhips by the motion of the veffel through the water; alfo to raife water out of a well of moderate depth.

C reprefents a portion of the main-pipe; B, *fig.* 2. is the ftop-valve fituated at the entrance of the pipe, and opening outwards fo as to ftop the paffage of the pipe when it is fhut; D, the afcending or fucking-pipe, communicating with the well at the bottom and with the main-pipe at the top; J is the air-veffel; and E the weight of the ftop-valve of the main-pipe. There is likewife a valve A opening from the air-veffel into the main-pipe.

The water in the main-pipe having acquired a proper velocity by the current, as in the former cafes, the ftop-valve B fhuts, and the water in the main-pipe continuing its motion for a time, draws air out of the air-veffel J, through the valve A. The momentum of the water in the main-pipe being foon expended it recoils, the receiving-valve A fhuts to prevent the return of the water into the air-veffel, and the ftop-valve B opens by the action of the weight E, the water thus regains its paffage, and foon acquires fufficient velocity to clofe the ftop-valve again, and the operation is repeated.

Thus in a few ftrokes the exhauftion is increafed till the air-veffel fucks up water from below, through the afcending-pipe D, or rather the preffure of the atmofphere on the furface of the valve below forces it up, when the preffure on the furface within the air-veffel is removed by the exhauftion. This action being continued, the afcending-pipe fills by degrees to the top, after which, at every fucceffive ftroke, a portion of the water from below paffes into the main-pipe, and is carried off into the pipe C, where it mixes with the upper water.

In cafes where the water of the tide or other alternating current is employed as the motive power, the apparatus may be conftructed in two ways, either by applying a ftop-valve, air-veffel, and afcending-pipe, fuch as is fhewn at one end in *fig.* 4. to each end of the main-pipe C, to be ufed alternately, according as the tide fets in the one direction or the other; or otherwife by applying two main pipes to one air-veffel, their mouths being placed in oppofite directions and to be ufed alternately, and applied to the raifing of water, for the ufe of falt-works, or for other ufes, fuch as the fupply of a country-houfe.

The firft machine above defcribed may be employed to raife water to fmall heights by the motion of the waves of the fea, or of any large pieces of water; in which cafe the mouth or receiving end of the main-pipe fhould be formed like a fpeaking-trumpet, as fhewn in *fig.* 4. and placed oppofite to the direction in which the waves beat upon the fhore at the place where the machine is. The water of the waves will enter the main-pipe, and rufh through it until

the

the ſtop-valve ſhuts; when the contained water will in part enter the air-veſſel by the action already deſcribed, and the next wave will produce another ſtroke.

Momentum-Pump, or Momentum-Machine, to raiſe Water by the Application of mechanical Power.—Where a fall of water cannot be obtained, *fig.* 1. ſhews an application of this momentum principle, in lieu of pumps for raiſing water, the main-pipe being put in motion through the water by the ſtrength of men, or other mechanical power in default of a current, as in the other caſes.

C C is the main-pipe bent in a ſpiral form round the air-veſſel J; it may either be made to touch it, or be kept at a diſtance from it, and may make one or more revolutions round the ſaid veſſel; the whole of the main-pipe is immerſed in the external water which is to be raiſed. Both ends of the pipe are open to the water; but one of them has the ſtop-valve opening inwards, which will occaſionally cloſe it, and near this latter end, a communication is made by a ſide-pipe with the air-veſſel, the orifice being covered by a valve opening into the veſſel. The whole turns upon a pivot K, at the lower end of the aſcending-pipe D, which ſerves as an axis, and is kept upright by a collar, in which it turns, as ſhewn at L. Upon this axis a toothed wheel M is fixed, and is put in motion by another wheel N, turned by a winch, crank, or other contrivance.

At the top, or upper end of the aſcending-pipe, the water is diſcharged into a trough, which ſurrounds it, and conveys it to the place of its deſtination.

This apparatus is made to raiſe water by a continued rotative motion, the open end moving firſt, through the water which paſſes out again through the other end; but whenever, by that motion, the main-pipe has attained a proper velocity, the ſtop-valve ſhuts ſuddenly, and by the concuſſion the water paſſes into the air-veſſel, from whence the egreſs of the water is prevented by the ſhutting of the exit-valve. The ſtop-valve then opens by means of a ſpring in lieu of a weight, as in the former caſes, and the apparatus continuing to revolve in the ſame direction, more ſtrokes are made at intervals proportioned to the velocity with which it moves. The ſpring of the ſtop-valve ſhould be ſo regulated in force as to allow the relative motion of the water in the main-pipe to ſhut the ſtop-valve at proper intervals. The perpendicular ſection of the main-pipe is drawn ſquare, but may be circular, or of any other convenient figure. A horizontal ſection of it is ſhewn at *fig.* 6, with the main-pipe and the air-veſſel.

In lieu of the wheel N, which produces a continued rotatory motion, the machine may be made to vibrate or ſwing upon an axis, backwards and forwards, the limits of the vibration or ſtroke being determined by a detent ſtriking againſt a ſtiff ſpring. In this caſe, the main-pipe ſhould be provided with ſtop-valves at both ends, and alſo have a communication at each end with the air-veſſel, which openings ſhould be cloſed by valves to prevent the return of the water from it. Such a machine may be put in motion by the following means: upon the aſcending-pipe D, a double pulley is fixed, round which are wound the ropes, and by pulling the ends of theſe alternately, the apparatus may be made to revolve in either direction. The main-pipe and the aſcending-pipe being filled with water by hand or otherwiſe, if the ropes are pulled alternately, they will make the pipe move through the water with ſufficient velocity to make the apparatus act. It is found if the apparatus makes about thirty vibrations in each minute, that it will act very completely.

Hydraulic machines are of the greateſt importance to ſociety, whether we look to a ſupply of the firſt neceſſity for domeſtic uſes, or to the advantageous uſes of neglected though valuable firſt movers. Theſe machines muſt, in moſt caſes, be modified by localities, and other circumſtances; and conſequently the moſt uſeful practical knowledge will not conſiſt in any acquaintance with one or more of the beſt engines, but with that great variety of happy contrivances which inquiry and reflection muſt point out. We have, as far as our limits permit, given all the machines which are practically uſeful, and we ſhall conclude this article by giving Dr. Young's catalogue of the moſt important and valuable writings on hydraulic engines.

A fhort account of the invention, theory, and practice of fire-machinery; or introduction to the art of making machines, vulgarly called fteam-engines, in order to extract water from mines, convey it to towns, and jets d'eaux in gardens, to procure water-falls for fulling, hammering, ftamping, rolling, and corn-mills, by William Blakey, 1793. Egerton.

Machines actuated by the Force of Currents or Streams of Water.—Thefe are very numerous, but all may be reduced to two kinds.

Firft, thofe which are adapted to receive the impulfe of moving water; that is, water which has been put in motion in confequence of a defcent towards the earth previoufly to its operating on the machine, which muft be provided with parts proper to refift and take away fome of the motion of fuch water, and it will thereby receive motion which may be applied to produce fome mechanical effect. Of this kind are underfhot and horizontal water-wheels.

Secondly, thofe machines which are provided with fome kinds of buckets or veffels to contain water, the weight of which buckets, and the water they contain, is fupported by the machine, fo that the water cannot defcend towards the earth in confequence of its gravitation, without giving motion to the buckets or veffels which contain and fupport it. Of this kind is the over-fhot water-wheel, breaft-wheel, chain of buckets, and preffure-engine.

In either cafe, the motive force or power is the fame; *viz.* the gravitation and motion of fuch bodies or maffes of water as are found more elevated above the furface of the earth than the general level of the fea, or of fome other water in its neighbourhood; fuch water will defcend by the force of gravity until it joins the fea, or until it is fupported or held up by fome fixed obftacle.

The difference between the two kinds of machines is, that in the firft cafe the water is fuffered to defcend before it operates upon the machine, and in confequence of its gravitation, acquires motion with a velocity proportioned to the fpace through which it has defcended; and the office of the machine is to take from the moving water as much of its compounded weight and motion, or power, as it can obtain.

In the other cafe, the machine receives its motion and power at the fame time, when the water acquires it, by defcending; or, in other words, the machine moves with the water.

The word *power*, as ufed in practical mechanics, fignifies the exertion of ftrength, gravitation, impulfe, or preffure, fo as to produce motion; and a machine actuated by means of ftrength, gravitation, impulfe, or preffure, compounded with motion, is capable of producing an effect: and no effect is properly mechanical but what requires fuch a kind of power to produce it.

The mufcular power of animals, as likewife preffure, impact, gravity, electricity, &c. are looked upon as forces, or fources of motion; for it is an incontrovertible fact that bodies expofed to the free action of either of thefe are put in motion, or have the ftate of their motion changed. All forces, however various, can be meafured by the effects they produce in like circumftances; whether the effects be creating, accelerating, retarding, or deflecting motions: the effect of fome general and commonly obferved force is taken as unity.

The moft proper meafure of power is the act of raifing fome weight with fome velocity of motion; that is, the overcoming of the gravitating force of a weight in fuch degree as to produce motion in oppofition to gravity. In confidering the quantum, the weight or mafs of matter operated upon muft be one quantity, and the velocity of the motion communicated is the other; the mechanical power is the

the compound of both. We can only meafure the weight of any body or mafs of matter by its relation to fome other weight with which we are acquainted ; hence we fay, the weight is equal to fo many pounds, or fo many cubic feet of water. In like manner, we meafure the velocity or intenfity of the motion, by ftating the height or perpendicular diftance from the earth, (meafured by relation to fome known diftance, as a foot or a yard,) through which height the weight is raifed in fome known fpace of time, as a fecond or a minute.

For inftance, 528 cubic feet of water is a known weight or mafs of water : let a machine operate upon this, and raife it upwards, through the fpace of one foot in the time of one minute ; then $528 \times 1 \times 1 = 528$ is the number which reprefents the power which the machine exerts. Suppofe another machine to operate on 132 cubic feet of water, and raife it four feet in one minute, then ufing the fame meafures to determine the quantities of weight, height, and time, we fay $132 \times 4 \times 1 = 528$; hence thefe two machines are equal in the power which they exert ; for in all cafes the weight raifed is to be multiplied by the height to which it can be raifed in a given time, and the product is the meafure of the power expended in raifing it ; confequently, all thofe powers are equal whofe products made, by fuch multiplication, are equal ; for example, take two powers, if one can in any given time raife twice the weight to the fame height, or the fame weight to twice the height, in the fame time that the other power can, the firft power is double the fecond ; or, if one power can raife half the weight to double the height, or double the weight to half the height, in the fame time that another can, thofe two powers are equal : but note, all this is to be underftood only in cafes of flow or equable motion of the body raifed, for in quick, accelerated, or retarded motions, the *vis inertiæ* of the matter moved will make a variation.

The machines actuated by the impulfe of flowing water are, the underfhot water-wheel, horizontal wheels, and Dr. Barker's mill. It is a common expreffion to call all wheels in which the water runs or fhoots under the wheel, underfhot ; but in this place we fhall only fpeak of

Underfhot Water-Wheels, acting by the Impulfe of flowing Water.—Thefe are the moft ancient and original forms of water-machines, although if they had been invented from the refult of reafoning, fuch as we have given, they would have been the laft, becaufe their manner of action is lefs obvious ; but this was not the cafe. The firft machines were wheels placed in a river or running ftream, and provided with vanes or wings on the circumference, called floats ; the floats at the lower part of the wheel, dipped into the ftream to intercept the water. When the plane of the floats became perpendicular to the direction of the current, or nearly fo, they would refift or oppofe the motion of the water, and the wheel would obtain motion from it in proportion to the quantity of motion, its floats abftracted from the water of the ftream. The power thus obtained would be found to be only a fmall proportion of the power of the ftream, becaufe the water would eafily efcape fideways from the floats, particularly if it were attempted to take away any confiderable fhare of the velocity of the water, by refifting or loading the wheel, fo as to make it move flowly. Hence it became an obvious improvement to contract the river to the exact fize of the float-boards of the wheel, or to make a clofe channel in which the wheel exactly fits. The next improvement would be to intercept the river or ftream of water by a dam, or obftacle, in order to make it pen up, or accumulate, till it had rifen to the greateft height which could be obtained, and to let the water out of the dam or refervoir into the channel or wheel-courfe, through a vertical aperture or door, level with the bottom of the wheel-courfe ; in this way, the water would be urged by the preffure of the water in the dam, and would rufh out from the aperture in a ftream or fpout, with a velocity proportioned to the perpendicular preffure, and would ftrike the float-boards of the wheel fo as to urge them forwards. Such is the form of the underfhot wheels ftill generally employed in France and on the continent ; but in England they have been long fuperfeded by more effectual applications of the power of the water, and it is very rarely we meet with an underfhot wheel acting by the impulfe of the water. They are called ground-fhot wheels, becaufe the water runs or fhoots along the ground or floor of the channels in which the wheels work.

It was firft proved by Mr. Smeaton, in 1754, that only a portion of the power of any fall of water could be obtained by means of an underfhot wheel ; for M. Belidor had not long before ftated the underfhot wheel as the beft mode of applying a fall of water. It was one of the continual occupations of Mr. Smeaton, during forty years, to improve the old water-mills, by fubftituting breaft-wheels for underfhot ; and the advantages were uniformly fo great, that thefe mills were copied by others, until fcarcely any of the original conftruction remained. We do not mean that Mr. Smeaton invented the breaft-wheel, for it is defcribed by Leopold ; but he firft inveftigated its comparative advantages.

It is from this circumftance that we find, in all the mechanical writings of foreign authors, much more mathematical inveftigation relative to the underfhot water-wheels than the importance of the fubject deferves, and we fhall difmifs it more briefly.

The excellent paper by Mr. Smeaton, in the Philofophical Tranfactions for 1759, contains a numerous lift of experiments moft judicioufly contrived by him, and executed with the accuracy and attention to the moft important circumftances which are to be obferved in all that gentleman's performances.

Mr. Smeaton's rules were originally deduced from experiments made on working models, which are the beft means of obtaining the outlines in mechanical enquiries ; but in every cafe it is neceffary to diftinguifh the circumftances in which a model differs from a machine at large, otherwife a model is more apt to lead from truth than towards it ; and we muft not, without great caution, transfer the refults of fuch experiments to large works. But we may fafely transfer the laws of variation, which refult from a variation of circumftances, although we muft not adopt the abfolute quantities of the variations themfelves. Mr. Smeaton was fully aware of the limitations to which conclufions drawn from experiments on models are fubject, and has made the applications with his ufual fagacity. The beft ftructure of machines cannot be fully afcertained but by making trials with them, when made of their proper fize.

Mr. Smeaton's Principles for Underfhot Wheels.—In comparing the effect produced by water-wheels with the powers producing them ; or, in other words, to know what part of the original power is neceffarily loft in the application, we muft previoufly know how much of the power is fpent in overcoming the friction of the machinery, and the refiftance of the air ; alfo, what is the real velocity of the water at the inftant it ftrikes the wheel ; and the real quantity of water expended in a given time.

The velocity Mr. Smeaton meafured in a moft fatisfactory manner in every experiment, by applying a cord and weight to the axle of the wheel, not to wind up the weight by the motion

motion of the wheel, but that the weight by deſcending ſhould turn the wheel. He applied ſo much weight as would make the wheel turn, and make its floats move with the velocity which he deſired or expected the effluent water to have; and this weight he adjuſted until he found, by repeated trials, that the wheel moved juſt at the ſame rate, whether the water was ſuffered to flow and ſtrike its floats, or whether the water was ſtopped, which proved that the floats of the wheel moved with preciſely the ſame velocity as the effluent water; then by meaſuring the circumference of the wheel, and counting the number of turns it made in a minute, he obtained the meaſure of the velocity.

From the velocity of the water at the inſtant that it ſtrikes the wheel, the height of head productive of ſuch velocity can be deduced from acknowledged and experimented principles of hydroſtatics; ſo that by multiplying the quantity or weight of water really expended in a given time by the height of a head ſo obtained, which muſt be conſidered as the effective height from which that weight of water had deſcended in that given time, we ſhall have a product equal to the original power of the water, and clear of all uncertainty that would ariſe from the friction of the water in paſſing ſmall apertures, and from all doubts ariſing from the different meaſure of ſpouting waters, aſſigned by different authors.

On the other hand, the ſum of the weights raiſed by the action of this water, and of the weight required to overcome the friction and reſiſtance of the machine, multiplied by the height to which the weight can be raiſed in the time given, the product will be equal to the effect of that power; and the proportion of the two products will be the proportion of the power to the effect: ſo that by loading the wheel with different weights ſucceſſively, we ſhall be able to determine at what particular load and velocity of the wheel the effect is a maximum.

From experiments conducted in this manner, Mr. Smeaton ſettled the following maxims:

Maxim 1. That the virtual or effective head of water, and conſequently its effluent velocity being the ſame, the mechanical effect produced by a wheel actuated by this water will be nearly in proportion to the quantity of water expended.

Note. The virtual or effective head of any water which is moving with a certain velocity, is that height from which a heavy body muſt fall in order to acquire the ſame velocity.

The height of the virtual head, therefore, may be eaſily determined from the velocity of the water; for the heights are as the ſquare of the velocities; and the velocities, conſequently, as the ſquare roots of the heights. Mr. Smeaton obſerved the velocity of the effluent water in all his experiments, and thence calculated the virtual head; he ſtates that the virtual head bears no proportion to the real head or depth of water; but that when either the aperture is greater, or when the velocity of the water iſſuing therefrom leſs, they approach nearer to a coincidence; and conſequently, in the large openings of mills and ſluices, where great quantities of water are diſcharged from moderate heads, the actual head of water, and the virtual head, as determined by theory from the velocity, will nearly agree.

For example of the application of his firſt maxim. Suppoſe a mill driven by a fall of water, whoſe virtual head is 5 feet, and which diſcharged 550 cubic feet of water *per* minute; and that it is capable of grinding four buſhels of wheat in an hour. Now another mill, having the ſame virtual head, but which diſcharges 1100 cubic feet of water *per* minute, will grind eight buſhels of corn in an hour.

Maxim 2. That the expence of water being the ſame, the effect produced by an underſhot wheel will be nearly in proportion to the height of the virtual or effective head. This is proved in the preceding example.

Maxim 3. That the quantity of water expended being the ſame, the effect will be nearly as the ſquare of the velocity of the water; that is, if a mill driven by a certain quantity of water, moving with the velocity of 18 feet *per* ſecond, is capable of grinding 4 buſhels of corn in an hour, another mill, driven by the ſame quantity of water, but moving with the velocity of $22\frac{1}{2}$ feet *per* ſecond, will grind nearly 7 buſhels of corn in an hour; becauſe the ſquare of 18 is 324, and the ſquare of $22\frac{1}{2}$ is $506\frac{1}{4}$. Now ſay, as 324 is to 4 buſhels, ſo is $500\frac{1}{4}$ to $6\frac{1}{6}$ buſhels; that is, as 4 to $6\frac{1}{6}$.

Maxim 4. The aperture through which the water iſſues being the ſame, the effect will be nearly as the cube of the velocity of the water iſſuing; that is, if a mill driven by water ruſhing through a certain aperture with the velocity of 18 feet *per* ſecond will grind 4 buſhels of corn in an hour, another mill, driven by water moving through the ſame aperture, but with the velocity of $22\frac{1}{2}$ feet *per* ſecond, will grind 51 buſhels; for the cube of 18 is 5832, and the cube of $22\frac{1}{2}$ is $11390\frac{3}{4}$; then, as 5832 is to 4, ſo is $11390\frac{3}{4}$ to $7\frac{3}{4}$.

Maxim 5. The proportions between the power of the water expended, and the effect produced by the wheel, was 3 to 1. Upon comparing ſeveral experiments, Mr. Smeaton fixed the proportions between them for large works; that is, if the weight of the water which is expended in any given time be multiplied by the height of the fall, and if the weight raiſed be alſo multiplied by the height through which it is raiſed, the firſt of theſe two products will be three times that of the ſecond.

Maxim 6. The beſt general proportions of velocities between the water and the floats of the wheels will be that of 5 to 2; for inſtance, if the water when it ſtrikes the wheel moves with a velocity of eighteen feet *per* ſecond, the wheel muſt be ſo loaded that its float-boards will move with a velocity of 7.2 feet *per* ſecond, and the wheel will then derive the greateſt power from the water, becauſe as 5 to 18, ſo is 2 to 7.2.

Maxim 7. There is no certain ratio between the load that the wheel will carry when producing its maximum of effect, and the load that will totally ſtop it; but it approaches neareſt to the ratio of 4 to 3, whenever the power exerted by the wheel is greateſt, whether it ariſes from an increaſe of the velocity, or from an increaſed quantity of water; and this proportion ſeems to be the moſt applicable to large works. But when we know the effect a wheel ought to produce, and the velocity it ought to move with whilſt producing that effect, the exact knowledge of the greateſt load it will bear is of very little conſequence in practice.

Maxim 8. The load that the wheel ought to have, in order to work to the moſt advantage, can be always aſſigned thus: aſcertain the power of the whole body of water, by multiplying the weight of the water expended in a minute by the height of the fall, take one-third of the product, and it gives the effect of power which the wheel ought to produce: to find the load, we muſt divide this product by the velocity which the wheel ſhould have, and that, as we have before ſettled, ſhould be two-fifths of the velocity with which the water moves when it ſtrikes the wheel.

The wheel muſt not be placed in an open river to be actuated by the natural current, in which caſe, after it has communicated its impulſe to the float, it has room on all ſides to eſcape: this is the ſuppoſititious caſe on which moſt mathematicians have proceeded; but in all theſe experiments,

ments, the wheel is placed in a conduit or race, to which the float-boards are exactly adapted, and the water cannot otherwiſe eſcape than by moving along with the wheel. It is obſervable in a wheel working in this manner, that as ſoon as the water meets the float, it receives a ſudden check, and riſes up againſt the float, like a wave againſt a fixed object, inſomuch that when the ſheet of water is not a quarter of an inch thick before it meets the float, this ſheet will act upon the whole ſurface of a float, whoſe height is three inches; and conſequently, where the float is no higher than the thickneſs of the ſheet of water, as theory alſo ſuppoſes, a great part of the force would have been loſt by the water daſhing over the float.

The wheel which Mr. Smeaton uſed had originally twenty-four floats, and was afterwards reduced to twelve, which cauſed a diminution in the effect, on account of a greater quantity of water eſcaping between the floats and the floor of the channel in which it moved; but a circular ſweep being adapted thereto, of ſuch a length, that one float entered the curve before the preceding one quitted it, the effect came ſo near to the former as not to give hopes of advancing it, by increaſing the number of floats beyond twenty-four in this particular wheel.

Mr. Smeaton obſerves that, in many of the experiments, the reſults were by different ratios than thoſe which his maxims ſuppoſed; but as the deviations were never very conſiderable, the greateſt being about one-eighth of the quantities in queſtion, and as it is not practicable to make experiments of ſo compound a nature with abſolute preciſion, he ſuppoſes, that the leſſer powers are attended with ſome friction or work under ſome diſadvantages, which have not been duly accounted for; and, therefore, he concludes that theſe maxims will hold very nearly, when applied to works in large.

Application of theſe Principles to Practice.—The firſt thing to be done in a ſituation where an underſhot wheel is intended to be fixed, is to conſider whether the water can run off clear from the wheel, ſo as to have no back water to impede its motion; and whether the fall which can be obtained by conſtructing a proper dam to pen up the water and ſluice for it to paſs through, will cauſe it to ſtrike the float-boards of the wheel with a ſufficient velocity to impel them forcibly forwards; and alſo, whether the quantity of the ſupply will be ſufficient to keep a wheel at work for a certain number of hours each day.

When we have aſcertained the height of the fall of water, that is, the height of the ſurface above the centre of the opening of the ſluice, we muſt find what will be the continual velocity of the water iſſuing out from ſuch opening.

In ſome caſes, we have the velocity of the water given when it iſſues from the opening of the ſluice, and we then require to know what height of column will produce that velocity. Theſe two things we may find by a ſingle rule, and an eaſy arithmetical operation, which is as follows:

1ſt. The perpendicular height of the fall of water being given in feet and decimals of feet, the velocity that the water will acquire *per* ſecond, expreſſed in feet and decimals, may be found by the following rule:

Multiply the conſtant number 64.2882 by the given height, and the ſquare root of the product is the velocity required.

Example 1.—If the height is two feet, the velocity will be found 11.34 feet *per* ſecond.

Example 2.—If the height is 16,0913 feet, the velocity will be 32,1826 feet *per* ſecond.

Example 3.—If the height is fifty feet, the velocity will be 56,68 feet *per* ſecond.

Note. The velocities thus obtained will be only the theoretic velocity, that is, the velocity any body would acquire by falling through ſuch height *in vacuo*, the velocity in reality will be leſs, generally ſix or ſeven-tenths.

The uniform velocity of a fluid being given, expreſſed in feet and decimals of feet *per* ſecond, the height of the column or fall to produce ſuch a velocity may be found by the following rule:

Multiply the given velocity into itſelf, and divide the product by 64,2882; the quotient will be the height required, expreſſed in feet and decimals.

Example 1.—If the velocity given is three feet *per* ſecond, the height will be 0.139 of a foot.

Example 2.—If the velocity given is 32,1826 feet *per* ſecond, the height will be found 16,0913 feet.

Example 3.—Let the velocity be 100 feet *per* ſecond, the height will be 155,649 feet.

The knowledge of the foregoing particulars is abſolutely neceſſary for conſtructing an underſhot water-wheel; but the moſt advantageous method of ſetting it to work, and to find out the utmoſt it could perform, would be very difficult, if we were not furniſhed with the maximum which Mr. Smeaton ſettled, by ſhewing, that an underſhot water-wheel will act to the greateſt advantage, when the velocity of its float-boards is equal to two-fifths or four-tenth parts of that of the water which gives it motion.

To illuſtrate this, let us conſider a wheel equally balanced on all ſides, and turning freely round upon its pivots, its circumference would ſoon move as faſt as the current it was placed in. Suppoſe the water to move at the rate of three feet in a ſecond, the circumference of the wheel would paſs through three feet in a ſecond. In this caſe, the wheel performs no work, and the effect produced is nothing.

Now in attempting to apply the power of this wheel to turn any kind of machinery, ſuppoſe the work to be ſo proportioned, that the reſiſtance would cauſe the wheel to ſtand ſtill and ſtop the water, or make it run over the floats, in conſequence of its not having ſufficient force to carry the float-boards along with it. In this caſe alſo, there being no motion, there could be no mechanical effect produced; but if the reſiſtance be diminiſhed by degrees, the wheel would begin to partake of the motion of the current of water, and being loaded, would produce a mechanical effect proportioned to the load and velocity. The wheel would increaſe in its velocity in proportion as the reſiſtance was diminiſhed, and the mechanical effect would increaſe alſo until a certain point when the wheel moved ſo faſt, that the water would not ſtrike the float-boards quick enough to produce the greateſt effect: this is found to be as before mentioned, when the floats move four-tenths as faſt as the water, becauſe then ſix-tenths of the water is employed in driving the wheel with a force proportional to the ſquare of its velocity.

If we multiply the ſurface or area of the opening by the height of the column, we ſhall aſcertain the body or column of water which ſhould preſs againſt that float-board, which is immediately under the wheel, ſuppoſing it has no motion; but it will be found, that a ſmall proportion of the weight of the original column hung on the oppoſite ſide of the wheel, would arreſt its motion entirely; but when we would have it to move with a proper velocity, that is, two-fifths of that velocity with which the water moves, $\frac{133}{1000}$ of the weight of the original column, is the weight which the wheel would raiſe with four-tenths of the velocity that the water moves with, and the power which the wheel would exert on the machinery to grind corn, lift hammers, raiſe water,

water, &c. is $\frac{133}{1000}$ of the weight of the water multiplied by $\frac{4}{10}$ of its velocity.

Thus it appears that an underſhot water-wheel, conſtructed after the foregoing manner, would only raiſe one-third part of the water expended to the ſame height, as the original head or level. This is the utmoſt that can be expected, though often leſs is done; becauſe here we ſuppoſe every part exactly performed, and the water applied to the wheel in the beſt manner; therefore, as we cannot come up to the maximum, we muſt come as near it as we can by loſing the leaſt poſſible of the power's impulſe.

It is no advantage to have a very great number of float-boards round the wheel, becauſe when they are ſtruck by the water, as applied in the beſt manner poſſible, the ſum of the impulſes exerted on the different floats, will but be equal to the impulſe made againſt one float-board ſtruck by all the water iſſuing from the ſluice at right angles to its ſurface. But as this float-board muſt move forward, there muſt be a ſucceſſion of float-boards to receive the impulſe of the water, and ſince they cannot receive it at right angles, there will be ſome loſs of impulſe in that ſucceſſion. Beſides when the firſt float-board is ſo far paſt the perpendicular, as to have the action of the water intercepted by the ſucceeding one, it is checked by the back water through which it muſt paſs in riſing out of the water, and thereby be ſo far retarded as to take from the full effect of the impulſe on the following float. Indeed if all the water could run off immediately after having performed its office, this would not happen; but it can ſeldom be effected in underſhot-mills, eſpecially thoſe built upon rivers. All the remedy in ſuch caſe is, (when the diameter of the wheel is ſettled) to fix juſt ſuch a number of floats upon it, that each one, after it has received the full impulſe of the water, may come out of the water as ſoon as poſſible, that another ſucceeding float may be brought to receive the impulſe, otherwiſe the wheel would remain a moment without any impulſe.

In the article MILL we have given a table for the dimenſions and proportions for underſhot wheels, which was calculated by Mr. Ferguſon. Dr. Brewſter, in his new edition of Mr. Ferguſon's works, has given an improved table, which is calculated upon the following principles.

It is evident that the water-wheel muſt always move with leſs velocity than the water, even when there is no work to be performed; for a part of the impelling power is neceſſarily ſpent in overcoming the *inertia* of the wheel itſelf; and if the wheel has little or no velocity, it is equally manifeſt that it will produce a very ſmall effect.

There is conſequently a certain proportion between the velocity of the water and the wheel, when the effect is a maximum. Mr. Smeaton has ſhewn the greateſt effect is produced when the velocity of the wheel is between one-third and one-half, but the maximum is much nearer to one-half than one-third. He obſerves alſo that one-half would be the true maximum, if nothing were loſt by the reſiſtance of the air, the ſcattering of the water carried up by the wheel, and thrown off by the centrifugal force, and the leakages of the water between the floats and the water-courſe, all which tend to produce a greater diminution of the effect at that velocity, which would be the maximum if theſe loſſes did not take place, than they do when the motion is a little ſlower. The great hydraulic machine at Marly, the wheels of which are underſhot, was found to produce a maximum effect when the velocity of the wheel was two-fifths that of the current. Hence Dr. Brewſter concludes that in theory the velocity of the wheel is one-half that of the current, and that in practice it is never more than three-eighths of the ſtream's velocity, when the effect is a maximum.

Dr. Brewſter's Table of underſhot Water-Wheels, in which the velocity of the wheel is three-ſevenths of the velocity of the water, and the effects of friction on the velocity of the ſtream are reduced to computation. The wheel is ſuppoſed to be fifteen feet diameter.

Height of the Fall of Water.	Velocity of the Water *per* Second, Friction being conſidered.	Velocity of the Wheel *per* Second being three-ſevenths that of the Water.	Revolutions of the Wheel *per* Minute, its Diameter being fifteen Feet.
Feet.	Feet and Decimals.	Feet and Decimals.	Revolutions and Decimals.

Another Manner of applying Water to an underſhot Wheel.—This was propoſed by M. Fabre as the reſult of much mathematical inveſtigation, and has been ſo frequently recommended by authors of eminence, that we ſhall give a ſhort deſcription without entering into all his rules for the proportions. The principal difference in this wheel from that in common uſe is, that the water is made to run down a rapid ſlope or inclined plane, in order to ſtrike the floats of the wheel, inſtead of iſſuing from an aperture or ſluice ſituated beneath the ſurface of the water in the reſervoir. A mill is uſually ſituated at a diſtance from the river, with a canal or water-courſe to conduct the water to the mill; as it is of the higheſt importance to have the height of the fall as great as poſſible, the bottom of the canal or water-courſe, which conducts the water from the river to the mill, ſhould have a very ſmall declivity; for the height of the water-fall at the mill will diminiſh in proportion as the declivity of the canal is increaſed: it will be ſufficient to make it ſlope about one inch in 200 yards, taking care to make the declivity about half an inch in the firſt 48 yards, in order that the water may have a velocity ſufficient to prevent it from flowing back into the river.

When the water is thus brought to the channel in which the wheel is placed, the water is recommended to be conducted down a ſlope or inclined plane, making an angle of $64\frac{1}{2}$ degrees with the horizon; that is, in a perpendicular of ten feet, the ſlope ſhould deviate from it $4\frac{3}{4}$ feet: at the bottom of this ſlope the water is to be again conducted horizontally, and then to ſtrike the float-boards of the wheel.

wheel. To render the fall of the water eafy, the flope is to be rounded off by a convexity at top and a concavity at bottom, to lead the water from the horizontal to the flope, and again from the flope without abruptnefs. It is fuppofed that the water, in running down this inclined plane, will acquire the fame velocity as if it had fallen perpendicularly through a height equal to the perpendicular height of the flope.

The diftance through which the water runs horizontally, from the foot of the flope before it acts upon the wheel, fhould not be lefs than two or three feet, in order that the different portions of the fluid may have obtained an horizontal direction; but if this horizontal diftance be much larger, the velocity of the ftream would be diminifhed by its friction on the bottom and fides of the water-courfe. That lefs water may efcape between float-boards and the bottom of the courfe, it fhould be formed into the arch of a circle concentric with the wheel, which fweep fhould be prolonged, fo as to fupport the water as long as it can act upon the float-boards; beyond this fweep fhould be a ftep or fall of not much lefs than nine inches with a flope of about 45 degrees, that the water having fpent the greater part of its force in impelling the float-boards, may not accumulate below the wheel and retard its motion. After this ftep the courfe of difcharge, or tail water-courfe to run off the water from the wheel, fhould be floored with wood or mafonry about 16 yards long, having an inch of declivity in every two yards.

The canal which conducts the water from the courfe of difcharge to join the river again, fhould flope about four inches in the firft 200 yards, and three inches in the fecond 200 yards, and fo decreafing gradually till it terminates in the river. But if the river to which the water is conveyed, fhould be fubject to be fwollen by the rains, fo as to force the water back upon the wheel, the canal muft have a greater declivity, in order to prevent this from taking place. Hence it will be evident, that very accurate levelling is neceffary for the proper formation of the mill-courfe. The tail water-courfe ought always to have a very confiderable breadth, which fhould be greater than that of the wheel-race, or part in which the wheel acts, that the water having room to fpread may have lefs depth. The fection of the fluid at the point where it ftrikes the wheel fhould be rectangular, the breadth of the ftream having a determinate relation to its depth. If there is a great ftream of water, the breadth fhould be triple the depth; if there is a moderate quantity, the breadth fhould be double the depth; and if there is very little water, the breadth and the depth fhould be equal. The depth of the water here alluded to is its natural depth, or that which it would have, if it did not meet the float-boards. The effective depth is generally two and a half times the natural depth, and is occafioned by the impulfe of the water on the float-boards, which forces it to fwell, and increafes its action upon the wheel.

As it is of great confequence that none of the water fhould efcape, either below the float-boards or at their fides, without contributing to turn the wheel, the breadth of the float-boards fhould be wider than the fheet of water which ftrikes them. The diameter of the water-wheel fhould be as great as poffible, unlefs fome particular circumftances in the conftruction prevent it; but ought never to be lefs than feven times the natural depth of the ftream or thicknefs of the fheet of water, where it meets the float-boards. The wheel will move irregularly, fometimes quick and fometimes flow, according to the pofition of the floats with refpect to the ftream; unlefs the number of float-boards is confiderable, the wheel muft have fo many floats, that two floats will at leaft be always in the circular fweep at the bottom of the wheel; but in order to remove any inequality of motion in the wheel, and prevent the water from efcaping beneath the tips of the float-boards, it fhould have as many float-boards as poffible, without loading it, or weakening the rim on which they are placed. The float-boards fhould not be perpendicular to the rim, or, in other words, a continuation of the radius, but fhould be inclined to the radius; the water will thus heap upon the float-boards, and act not only by its impulfe, but alfo by its weight. When the velocity of the ftream is eleven feet *per* fecond, or above this, the inclination fhould never be lefs than thirty degrees; or when this velocity is lefs, the inclination fhould diminifh in proportion; fo that when it is four feet, or under, the inclination fhould be nothing, that is, the float-boards fhould point to the centre of the wheel.

It is a ftrong practical objection to this manner of applying the water to the wheel, that when the water of the river finks in dry weather from a deficiency of water, it would not run over the top of the fall, and the mill could not work at all even if it funk only ten or twelve inches: in like manner, when the water rifes in floods, the water at the top of the fall would become fo deep, as to require fome fhuttle to prevent it from inundating the wheels, at the fame time that the ftagnant water in the mill-race would prevent the wheel from working. Almoft all rivers are fubject to floods, and often they rife and fall, three, four, fix, and eight feet above their ordinary level in fair weather; now the water moftly rifes at the tail or difcharge of the water as much as the head, and the wheel-race will therefore be full of ftagnant water, which is called tail-water, and obftructs the motion of the wheel.

In a ground-fhot wheel, where the water iffues from a fhuttle on a level with the bottom of the wheel-race, it can always work in dry feafons, as long as the river contains any water, although the power diminifhes almoft to nothing, when the water finks low, and will not rufh out with force from the fhuttle. In floods of water, this wheel has a greater advantage, becaufe the depth of head which urges the flowing water is increafed when the water is high, and this makes it drive the tail-water forcibly out of the wheel-race, and enable the wheel to work, when a wheel with an inclined fall would infallibly be ftopped.

Breaft-wheels and overfhot-wheels, properly conftructed, have ftill greater advantages, in clearing themfelves from tail-water, and this is a very important object.

Floating-Mill with underfhot Wheels.—A large floating water-mill, to be worked by the tides or currents, was ftationed fome years ago in the river Thames, between London and Blackfriars bridge, by permiffion of the Board of Navigation. Such permiffion having been granted with the view of reducing, if poffible, the price of flour in the metropolis, and contributing to a conftant fupply of that neceffary article of fubfiftence. The fimplicity of this invention renders a long defcription fuperfluous, as it confifts in merely applying the force of two large underfhot water-wheels on each fide of a barge, or any other veffel calculated to contain the interior part of the machinery; the float-boards are difpofed in a proper manner to be acted on by the tide or current, fo as to give the wheels a rotatory motion, and by connecting them with proper machinery, to anfwer the purpofes for which the mill is intended.

Any fhip, brig, floop, or other veffel, may be ufed for this purpofe, provided it is of fufficient fize to accommodate the works to be erected, yet in point of expence it will be better to employ fuch as are rendered unfit for fea-fervice.

When it is intended that the ſhip or mill ſhould be ſtationary, it muſt be anchored, moored, or otherwiſe made faſt, ſo as to ſwing with the tide when neceſſary; but the mill may be worked while the veſſel in which it is erected is ſailing, when wind and other circumſtances permit.

The number and ſize of the water-wheels to be uſed may be varied, according to the ſize of the ſhip or veſſel, or to the ſtrength of the tide or current, and the power required; and the wheels may be conſtructed as in common underſhot mills, or with folding-floats, for the more readily freeing them from the water: two wheels are to be placed vertically, on an horizontal axis, of ſuch length, that, the axis being placed acroſs the ſhip or veſſel, one wheel may run on each ſide of it on the ſame axis.

A mill conſtructed in the manner above deſcribed may be moved by the ſtrength of from two to ſix large water-wheels, or ſuch other number as the ſhip or veſſel will accommodate. Theſe water-wheels may dip into the water from three to four, or more feet deep; they ſhould be ſo connected together as to be eaſily engaged with and diſengaged from each other, ſo that during the weak part of the tide they may all be made to act on one pair of mill-ſtones, if neceſſary; and as the ſtrength of the tide increaſes, more ſtones or other machinery may be put in motion, ſo as at all times to do buſineſs in proportion thereto.

In a mill of this kind the water-wheels do not admit of having water-courſes, or any equivalent contrivances, to conduct the water to the wheels, as in other underſhot wheels; but the float-boards muſt be large enough to receive the power required from merely dipping into the current of the tide-water.

The veſſel of the mill in the Thames is the hull of an old ſhip of two or three hundred tons burthen, which being moored in the river by chains, ſo that it can ſwing round when the tide changes, the wheels will always turn the ſame way round; one water-wheel is fixed on each ſide of the veſſel, a long iron axis being common to both; the extreme ends of the axis are ſupported in a frame-work of timber, and another very ſtrong frame of timber is fixed outſide of the wheels at the level of the water, which floats in the water, and is only attached to the mill by chains; this is to protect the wheels from injury, by veſſels which paſs and repaſs. Each water-wheel is 18 feet diameter, and 14 feet broad; the float-boards are each 3 feet deep, and are about ſixteen in number, affixed on the circumference of cart iron-wheels, or circles, which are 12 feet diameter, there are three of theſe circles for each wheel; hence we find each float-board expoſes a ſurface of 42 ſquare feet to the action of the current, and if we ſuppoſe each wheel to have two floats in action at the ſame time, the power of the mill will be derived from 168 ſquare feet acted upon by the water, which ſeldom exceeds a velocity of four miles *per* hour, or 352 feet *per* minute.

The iron axis of the water-wheels is a hollow tube of nine inches diameter outſide, and five inches within, made in four lengths of 12 feet each, properly joined together, and extending acroſs the veſſel from one wheel to the other. On the middle of this axis a large wheel of 11 feet diameter is fixed, and ſurrounded by a brake or gripe like that uſed in a wind-mill, the uſe of which is to ſtop the mill when it requires repairing. Near to this brake-wheel is a large bevilled cog-wheel 13 feet diameter, with 89 cogs, which gives motion to a bevilled pinion two feet eight inches diameter, with eighteen cogs fixed on the top of a vertical axis. On this axis is alſo a large horizontal ſpur-wheel 12 feet diameter, with 201 cogs, which gives motion to pinions of one foot diameter, and 17 cogs fixed on the ſpindles of the mill-ſtones. There are four pair of mill-ſtones, two pair of $4\frac{1}{2}$ feet and two pair of $3\frac{1}{2}$ feet diameter, and the mill alſo works a dreſſing-machine for the flour. The mill-ſtones make $57\frac{1}{2}$ revolutions for one revolution of the water-wheels, which move very ſlow, ſcarcely two turns *per* minute, in the moſt favourable periods of the tide. The circumference of each taken through the middle of the float-boards is 47 feet; hence the float-boards move about 94 feet *per* minute, when the mill-ſtones make their proper number of revolutions to grind with the greateſt effect.

It was found that on a flood-tide, this mill would drive two pair of $3\frac{1}{2}$ feet mill-ſtones, and a flour dreſſing-machine, but on the ebb-tide only one pair of 4-feet ſtones and the machine; thus it is only the performance of a ſmall mill, although the wheels are of large dimenſions, and it would require enormous wheels to make an effective floating mill in the river Thames.

This machine is now removed from the river, becauſe it was found to do ſo much injury to the veſſels which continually ran againſt its floating frame, and the repairs of the damages frequently done to the mill by ice and the craft took away all the advantages of the mill.

Underſhot Wheels with oblique Floats.—Attempts have been made to conſtruct water-wheels for tide-rivers which receive the impulſe obliquely, like the ſails of a common wind-mill. This would in many ſituations be a great advantage. A very ſlow but deep river could in this manner be made to drive mills; and although much power would be loſt by the obliquity of the impulſe, the remainder might be very great. Dr. Robinſon ſpeaks of a wheel of this kind which was very powerful; it was a long cylindrical frame, having a plate ſtanding out from it about a foot broad, and ſurrounding it with a very oblique ſpiral like a cork-ſcrew. This was immerſed about one-fourth of its diameter (which was nearly 12 feet), having its axis in the direction of the ſtream. By the work which it was performing, it ſeemed more powerful than a common wheel which occupied the ſame breadth of the river. Its length was not leſs than 20 feet; had it been twice as much it would have been nearly redoubled in its power without occupying more of the water-way. It is probable ſuch a ſpiral continued quite to the axis, and moving in a hollow canal wholly filled by the ſtream, might be a very advantageous way of employing a deep and ſlow current.

In the Tranſactions of the Society of Arts, vol. xix. a water-wheel is deſcribed, in which the float-boards are placed obliquely to the axis of the water-wheel at about an angle of 40 degrees, being fixed to the rim in pairs, which are inclined equally to the axis of the wheel, but in oppoſite directions to each other; ſo that the two float-boards of each pair point towards each other in an angle of about 80 degrees, and if the pair of floats were continued they would meet in the middle of the breadth of the wheel. The water is made to ſtrike the floats within this angle, and in conſequence all the water which is emitted by the ſluice and ſtrikes upon the oblique floats will be reflected from the ſides or ends of the two pair of float-boards towards the vertex of the angle, which they make; but the pair of floats do not touch each other, ſo that the vertex of the angle is open; but to prevent the water paſſing freely through the open angle, one of the float-boards is made to extend far beyond the vertex, or point, where they would interſect, and the other is made to fall ſhort of it, nevertheleſs the water would certainly paſs through the opening. It is ſtated, that the motion of the ordinary wheel with parallel floats is greatly retarded by the reſiſtance which they experience in riſing up or quitting the tail-water of the ſtream, from the

preſſure

preſſure of the atmoſphere on their upper ſurface before the air gets admiſſion beneath the floats; but in Beſant's wheel this reſiſtance is greatly diminiſhed, as the floats emerge from the ſtream in an oblique direction. The water-wheel is conſtructed in the form of a hollow drum, ſo as to reſiſt the admiſſion of the water. Although this wheel is much heavier than thoſe of the common conſtruction, yet it revolves more eaſily upon its axis, as the ſtream has a tendency to make it float. We cannot recommend this wheel, but on the contrary think it one of the worſt forms, as it tends to increaſe that loſs which ariſes in all underſhot-wheels from the change of figure which the water muſt undergo when it ſtrikes the float, and we ſhould not have mentioned it, but that it has been ſo frequently copied and recommended by different authors.

Horizontal Water-wheels actuated by the Impulſe of Water.—Theſe have been conſiderably in uſe on the continent, and deſerve our notice from the ſimplicity of their conſtruction. The wheel is conſtructed in the ſame manner as an underſhot-wheel, having float-boards fixed round its circumference in the form of radii; it is mounted on a vertical axis, the upper end of which is fixed to the ſpindle of the mill-ſtone, if the mill is intended to grind corn; but in ſome caſes, it is better to fix a cog-wheel on the upper part of the vertical axis with teeth round its edge, to give motion to trundles or pinions on the ſpindles of the mill-ſtones, becauſe the floats of the wheel muſt always be made to move with a given proportion of the velocity of the water. The wheel-race or water-courſe may be made nearly the ſame as for an underſhot-wheel, if we ſuppoſe it laid down in an horizontal poſition; that is, a trough or channel of maſonry is conſtructed in which the wheel works, and the float-boards of the wheel are exactly fitted to it: at one end of this channel is the aperture or ſluice through which the ſtream of water iſſues, and ſtrikes the floats of the wheel ſo as to turn it round, and the water paſſes forwards and eſcapes at the other end of the channel. When the water is delivered upon the wheel in an horizontal direction, or perpendicular to its axis, the float-boards ſhould be inclined about twenty-five degrees to the plane of the wheel, and the ſame number of degrees to the radius, ſo that the loweſt and outermoſt ſides of the float-boards may be fartheſt up the ſtream and be met by the water firſt.

In many caſes, the water-courſe is made inclined to the plane of the wheel in ſuch a degree, that the water may ſtrike the float-boards perpendicular to their ſurfaces.

In the ſouthern provinces of France, where horizontal water-wheels are generally employed, the float-boards are made of a curvilineal form ſo as to be concave towards the ſtream; they are generally ſegments of ſpheres, or hollow wooden bowls or ladles fixed on the rim of the wheel: the water, in this caſe, is conducted through a pipe, and projected in a jet on a direction a little inclined to the horizon. When the height of water is very conſiderable, this is, perhaps, the beſt form for the floats, or ladles, as they are called.

The chevalier de Borda obſerves, that in theory a double effect is produced when the float-boards are concave, but that the effect is diminiſhed in practice, from the difficulty of making the fluid enter, and leave the curve in a proper direction. Notwithſtanding this difficulty, however, and other defects which might be pointed out, horizontal wheels with concave float-boards are always ſuperior to thoſe in which the float-boards have plane ſurfaces.

Mr. Smeaton conſtructed a ſmall corn-mill with a horizontal water-wheel, of which the following are the principal dimenſions. Fall of water $52\frac{1}{2}$ feet; diameter, or bore of the noſe-pipe through which the water iſſued in a jet to ſtrike upon the wheel, $1\frac{1}{2}$ inch; diameter of the water-wheel 10 feet to the centre of the floats or ladles, which were twelve in number; they were made of a concave form, nearly ſegments of ſpheres, and about 14 inches in diameter; and fixed round the circumference of the wheel, ſo that the planes of the circular rims, or edges of the hollow ladles, were not perpendicular to the plane of the wheel, but inclined thereto in ſuch a degree, that the jet of water iſſuing from the noſe-pipe at an angle of 22 degrees from the horizontal line, would ſtrike the floats in the centre and perpendicular to the circular edge of the hollow; the internal ſurface of the floats being really ſpherical, the water would always ſtrike perpendicularly into the concavity of the bowl. The water-wheel axis roſe up perpendicularly into the mill-houſe, and on the top a wheel of 4 feet 8 inches in diameter, and 44 cogs, was fixed for giving motion to the pinions on the axis of the mill-ſtones. The largeſt pinion of 17 cogs was fixed on the axis of a pair of ſtones 4 feet 6 inches in diameter, and the ſmaller pinion of 13 cogs on the axis of a ſtone 3 feet 6 inches in diameter. It was not intended to turn both theſe pairs of ſtones at the ſame time, but it was neceſſary to have two pairs for different uſes.

When this mill moved with a proper velocity to grind to the greateſt advantage, if the 4 feet 6 inches ſtones were uſed, the water-wheel made 25 revolutions *per* minute, and the ſtones therefore made 65 revolutions *per* minute, and the float-boards moved with a velocity of 784 feet *per* minute; but when turning the ſmaller mill-ſtones of 3 feet 6 inches diameter, the water-wheel went beſt when it made 26 revolutions, and therefore turned the mill-ſtone 88 turns *per* minute; and the velocity of the floats was 816 feet *per* minute.

Mr. Smeaton calculated the velocity of the water iſſuing from the pipe at 3403 feet *per* minute, which is the velocity due to a 50 feet feet, becauſe he allowed the $2\frac{1}{2}$ feet to overcome friction, and the expenditure of the $1\frac{1}{2}$ inch noſe-pipe at 30 cubic feet *per* minute allowing for friction. This mill ground one buſhel of wheat *per* hour, on the average of a great many experiments, now $30 \times 50 = 1500$ cubic feet, falling one foot *per* minute. It is found by repeated experiments, that 600 cubic feet falling one foot *per* minute on a good water-wheel is an ample allowance for grinding a buſhel of wheat, as it may be done by 530; hence this fall of water ought to have ground $2\frac{1}{2}$ buſhels *per* hour inſtead of one. The mill, however, admits of improvement in making the floats of the wheel move quicker.

When the mill-ſtone of an horizontal mill is fixed on the upper end of the axis of the water-wheel, if the mill-ſtone be five feet in diameter, it ſhould never make leſs than ſixty turns in a minute, and the wheel muſt perform the ſame number of revolutions in the ſame time; and in order that the effect may be a maximum, or the greateſt poſſible, the velocity of the current muſt be more than double that of the wheel.

Suppoſe the mill-ſtone, for example, to be 5 feet diameter, and the water-wheel 7 feet, it is evident that the mill-ſtone and wheel muſt at leaſt revolve 60 times in a minute; and ſince the circumference of the wheel is 22 feet, the float-boards will move through that ſpace in the 60th part of a minute, that is, at the rate of 22 feet *per* ſecond; which being doubled, makes the velocity of the water 44 feet one ſecond, anſwering, as appears from the rule, for the velocity of falling water, to a fall of 30 feet. But if the given fall of water be leſs than 30 feet, we may procure the ſame velocity to the mill-ſtone, by diminiſhing

ing the diameter of the wheel. If the wheel, for inftance, is only 6 feet diameter, its circumference will be 18.8 feet, and its floats will move at the rate of 18.8 feet in a fecond, the double of which is 37.6 feet *per* fecond, which anfwers to a head of water 22 feet high. The diameter of the water-wheel, however, fhould never be lefs than 6 or 7 feet, becaufe the float-boards change their direction fo rapidly, in confequence of their proximity to the centre, that they will not receive the full action of the water, becaufe it acts in a perpendicular direction to the float-board only for a moment. Hence there will be a certain height of the fall, beneath which the fimple horizontal wheel cannot be employed; and beyond that, wheel-work muft be introduced to obtain the requifite velocity for the millftones.

In the provinces of Guienne and Languedoc, in France, another fpecies of horizontal wheel is employed for turning machinery. It confifts of an inverted cone, with fpiral float-boards of a curvilineal form winding round its furface. The wheel moves on a vertical axis in a pit or well of mafonry, to which it is exactly fitted, like a coffee-mill in its box. It is driven chiefly by the impulfe of the water, conveyed by a fpout or canal in a ftream, which ftrikes the oblique float-boards; and when the water has fpent its impulfive force, it defcends along the fpiral float-boards, and continues to act by its weight till it reaches the bottom, where it is carried off by a canal. The idea of this machine is ingenious. The jet of water, being firft applied to the upper or largeft part of the cone, ftrikes the float-boards at the part where they move with the greateft velocity, in confequence of their being on the largeft radius; but as the water lofes its velocity, in confequence of the motion it has imparted to the wheel, it defcends in the cone, and acts upon the floats lower down, where, the radius being lefs, the floats move more flowly, and are therefore better adapted to receive the action of the water with its diminifhed velocity.

M. Mannoury Dectot's horizontal Water-Wheel, which he calls Danaide.—This receives the impulfe of the water in a different manner from any which we have defcribed, and is defcribed in a report to the Inftitute of France in 1813. The water-wheel is fixed in a horizontal pofition upon a vertical axis, and fupported upon the pivots thereof, fo as to be capable of turning round. It is not in reality a wheel, but a hollow cylinder or drum capable of containing water; it is open at top, and united to the axis in the centre of the circular plane, which forms the bottom. Within this drum, and concentric with it, a folid cylinder is fixed; it is of lefs dimenfions than the drum itfelf, and occupies fuch portion of the content of the drum as to reduce the open part which can contain water to a hollow ring or circular trough, open at top, and of a confiderable depth, but only a few inches in width. The depth is defcribed as being nearly as great as the diameter of the wheel.

The water coming from an elevated refervoir, is projected in jets from one or more pipes into this annular fpace which furrounds the rim of the wheel. Thefe pipes defcend in an inclined direction, till they are nearly on a level with the furface of the water in the annular fpace; and the extremities turn horizontally, fo as to project the jet horizontally, and in the direction of tangents to the mean circumference of the water contained in the annular fpace.

Suppofe this fpace which furrounds the wheel is full of water, then the ftream iffuing from the jet caufes the wheel to turn round upon its axis, becaufe it takes hold or acts upon the water in the annular fpace, and tends to give the water a circulating motion within the annular fpace; but the friction, or refiftance, which the water would find in fuch circulation, caufes the wheel to turn round with the water, unlefs the load on the wheel, or refiftance to its motion, is too great.

The water which is continually thrown into the wheel efcapes from the annular fpace by paffages which proceed from the bottom thereof to the centre of the wheel; and there are openings at the centre, where the water can drop out *below*. To form the paffages for this purpofe, the folid cylinder which is fixed in the centre of the hollow drum is of lefs depth than the other, and leaves a fpace between the bottom of the folid and the bottom of the hollow, which is divided into compartments by diaphragms fixed upon the bottom of the trough, and proceeding like radii from the circumference to a central hole in the bottom of the trough, which is left open to allow the water to efcape. The report ftates, that the velocity with which the water iffues from the jets makes the machine move round its axis; and this motion accelerates by degrees, till the velocity of the water in the annular fpace equals that of the water from the refervoir, fo that no fenfible fhock is perceived of the affluent water upon that which is contained in the machine. The motion of the wheel is regular, becaufe the action is continual; but in the cafe of other water-wheels, where the water ftrikes againft float-boards, fuch boards muft neceffarily be of a determinate number, and the motion muft be given to the wheel by a fucceffion of impulfes, as the floats arrive before the ftream. We might indeed fuppofe a wheel with an infinite number of floats, but it would then amount to a plain cylindrical or flat furface, upon which the water would not take fufficient hold to produce any fenfible effort to turn it round.

Now in M. Dectot's wheel, in place of float-boards, the rim of the wheel is clothed with water, which is capable of being acted upon by the water iffuing from the jets. This action tends to put the water in the annular fpace in motion, and to carry the wheel along with it, by the adhefion it muft naturally have to the fides of the channel which contains it. The velocity of the wheel will be in proportion to the refiftance that the load makes to its motion.

The circular motion of the wheel communicates a centrifugal force to the water contained in the annular cavity of its rim, which caufes it to prefs againft the outermoft fide of the channel. This centrifugal force acts equally upon the water contained in the compartments at the bottom of the faid rim; but its action diminifhes as the water approaches the centre.

The whole mafs of water is then animated by two oppofite forces, *viz.* gravity and the centrifugal force. The firft tends to make the water run out at the hole in the bottom of the wheel at the centre, and the fecond to drive the water from that hole.

To thefe two actions are joined a third, *viz.* friction or refiftance, which acts an important and fingular part; and in this machine the friction of the water produces its powers of action, while in moft other machines it always diminifhes their powers. The effect in this machine would be nothing, were it not for the refiftance which the water finds oppofed to its free circulation in the annular fpace round the rim of the wheel.

By the combination of thefe three forces there ought to refult a more or lefs rapid flow of water from the hole in the centre at the bottom of the wheel; and the flower this water iffues, the greater will be the effective power of the machine for producing the ufeful effect for which it is deftined.

The moving power in this machine, like all others, is the weight of the water which runs into the wheel, multiplied by by the elevation the reſervoir has above the bottom of the wheel, or orifice from which it iſſues in quitting the ſame; but the uſeful mechanical effect is ſtated to be equal to that product, diminiſhed by half the force which the water retains, when it flows out at the orifice below, and quits the machine.

In order to aſcertain, by direct experiment, the magnitude of this effect, Meſſrs. Prony and Carnot fixed a cord to the axis of the machine, which paſſing over a pulley, raiſed a weight by the motion of the machine. By this means the effect was found to be $\frac{7}{10}$ths of the power, and often approached $\frac{75}{100}$ths, without reckoning the friction of the pulleys, which has nothing to do with the effect.

We cannot help ſuſpecting ſome miſtake in theſe experiments, or in the ſtatement of them, but think the machine deſerves a trial; and if it ſhould produce near the reſult above ſtated, it would be a moſt valuable addition to our means of employing falls of water; and its ſimplicity would be a great recommendation, particularly for corn-mills, becauſe the perpendicular axis is immediately adapted for that purpoſe, without any wheel-work.

Horizontal Mill with oblique Vanes.—In Belidor's Architecture Hydraulique he deſcribes a different form of horizontal mill. The wheel is a circular rim, and the radii or arms are all oblique vanes or floats, preciſely the ſame as the common ſmoke-jack. This wheel is placed horizontally in a well, to which it is exactly fitted, but the rim of the wheel does not touch the circular wall of the well. The axis of the wheel aſcends upwards into the mill-houſe, and the ſpindle of the mill-ſtone is fixed into it. A horizontal arch-way is conducted to the well ſideways, and above the part where the wheel is ſituated. This arch conveys the water into the well over the wheel; and beneath the wheel there is a ſimilar horizontal arch to carry away the water, after it has paſſed through the wheel, that is, in the ſpaces between its vanes or floats. The weight of the water preſſes upon them in a perpendicular direction, and the planes of theſe floats being all inclined to the horizon, the action of the preſſure tends to turn the wheel round on its axis, by the ſame action as the ſmoke upon the vanes of a jack, or like a wind-mill.

The water is ſupplied in ſuch a body through the upper arch, that the well is always kept full, with a conſiderable depth of water preſſing upon the wheel; whilſt the lower arch carries away the water ſo freely, that it runs away from beneath the wheel as faſt as it can paſs through the vanes of the ſame.

The mill deſcribed by Belidor was at Toulouſe, and contained a number of ſuch wheels in a row, each giving motion to one pair of ſtones.

Horizontal Machines moved by the Reaction of Water.—The reaction of water, iſſuing horizontally through a ſpout or orifice, may be employed to communicate motion to machinery; and though this principle has not yet been adopted in practice, it appears from theory, and from ſome detached experiments on a ſmall ſcale, that a given quantity of water, falling through a given height, will produce greater effects by its reaction than by its impulſe. If we ſuppoſe a vertical pipe of any given height, open at both ends, and that water is poured into it at the top, the water will iſſue at the bottom of the pipe with a velocity proportioned in a certain manner to its altitude, becauſe every particle of water which iſſues is preſſed upon and impelled by the weight of all the particles which are above it. Now, ſuppoſe the pipe bent or curved at the bottom, ſo that it will turn the ſtream of water into a horizontal poſition; in this caſe, the preſſure and force, of which we have ſpoken, will be deflected from the vertical direction to the horizontal. Now it is clear that the bent part of the pipe, or ſome part of the interior ſurface of the tube oppoſite to the orifice, muſt ſuſtain all the preſſure which is thus deflected or tranſmitted in another direction; and if the tube is freely ſuſpended, it will retreat before this preſſure, and be put in motion. If we ſuppoſe the tube to have no reſiſtance to motion, then it would receive all the motion of the water, which would not move at all after it iſſued from the orifice, but the orifice and tube would move away from the water. This is an impoſſible caſe, and in reality the motion of the effluent water will be divided between the pipe or tube and the iſſuing water, in proportion to the reſiſtance with which each is loaded. Another and perhaps more familiar explanation is, that the water preſſes againſt every part of the interior part of the pipe, except againſt the orifice or aperture, which is open; and in conſequence, the unbalanced preſſure on the part oppoſite to the orifice will tend to put the pipe in motion. A ſky-rocket mounts in the air from a ſimilar cauſe.

Dr. Barker's mill by the reaction of water was the firſt of this kind of machines, and is deſcribed by Deſaguliers, in 1743. In his Experimental Philoſophy, vol. ii. p. 460, he calls it a machine to prove Mr. Parent's propoſition experimentally, *viz.* that an under-ſhot water-mill does moſt work, when the water-wheel moves with only a third part of the natural velocity of the water that drives it. He ſays, that Dr. Barker had this thought, and communicated it to him, ſaying, that it would be an experimental proof of Mr. Parent's propoſition; in conſequence of which, Deſaguliers made a working model of it, which he ſhewed to the Royal Society, and the experiments upon it, at their meeting in 1742.

It conſiſts of an upright pipe or trunk, communicating with two horizontal branches, like an inverted T; thus, ⊥. This perpendicular pipe is poiſed upon a pivot at the lower end, and the upper end is connected with the ſpindle of the mill-ſtone, or other machine to which it is to communicate motion. The top of the pipe is formed into a funnel, into which a ſtream of water is conducted, and runs down the pipe: the water eſcapes through a hole in each of the horizontal arms, which holes are near the ends of the arms, and open in oppoſite directions, and in ſuch a poſition that they will direct the ſtream of water horizontally, and nearly at right angles to the length of the arms.

Suppoſe water to be poured in at the top of the tube from the ſpout, it will then run out by the holes at the ends of the arms, with a velocity correſponding with the depth of theſe holes beneath the ſurface of the water in the vertical pipe. The conſequence of this muſt be, that the arms muſt be preſſed backwards, for there is no ſolid ſurface at the hole on which the lateral preſſure of the water can be exerted, while it acts with its full force on the inſide of the tube oppoſite to the hole. This unbalanced preſſure, acting upon the oppoſite ſides of both arms, will make the tube and the horizontal arm revolve upon the ſpindle as an axis.

This will be more eaſily underſtood, if we ſuppoſe the orifices to be ſhut up, and conſider the preſſure upon a circular inch of the arm oppoſite to the orifice, the orifice being of the ſame ſize.

The preſſure upon this circular inch will be equal to a cylinder of water, whoſe baſe is one inch in diameter, and whoſe altitude is the height of the fall; and the ſame force is exerted upon the ſhut-up orifice. Theſe two preſſures being equal, and acting in oppoſite directions, the arm will remain at reſt; but as ſoon as the orifice is opened, the water will iſſue with a velocity due to the height of the fall. The preſſure of the water upon the orifice will now be removed, and as the preſſure upon the circular inch oppoſite to to the orifice ftill continues, the equilibrium will be deftroyed, and the arm will move in a retrograde direction, unlefs it is withheld by fome force greater than that preffure.

In the original model made by Defaguliers, the vertical tube was a cylindrical pipe, but the lower arms were of a fquare figure in their crofs fection, and the apertures through which the water iffued were likewife of a rectangular figure, and provided with fliders or fluices, which were regulated by fcrews fo as to increafe or diminifh the openings.

It is clear that the machine muft prefs backwards, and there is no difficulty in underftanding the intenfity of this preffure, when the machine is at reft. But when it is allowed to run backwards, withdrawing itfelf from the preffure, the intenfity of it is diminifhed; and if no other circumftances intervened, it might not be difficult to fay what particular preffure correfponded to any rate of motion. Defaguliers affirms the preffure to be the weight of a column, which would produce a velocity of efflux equal to the difference of the velocity of the fluid and of the machine: and hence he deduces, that its performance will be the greateft poffible, when its retrograde velocity is one-third of the velocity acquired by falling from the furface; in which cafe, it will raife $\frac{8}{27}$ths of the water expended to the fame height.

But this is not a perfect account of the operation; for the water which iffues defcends in the vertical trunk, and then moving along the horizontal arms, partakes of their circular motion. This excites a centrifugal force, which muft be exerted againft the ends of the arms by the intervention of the fluid. The whole fluid contained in the arms is fubject to this action, each part in a degree proportioned to its diftance from the axis, becaufe every particle is preffed with the accumulated centrifugal forces of all the fections that are nearer to the axis. This increafes the velocity of revolution, and this mutual co-operation would feem to lead to a continual acceleration in the velocity of both motions. But, on the other hand, this circular motion muft be given anew to every particle of water, when it enters the horizontal arm. This can be done only by the motion already in the arm, and at its expence; neither can the perpendicular tube furnifh an unlimited fupply. Thus there muft be a velocity which cannot be exceeded even by an unloaded machine.

Improved Form of Dr. Barker's Mill.—This confifts in introducing the fupply of water at the lower end of the tube, inftead of the upper end. It was firft propofed by M. Mathon de la Cour, in the Journal de Phyfique, 1775; and the invention was, 20 years afterwards, claimed by a Mr. Ramfey, and very recently by M. Mannoury Dectot in France. This laft machine is very highly recommended by Meffrs. Perier, Prony, and Carnot, in a report to the Inftitute, from which we make the following extracts.

The water is introduced into the revolving arms at the lower part, through the axle: the pipe which brings the water enclofes the pivot, upon which it turns. This water is brought to the refervoir through a curved canal, by means of which the revolving arms, and the mill which it puts in motion, are placed by the fide of the refervoir, and neither above nor below it, which would much injure the working, and the fimplicity of the machine. By bringing the water from below, by means of a canal, the machine is reduced to a fimple water-wheel, the axis of which is fixed immediately to the moving mill-ftone.

Although the water enters with little velocity into the revolving arms, it caufes them to turn very faft, becaufe the apertures for its egrefs being much fmaller than thofe for its entrance, the velocity at the entrance is reciprocally much fmaller than it is at the egrefs. But this velocity at the egrefs is not an abfolute motion; it is only a relative motion with refpect to the tube from which it iffues, otherwife there would refult a fpontaneous augmentation of power, which would not agree with the principles of mechanics.

The apertures for the entrance and the egrefs of the water being proportioned as they ought to be, in order to obtain the greateft effect; then the report ftates,

1. The reaction, that is, the force of preffure which acts upon the revolving arms, at each of the apertures of egrefs, is equal to the weight of a column of water of the fame bafe as the aperture, and of the height of the level of water in the refervoir.

2. The velocity of the rotation of the arms meafured at the fame points is to the velocity due to the height of the level of the water in the refervoir, as the aperture for the entrance of the water into the mill-wheel is to the fum of the apertures of egrefs.

Whence it follows, by multiplying this force and this velocity, that the effect produced by the machine in a given time is equal to the weight of all the water that the refervoir can furnifh during this time, by the height of the level of the water in the refervoir. Now this product, it is well known, is the utmoft that can be obtained by the beft hydraulic machines.

This difpofition of Dr. Barker's machine has a confiderable advantage, which is, that the column of water which enters into the arms, by preffing from below on the part above, with all the weight of the refervoir, fuftains a great part of the weight of the machine, and confequently greatly diminifhes the friction of the pivot againft the focket in which it turns; while, on the contrary, when the water enters at the top, as in the old reacting machines, which is already very heavy of itfelf, this flowing water confiderably augments the weight, and confequently the refiftance.

This difpofition cannot be ufed, except where the bulk of water is not very confiderable.

As the arms turn, while the conduit which brings the water is immoveable, the pipe that brings the water to enter the collar of the arms is rather lefs than the collar, fo as to leave very little play between them, and is made tight by furnifhing this fmall interval with a leather collar. Another method is by furnifhing the tube at bottom, which is fixed, and the moveable collar of the wheel, with feveral cylindrical and concentrical furfaces, which fit one into the other without touching. The water fills the deep and clofe grooves formed by the cylindrical furfaces, and is fufficient to prevent that which is forced into the wheel from efcaping by the fides.

Dr. Robinfon defcribes a fuperior method of making fuch a joint, as will admit of a free motion, without any lofs or leakage. This is to make the fixed and moveable tubes very true at the joints, fo that one enters into the other, but do not touch. The two tubes are to be made exactly of the fame diameter withinfide at the joint, fo that a band of thin leather can be applied withinfide of the joint, to cover the crevice: this muft be fixed to the interior of the ftationary tube, and the revolving part being fmooth withinfide, will have very little friction, as it is only rubbed by the leather; but there can be no leakage at the joint, becaufe the water will prefs the leather clofe to the moving tube, but as much water will get in between the leather and the moving tube as to make it move fmoothly.

Theory of Barker's Mill.—This is a moft delicate fubject, and

and upon which it does not appear that fufficient experiments have been made to found a certain theory.

Mr. Waring, of the American Philofophical Society, has given a theory of Barker's mill with the laft-mentioned improvement, and, contrary to every other philofopher, he makes the effect of the machine equal only to that of a good underfhot wheel, moved with the fame quantity of water falling through the fame height.

Mr. Gregory, in his Mechanics, vol. ii. has given this paper with fome corrections, and recommends it as the beft theory. The following rules, deduced from his calculus, may be of ufe to thofe who may wifh to make experiments on the effect of this interefting machine.

1. Make each arm of the horizontal rotatory tube or arm of any convenient length, from the centre of motion to the centre of the apertures, but not lefs than one-third (one-ninth according to Mr. Gregory) of the perpendicular height of the water's furface above their centres.

2. Multiply the length of the arm in feet by .6136, and take the fquare root of the product for the proper time of a revolution in feconds, and adapt the other parts of the machinery to this velocity; or if the required time of a revolution be given, multiply the fquare of this time by 1.629 for the proportional length of the arm in feet.

3. Multiply together the breadth, depth, and velocity *per* fecond, of the race, and divide the laft product by 18.47 times (14.27 according to Mr. Gregory) the fquare root of the height, for the area of either aperture.

4. Multiply the area of either aperture by the height of the fall of water, and the product by $41\frac{2}{3}$ pounds (55.775 according to Mr. Gregory) for the moving force, eftimated at the centres of the apertures in pounds avoirdupois.

5. The power and velocity at the aperture may be eafily reduced to any part of the machinery by the fimpleft mechanical rules.

The only account we have of an actual machine, except the firft model by Defaguliers, is by M. Mathon de la Cour, who faw one at Bourg Argental, of the following dimenfions. Length of the revolving arms feven feet eight inches, and diameter three inches; diameter of each orifice $1\frac{1}{8}$ inch; fall of water, from the level furface in the refervoir to the apertures in the revolving arms, twenty-one feet. The water was introduced at the lower end of the revolving axis, through an opening of two inches, the two furfaces being fitted together by grinding.

When this machine was performing no work, and emitted water by one hole only, it made 115 turns *per* minute. This gives a velocity of (24 feet circumference $\times$ 115 $=$) 2760 feet *per* minute for the hole; but the effluent velocity by theory would be only 2215 feet *per* minute at 21 feet height, and in reality would be little more than fix-tenths of that velocity, or about 1370 feet *per* minute. Dr. Robinfon fuppofes even this to be much lefs than the velocity with which the water iffued from the pipe, as we may readily believe, becaufe all the force of the machine was expended in working like a centrifugal pump, to draw the water out of the pipe of fupply, with a velocity greater than that with which it would run by the preffure of the column alone. The empty machine weighed 80 pounds, $28\frac{1}{2}$ pounds of which would be borne up by the preffure of the column of 21 feet on a two-inch bafe, fo that the friction of the pivot would be much diminifhed. We have no account of any work done by the machine, as it was only employed to turn a ventilator for a large hall.

Euler's Machine to act by the Reaction of Water.—His machine confifts of a hollow conchoidal ring, that is, a folid fhaped juft like a large church bell. Suppofe alfo another bell, of fmaller dimenfions, placed within the former, and leaving a fpace all round between the two, the two bells are joined at the lower edges, fo that the water cannot efcape from the fpace between them. This machine is mounted on a perpendicular axis, and on the top is a fort of funnel bafon, which receives the water from the fpout, not in the direction pointing towards the axis, but in the direction of a tangent, and the water is delivered with the precife velocity of the wheel's motion. This prevents any retardation by dragging forward the water. The water paffes down from the funnel or bafon between the outer conchoid or bell, and the inner conchoid, through fpiral channels formed by partitions foldered to both conchoids. The curves of thefe channels are determined by a theory which aims at the annihilation of all unneceffary and improper motions of the water, but which is too abftrufe to find a place here. The water thus conducted arrives at the bottom of the fpace between the two bells. On the lower circumference of this bottom is arranged a number of fpouts, one from each fpiral channel, which are all directed horizontally, and turned one way in tangents to the circumference.

The fame effects will be produced, if we fuppofe only one bell, with a number of tubes or pipes wound in a fpiral direction round its external circumference, the lower ends of each tube being turned horizontally, and in the direction of tangents to the circle which it defcribes, alfo the upper or higher extremities of the tubes, connected with a circular fuperficies into which the water flows from a refervoir. When the machine has this form, it has been fhewn by Albert that the effect will increafe as the velocity is augmented, and that the maximum effect would be produced if the velocity could be infinite, and that then the effect would be equal to the power. A confiderable portion of the power muft, however, be confumed, in communicating to the fluid the circular motion of the tubes; and, as the portion thus loft muft increafe with the velocity of the tubes, the effect will not in reality fuftain an augmentation from an increafe of velocity, beyond a certain point.

It is plain that this form of the machine muft be a moft cumbrous mafs; even in a fmall fize and height it would require a prodigious veffel, and muft carry an unwieldy load. If we examine the theory which recommends this conftruction, we find that the advantages, though real and fenfible, bear but a fmall proportion to the whole performance of the fimple machine, as invented by Dr. Barker. It is therefore to be regretted, that engineers have not attempted to realize the firft project.

Machines actuated by the Weight of Water.—The principal of thefe are breaft-wheels, overfhot-wheels, chains of buckets, and preffure-engines. All thefe have an effential difference from the machines which we have yet defcribed, becaufe the water is prevented from defcending, unlefs the machine moves before the water. This is not the cafe with the machines which receive their motion from the impulfe of the water, becaufe the water is fuffered to defcend and acquire its full velocity before it ftrikes the machine.

In reafoning without experiment, we might be led to imagine, that, however different thefe modes of application are, yet whenever the fame quantity of water defcends through the fame perpendicular fpace, the effective powers of two machines, which are actuated by fuch fall of water, would be equal, provided that the machines were free from friction, and equally well calculated to receive the full effect of the power of water, and to make the moft of it.

For if we fuppofe the height of a column of water to be thirty inches, and that it refts upon a bafe or aperture of one inch fquare, then every cubic inch of water that departs

from

from the lower end of the column will acquire the fame velocity of motion, from the uniform preffure of the thirty cubic inches which are above it, that one cubic inch let fall from the top would acquire in falling down to the level of the aperture, *viz.* fuch a velocity as in a contrary direction would throw or project it to the level from whence it fell, the weights and velocities in both thefe cafes being equal, the products, or what we have called mechanical powers, will alfo be equal. We might therefore be led to fuppofe, that a cubic inch of water, let fall through a fpace of thirty inches, fo as to inpinge upon a folid body, would be capable of communicating thereto an equal motion or mechanical effect by collifion, as if the fame cubic inch had defcended through the fame fpace with a flower motion, and produced the effect gradually; for in both cafes gravity acts upon an equal quantity of matter through an equal fpace.

It is true that the gravitating force acts a longer fpace of time upon the body that defcends flowly, than upon the other which falls quickly; but this cannot occafion the difference in the effect: for we find by experiment, that an elaftic body falling through any given fpace will, by collifion upon another elaftic body which is fixed, rebound nearly to the height from which it fell: or, by communicating its motion to a body equal to itfelf, will caufe that body to afcend to the fame height. On thefe principles we might conclude, as fome authors have done, that whatever was the ratio between the power and effect in underfhot wheels, the fame would hold true in overfhot, and indeed in all others.

However conclufive this reafoning may feem, it will appear, in the courfe of the following deductions, that the effect of the gravity of defcending bodies is very different from the effect of the ftroke, of fuch as are *non-elaftic*, though generated by an equal mechanical power.

It is true that, in the cafes we have above fuppofed, the power of the fall of water is the fame; but the problem propofed to the engineer is, to obtain from it all or as much as poffible of the power, and render it applicable to fome ufeful purpofe. We have already given our definition of *power*, that it is weight or matter compounded with motion. Now to obtain all the power from any ftream of water, we muft abftract from it all its weight and all its motion. In underfhot wheels, or any others moved by the impulfe of the water, we cannot come near this, becaufe we have already fhewn, that the greateft effect is produced, when the velocity of the wheel is two-fifths of the velocity of the moving water. The water, after it has finifhed its effect, is difcharged with that velocity; hence it retains and carries away with it three-fifths of its original power. Neither can we obtain the full effect of the weight of the water, for another lofs is fuftained, in the change of figure which the water experiences, when it ftrikes the float-board. This is much greater than is ufually fuppofed, in confidering machines, although it muft be familiar to any one who confiders the refiftance of a boat, or other body, when drawn through water. No weight is raifed in thefe cafes, unlefs the motion be rapid, (fo as to raife a wave before the moving body;) but all the power is expended in changing the figure of the water, by dividing the particles, and putting them in new pofitions, fo that the body can pafs between them.

It is to this fource that we muft look, for the difference between two-fifths of the power, which we find is abftracted from the whole power of the water by an underfhot-wheel, and one-third of the power, which is the utmoft we can obtain by means of an underfhot wheel.

In the other clafs of machines, which are actuated by the weight of water, we can obtain a much greater fhare of the power of the defcending water. The weight of the water is borne by the machine, which muft therefore receive the whole weight of the water, and the lofs is chiefly in the motion which the water ftill retains after departing from or quitting the machine; but as we are not confined, as in the former inftance, to any fixed velocity of motion for the wheel, we may make it move almoft as flowly as we pleafe, fo that the water will carry away with it a very fmall fhare of the velocity which it would have acquired by falling through the height of the fall. Indeed, if we could fuppofe a wheel to be without friction, and no water to leak or efcape from thofe veffels, or parts of the wheel which contain the water, it would be poffible to obtain an effect from it very nearly equal to the power.

Breaft-Wheels.—Thefe are very commonly called underfhot wheels, becaufe the water runs beneath the wheel, but improperly, becaufe the water does not fhoot againft the floats of the wheel, or at leaft the principal power is derived from the weight of the water. A breaft-wheel partakes of the nature of both an overfhot and an underfhot, and is conftructed as is reprefented in *fig.* 1. *Plate* I. of *Water-wheels.* The lower part of the wheel is furrounded by a curved wall or fweep of mafonry, which is made concentric with the wheel, and the float-boards of the wheel are exactly adapted to the mafonry, fo as to pafs as near as poffible thereto without touching it; and the fide walls are in like manner adapted to the end of the float-board or fides of the wheel, the intention being, that as little water as poffible fhall be able to pafs by the float-boards without caufing the boards to move before it. The water is poured upon the wheel over the top of the breafting at I, the efflux from the mill-dam R being regulated by the fluice or fhuttle M, which is placed in the direction of a tangent to the wheel, and is provided with a rack N, and pinion P, by which it can be drawn up fo as to make any required degree of opening, and admit more or lefs water to flow on the wheel.

The water firft ftrikes on the float, and urges it by its impulfe; but when the floats defcend into the fweep, they form as it were clofe buckets, each of which will contain a given quantity of water, and the water cannot efcape from thefe buckets except the wheel moves, at leaft this is the intention, and the wheel is fitted as clofe as it can be to the race with that view. Each of the portions of water contained in thefe fpaces bears partly upon the wall of the fweep, and partly upon the floats of the wheel; and its preffure upon the floats, if not exceeded by the refiftance, will caufe the wheel to move; hence the action upon all the floats which are within the fweep of the breafting is by the weight of the water alone; but the water is made to impinge upon the firft float-board with fome velocity, becaufe the furface of the water in the dam K is raifed confiderably above the orifice beneath the fhuttle where the water iffues.

The upper part of the fall at I is rounded off to a fegment of a circle called the crown of the fall, and the water runs over it. The lower edge of the fhuttle when put down is made to fit to this curve, fo as to make a tight joint; and in confequence when the fhuttle is drawn up, the water will run between its lower edge and the crown in a fheet or ftream which ftrikes upon the firft float that prefents itfelf, nearly in a direction perpendicular to the plane of the float-board, or of a tangent to the wheel. The float-boards of the wheel are directed to the centre, but there are other boards placed obliquely which extend from one float-board to the rim of the wheel, and nearly fill the fpace between one float-board and the next. Thefe are called rifing-boards, and the ufe of them is to prevent the water flowing over the float-board into the interior of the wheel; but the edges of thefe these boards are not continued so far as to join to the back of the next float, because that would make all the boards of the wheel close, and prevent the free escape of the air when the water entered into the spaces between the floats.

As the water strikes with some force, the rising-board is very necessary, to prevent the water from dashing over the float-boards into the interior of the wheel.

This is the form of breast-wheel employed by Mr. Smeaton in the great number of mills which he constructed ; but although he speaks of the impulse of the water striking the wheel, he always endeavoured to make the top of the breasting or crown of the fall as high as possible, so as to attain the greatest fall and the least of the impulsive action. All rivers and streams of water are subject to variation in height from floods or dry seasons, and in some this is very considerable ; it was therefore necessary to make the crown I of the fall at such a height as that in the lowest state of the water R, it would run over the crown in a sheet of three or four inches in thickness, and work the wheel. When the water rose higher in the mill-dam, it would then have a pressure to force it through, and in that case would strike the wheel so as to impel it by the velocity.

Mr. Smeaton was well aware that the power communicated by this impulse was very small. In some cases, where the water was very subject to variation, he used a false or moveable crown, that is, a piece of wood which fitted to the crown I, and raised the surface thereof a foot or more, so as to obtain the greatest fall when the water stood at a mean height ; but when the water sunk too low to run over this moveable crown, it could be drawn up to admit the water beneath it. This effect has since been produced in a more perfect manner by making the crown of the fall a moveable shuttle, to rise and fall according to the height of the water in the mill-dam, by which means the inconvenience before-mentioned is avoided.

Improved Breast-wheel, in which the Water runs over the Shuttle.—*Fig.* 7. is a section of one of this kind. A is the water which is made to flow upon the float-board B, and urges the wheel by its weight only, the water being prevented from escaping or flowing off the float-boards by the breast or sweep D D, and the side-walls which inclose the floats of the wheel. The upper part of the breast D D is made by a cast-iron plate, curved to the proper sweep to line with the stone-work. On the back of the cast-iron plate the moving shuttle *e* is applied ; it fits close to the cast-iron so as to prevent the water from leaking between them, and the water runs over its upper edge. F is an iron groove or channel let into the masonry of the side-walls, and in these, the ends of the sliding shuttle are received ; *f* is an iron rack, which is applied at the back of the shuttle, and ascends above the water-line where the pinion *g* is applied to it to raise or lower the shuttle. The axis of the pinion is supported in a frame of wood I I ; *h* H is a toothed sector and balance-weight, which bears the shuttle upwards, or it might otherwise fall down by its own weight, and put the mill in motion when not intended. G is a strong planking, which is fixed across between the two side-walls, and retains the water when it rises very high, as in time of floods ; but in common times the water rises only a few inches above the lower edge of the planking. When the shuttle is drawn up to touch this lower edge, the water cannot escape ; but when the shuttle is lowered down, it opens a space *e* through which the water flows upon the float-boards of the wheel. This was the form first adapted for the falling-shuttle, but its construction has since been much improved.

Fig. 4. *Plate* II. is a section of the most improved form for a breast-wheel, taken from the Royal Armoury Mills, at Enfield Lock, erected by Messrs. Lloyd and Ostel. The general description of this, is like the former, but it is constructed in a better manner, and unites strength with durability. The breast of masonry is surmounted by a cast-iron plate A $2\frac{1}{2}$ feet high, which is let into the masonry of the side walls at each end, and the lower part is formed with a flanch, by which it is bolted to the stone-breast at top. This plate is made straight at the back for the shuttle B to lie against, and it slides up and down. The ends of the gate are guided by iron groove pieces or channels which are let into the stone-work of the side walls, and being made wedge-like, they fix the ends of the cast-iron breast fast in its place. The grooves are not upright, but inclined to the perpendicular so much, that the plane of the gate is at right angles to a radius of the wheel drawn through the point where the water falls upon the wheel. D is a strong plank of wood, extended between the iron grooves just over the shuttle. When the shuttle is drawn up it comes in contact with the lower side of this piece of wood, and stops the water ; but the piece D is fixed at such a height, that the water will run clear beneath it, unless its surface rises above its mean height.

The float-boards of the wheel do not point to the centre of the wheel, but are so much inclined thereto that they are exactly horizontal at the point where the water first flows upon them. In this way, the gravity of the water has its full effect upon the wheel, and the boards rise up out of the tail-water in a much better position, than if they pointed to the centre of the wheel ; and this is more particularly observable when the wheel is flooded by tail-water penned up in the lower part of the race, so that it cannot run freely away from the wheel. The dimensions of this wheel are as follow :—Diameter 18 feet to the points of the floats, and 14 feet wide ; the float-boards are 40 in number, each 16 inches wide, and each rising-board 11 inches wide. The wheel is formed of four cast-iron circles or wheels, each 14 feet 8 inches diameter, placed at equal distances upon the central axis, which is 14 feet 8 inches long between the necks or bearings, and 9 inches square ; the bearing-necks are $9\frac{1}{2}$ inches diameter. The wheel is calculated to make four revolutions *per* minute, which gives near $3\frac{1}{2}$ feet *per* second for the velocity with which the float-boards move. The fall of water is six feet, and the power of the wheel, when the shuttle is drawn down one foot perpendicular, equal to 28-horse power.

Breast-Wheel with two Shuttles.—In this wheel the piece of wood marked D in the last figure, is fitted into the groove of the shuttle, and is provided with racks and pinions to slide up and down, independently of the lower shuttle. The intention of this is, to make the lower shuttle rise and fall, according to the height of the water, so that the water shall always run over the top of it, in the proper quantity to work the mill with its required velocity, whilst the upper shuttle is only used to stop the mill by shutting it down upon the lower shuttle, and preventing the water from running over it. This plan is used when the mill is to be regulated by a governor, or machine to govern its velocity ; in that case the governor is made to operate upon the lower shuttle, and will raise it up, or lower it down, according as the mill takes too much or too little water, and this regulates the supply ; but the upper shuttle is used to stop the mill, and by this means the adjustment of the lower shuttle is not destroyed, but when set to work again, it will move with its required velocity. *Fig.* 3. *Plate* II., *Water-wheels*, is a section of one of the water-wheels at the cotton-mills of Messrs. Strutt, at Belper, in Derbyshire. The width of this wheel is very great, and to render the shuttles A B firm, a strong grating

grating of caſt-iron, is fixed on the top of the breaſt K, and the ſhuttles are applied at the back of the grating E, ſo as to ſlide up and down againſt it, the ſtrain occaſioned by the preſſure of the water being borne by the grating. The lower ſhuttle is moved by means of long ſcrews, *a*, which have bevilled wheels, *b*, at the upper ends, to turn them, by a connection of wheel-work with the wheel-work of the mill. The upper ſhuttle, A, is drawn up or down by racks and pinions, *c*, which are turned by a winch, or handle. The bars of the grating E are placed one above the other, like ſhelves, but are not horizontal; they are inclined, ſo that the upper ſurfaces of all the bars form tangents to an imaginary circle of one-third the diameter of the wheel deſcribed round the centre thereof. Theſe bars are not above half an inch thick, and the ſpaces between them are $2\frac{1}{2}$ inches. The bars are of a conſiderable breadth, the object of them being to lead the water, with a proper ſlope, from the top of the lower ſhuttle A to flow upon the floats of the wheel. This diſpoſition allows the ſhuttles to be placed at ſuch a diſtance from the wheel as to admit very ſtrong upright bars of caſt iron to be placed between the wheel and the ſhuttles, for the ſhuttles to bear againſt, and prevent them from bending towards the wheel, as the great weight of water would otherwiſe occaſion them to do. Theſe upright bars are very firmly fixed to the ſtone-work of the breaſt at their lower ends, and the upper ends are faſtened to a large timber, D, which is ſupported at its ends in the ſide walls, and has a truſs-framing applied to the back of it, like the framing of a roof, to prevent it from bending towards the wheel. The upright bars are placed at diſtances of five feet aſunder, ſo as to ſupport the ſhuttles in two places in the middle of their length, as well as at both ends; and large rollers are applied in the ſhuttle, where it bears againſt theſe bars, to diminiſh the friction, which would otherwiſe be very great.

Theſe precautions will not appear unneceſſary when the ſize of the work is known. The wheel is $21\frac{1}{2}$ feet in diameter, and 15 feet broad; the fall of water is 14 feet, when it is at a mean height; the upper ſhuttle is $2\frac{1}{2}$ feet high, and 15 feet long; the lower ſhuttle is 5 feet high, and the ſame length, ſo that it contains 75 ſquare feet of ſurface expoſed to the preſſure of the water: now taking the centre of preſſure at two-thirds of the depth, or $3\frac{1}{3}$ feet, we find the preſſure equal to that depth of water acting on the whole ſurface; that is, the weight of $3\frac{1}{3}$ cubic feet of water = 208 lbs. bears on every ſquare foot of ſurface, which is equal to 15,600 lbs., or near 7 tons on the lower ſhuttle only; but if we take the two ſhuttles together, the ſurface is 112 ſquare feet, and the mean preſſure 312 lbs. upon each, or 16 tons in the whole. The wheel has forty float-boards pointing to the centre. The wheel is made of caſt-iron. There are two wheels of the dimenſions above ſtated, which are placed in a line with each other, and are only ſeparated by a wall which ſupports the bearings; for they work together as one wheel, and the ſeparation is only to obviate the difficulty of making one wheel of ſuch great breadth as 30 feet, though this is not impoſſible, for there is a wheel in the ſame works 40 feet in breadth, but it is of wood and not in iron, framed in a particular manner, as we ſhall ſoon deſcribe.

Mr. Buchanan's Bucket Water-Wheel for a low Fall.—We have already ſhewn, that where water can be made to act on a wheel by weight, it is much more effectual than when the ſame water is made to act by impulſe; and we ſhall ſhew this more fully in ſpeaking of overſhot-wheels.

Where the fall is leſs than half the diameter of the wheel, if the buckets are made in the uſual form of the buckets for overſhot-wheels, the difficulty of filling them with water, and the ſhort time they are able to retain the water, are ſuch great defects, that in ſuch caſes breaſt-wheels, with open float-boards, ſuch as we have deſcribed, have been found in practice to be more advantageous than bucket-wheels.

Mr. Buchanan ſuggeſts, that, by adopting another form of the buckets, they might be ſo made as to be eaſily filled, and at the ſame time capable of retaining the water in a ſituation to produce nearly its full effect altogether by weight, on a low fall.

In a wheel of this conſtruction, contrary to the uſual practice, the water muſt be poured into the buckets from within the circle of buckets inſtead of from without the circle of buckets. How the filling of the buckets from within can be accompliſhed may not at firſt be obvious; but it may be done without the pentrough, which ſupplies the water, making any interference with the arms of the wheel, if it is conſtructed as ſhewn in *figs*. 4. and 5. *Plate* I. *Water-wheels*. *Fig*. 4. is an horizontal ſection of the wheel, and plan of the pentrough; and *fig*. 5. an elevation of the water-wheel.

The buckets in the figure, empty themſelves by means of apertures on the outſide of the wheel, which are the whole length of the buckets, but no wider than juſt ſufficient to diſcharge the water from the buckets when they arrive at the bottom of the wheel, and before they begin to aſcend. A A is the pentrough, into which the ſupply of water is conducted. From B to C a part of the wheel is repreſented, with the ſhrouding removed, to ſhew the form of the buckets, and the ſituation of the water in them; *a*, *a*, *a*, are the apertures by which the water eſcapes from the buckets; *b* the aperture by which the water enters from the pentrough to the buckets. The plan, *fig*. 4., ſhews, that the arms, N N, of the wheel, and the circular rims which ſupport the buckets, occupy only a ſmall part of the breadth of the circular ring of buckets M; ſo that about one-third of the length of the buckets at each end is expoſed on the inſide of the circle, and againſt theſe parts the penſtock is applied, as ſhewn at A A, and the arms and rim of the wheel, move clear of it; but the buckets, as they paſs, receive water, which flows in a continual ſtream at the orifices, *b*, *b*, of the pentrough; the buckets there become filled from the inſide. The partition-boards or plates which form the buckets are repreſented by the white lines in *fig*. 5., and are ſo ſhaped, that they will retain nearly the whole of the water until they arrive at the loweſt *a*; the water then begins to eſcape, and by the time that each bucket arrives at the loweſt point of the wheel, it will have diſcharged all the water, and will riſe up empty.

This is a truly ingenious contrivance; but we fear that in the execution it would preſent many difficulties, particularly the ring of buckets M, which could not, we think, be ſo firmly affixed, ſupported by the narrow bearing of the two rings and arms N, as to preſerve their circular figure for any great length of time; and any bending or warping of ſuch a heavy maſs as a water-wheel will ſoon deſtroy it. Neither is the advantage which could be derived from receiving the water in cloſe buckets, inſtead of open float-boards, ſo great as is generally imagined.

On the Power and Effect of Breaſt-wheels.—We ſhall fully examine the different effects of the power of water, when acting by its impulſe and by its weight, under the title of *overſhot-wheels*. In breaſt-wheels of the common conſtruction, the effects of impulſe and weight are combined; but what is there deſcribed being carefully attended to, the application of the ſame principles in theſe combined caſes will be eaſy.

All

All kinds of machines, where the water cannot defcend through a given fpace, unlefs the wheel moves therewith, are to be confidered as of the fame nature with overfhot-wheels, and equal in power and effect to an overfhot-wheel, in which the perpendicular height that the water defcends from is the fame. All thofe machines that receive the impulfe or fhock of the water, whether in an horizontal, perpendicular, or oblique direction, are to be confidered of the fame nature as underfhot-wheels. Therefore, in a wheel which the water ftrikes at a certain point below the furface of the water in the mill-dam, and after that defcends in the arc of a circle, preffing by its gravity upon the floats of the wheel, the power will be equal to the effect of an underfhot-wheel, whofe fall is equal to the difference of level, between the furface of the refervoir and the point where it ftrikes the wheel, added to that of an overfhot, whofe height is equal to the difference of level between the point where it ftrikes the wheel and the level of the tail-water.

It is here fuppofed that the wheel receives the fhock of the water at right angles to its radii, and that the velocity of its circumference is properly adapted to receive the utmoft advantage of both thefe powers; otherwife a reduction muft be made on that account.

Mr. Oftel, an experienced engineer, informs us, that the velocity of the water-wheel's circumference fhould always be between three and four feet *per* fecond; but he has not been able to determine which of thefe two velocities is the beft, except in cafes where a wheel is fubject to be flooded by tail-water; and in that cafe four feet *per* fecond is beft. Mr. Smeaton advifed $3\frac{1}{2}$ feet.

On overfhot Water-Wheels.—An overfhot-wheel is fimply a circular ring of open buckets, fo difpofed round the circumference of a vertical wheel, as to receive the water from a fpout placed over the wheel in fuch a manner, that the buckets on one fide of the wheel fhall be always loaded with water, whilft the other fide is empty: in confequence, the loaded fide will caufe it to defcend; and by this motion the water runs out of the lower buckets, while the empty buckets of the rifing fide of the wheel, in their turn come under the fpout, and are filled with water.

A machine fo fimple does not appear to prefent any difficulties in its execution, which fhould require any application of theoretic reafoning to remove them; but in reality it is a matter of fome delicacy to conftruct a wheel in fuch a manner as to obtain the greateft effect from a given fall of water.

It is probable, that the earlieft overfhot water-wheels confifted of a number of wooden boxes or bowls, faftened on the circumference of the wheel; but thefe would foon give place to a better mode of conftruction, in which the circumference of the wheel being furrounded by a circular ring at each fide, the fpace between them was divided into feparate buckets by partition-boards. Thefe partitions did not point to the centre of the wheel in the direction of radii, but were inclined thereto nearly in an angle of forty-five degrees. By this means, the water which iffued from the fpout of the trough above, nearly in an horizontal direction, as a tangent to the wheel, would run into the buckets, and fill them as they arrived in fucceffion at the top or higheft point of the wheel; but as the buckets changed their pofition by the defcending-motion of one fide of the wheel, they would become inclined, and the water contained in the buckets would begin to run over the edges of the partitions between the buckets, and by the time the bucket arrived at the bottom point of the wheel, the whole of the water would be run out and leave the bucket empty, and they would remain empty whilft they afcended on the oppofite fide of the wheel. By this means, a conftant preponderance of one fide of the wheel would be kept up by the water falling into the buckets at the top of the wheel, and flowing from it at the bottom.

The points chiefly to be confidered in conftructing an overfhot-wheel are, firft, that the water fhall be applied on the circumference of the wheel, fo as to be incapable of defcending without communicating motion to the wheel, until the water has defcended to its loweft pofition, and that it fhall then quit the wheel entirely; fecondly, that the utmoft height of fall fhall be attained and ufefully employed; and thirdly, that the load or refiftance to the motion of the wheel fhall be fo adapted and proportioned to the weight of water which is applied in the defcending-buckets of the wheels, that the wheel will move flowly; becaufe we have before fhewn, that whatever velocity the wheel moves with, fo much velocity the water muft retain when it quits the wheel, and will thus carry away fome power with it.

We fhall now proceed to confider all the particulars which contribute to the attainment of thefe objects, taking Mr. Smeaton for our guide, and only adding fuch obfervations as appear neceffary to render his maxims more clear.

I. *On the maximum Effect which can be obtained from a Fall of Water by Means of an overfhot-Wheel.*—The effective power of the fall of water muft be reckoned upon the whole defcent, becaufe it muft be raifed that height, in order to be in a condition to produce the fame effect a fecond time. The ratio between the powers of the falling water fo eftimated, and the mechanical effects produced by the wheel at the maximum, deduced from the mean of feveral of Mr. Smeaton's experiments, is as 3 to 2 nearly. We have before, in our obfervations upon the effects of underfhot-wheels, fhewn that the general ratio of the power to the effect, when greateft, was 3 : 1. The effect, therefore, produced by an overfhot-wheel, under the fame circumftances of quantity and fall of water, is at a medium, double that produced by an underfhot. From this, it appears that non-elaftic bodies, when acting by their impulfe or collifion, communicate only a part of their original power; the other part being fpent in changing their figure in confequence of the ftroke.

The ratio of the power to the effect, computed upon the height of the wheel only, was, at a maximum, as 10 : 8, or as 5 : 4 nearly, becaufe Mr. Smeaton made the wheel of a lefs height than the fall of water, in order to allow fome run or defcent of the water through the fpout or trough, which conducted it into the buckets of the wheel. We find the ratio, between the power and effect, to continue the fame, in cafes where the conftructions are fimilar; hence we muft infer, that the effects, as well as the powers, are as the quantities of water and perpendicular heights multiplied together refpectively.

II. *On the moft proper Height of the Wheel, in Proportion to the whole Defcent.*—The preceding obfervation fhews, that the effect which can be obtained from the fame quantity of water, defcending through the fame perpendicular fpace, is double when it is made to act by its gravity upon an overfhot-wheel, to what could be obtained from it when made to act by its impulfe upon an underfhot-wheel.

Hence it follows, that the higher the wheel is, in proportion to the whole defcent, the greater will be the effect; becaufe an overfhot-wheel depends lefs upon the impulfe of the water when it firft ftrikes the wheel, and more upon the gravity of the water in the buckets. The water which is conveyed into the buckets can produce very little effect by its impulfe, even if its velocity be great; both on account of

 the

the obliquity with which it ftrikes the buckets, and in confequence of the lofs of water occafioned by a confiderable quantity of fluid being dafhed over their fides. Inftead, therefore, of expecting an increafe of effect from the impulfe of the water occafioned by its fall through fome part of the whole height, we fhould caufe it to act through as much as poffible of this height by its gravity, by making the diameter of the wheel as great as poffible. But a difadvantage attends even this rule; for if the water is conveyed into the buckets with a very fmall velocity, which muft be the cafe when the diameter of the wheel equals the height of the fall, the velocity of the wheel will be retarded by the impulfe of the buckets ftriking againft the water, in order to put it in motion, and much power would be loft by the water dafhing over them. In order, therefore, to avoid all inconveniences, the diftance of the fpout from the receiving-bucket fhould, in general, be about two or three inches, that the water may be delivered with a velocity a little greater than that of the wheel; or, in other words, the diameter of an overfhot-wheel fhould be two or three inches lefs than the greateft height of the fall; and yet it is no uncommon thing to fee the diameters of thefe wheels fcarcely one-half of that height. In fuch a conftruction, the lofs of power is prodigious.

It is always defirable that the water fhould have fomewhat greater velocity, than the circumference of the wheel in coming thereon, otherwife the wheel will not only be retarded by the buckets ftriking the water, but thereby dafhing a part of it over fo much of the power is loft.

The velocity that the circumference of the wheel ought to have, will be known by what we fhall fay next, and the depth of column requifite to give the water its proper velocity, is eafily computed from the rules and tables given in this article, and will be found much lefs than what is generally fuppofed.

This maxim obliges us to ufe a wheel, whofe diameter is nearly equal to the whole fall; but we fhall not gain any thing by employing a larger wheel. It is true, we could then apply the water upon a part of the circumference where the weight will act more perpendicularly to the radius, but we fhould lofe more, by the neceffity of difcharging the water at a greater height from the bottom, becaufe the water, in all cafes, begins to run out of the buckets long before they arrive at the bottom of the wheel.

Suppofe the buckets of both wheels equally well conftructed in either cafe, whether the wheel is only as high as the fall, or of a greater height, then the heights above the bottom, where they will difcharge the water, will increafe in the proportion of the diameter of the wheel. That we fhall lofe more by this, than we gain by a more direct application of the weight, is plain without any further reafoning, by taking the extreme cafe, and fuppofing our wheel enlarged to fuch a fize, that the ufelefs part below would be equal to our whole fall. In this cafe, the water would be fpilled from the buckets as foon as it is delivered into them. All intermediate cafes, therefore, partake of the imperfection of this. It was the object of Mr. Buchanan's bucket-wheel, which we have already defcribed, to avoid this difficulty, and employ a height of fall which bore only a fmall proportion to the whole height of the wheel. This obfervation neceffarily leads us to confider the beft form for the buckets.

III. *On the beft Form for the Buckets of overfhot Wheels.*—It is impoffible to conftruct the buckets fo that they will remain completely filled with water till they reach the bottom of the wheel: indeed, if the buckets were formed by partitions directed to the axis of the wheel, the whole water muft run out by the time they have defcended to the level of the axis; and, in confequence, there muft be a great diminution in the mechanical effect of the wheel. Millwrights have, therefore, turned their chief attention to the determination of a form for the buckets which fhall enable them to retain the water through a great portion of the circumference of the wheel. An infpection of *figs.* 2 and 3 will fhew at once the proper form which has been eftablifhed by long practice. Thefe are called elbow-buckets, becaufe each partition is formed by two boards, which are put together with an angle or elbow. The rule for fetting thefe out is, to divide the wheel into the number of buckets it is intended to have; then take four-fifths of the fpace or interval between two partitions for the depth of the fhrouding, that is, the breadth of the circular rings at the fides of the wheel, which form the ends of the buckets, and are called the fhrouds; whilft the planking, which forms the bottom of all the buckets, is called the fole of the wheel. That board of each partition which is in the direction of a radius to the wheel, rifes from the fole half the depth of the fhroud; the other board of the bucket is fo inclined, that its outer end fhall be advanced beyond the line of the next radius-board, if it was produced.

It is a great advantage to make the partitions of the buckets thin, particularly the edges of the partitions, which will meet and divide the ftream of water flowing upon the wheel; and if thefe edges are not made fharp, they will fplafh the water about; the edges are, therefore, finifhed by iron-plate, or it is better to make all the inclined parts of the partition of iron-plate. The greater number of buckets, and the fhallower they are, the more regularly the wheel will act. The limits are, that the mouths of the buckets fhall be of fuch width as to allow the air to efcape, at the fame time that the ftream of water flows in; and alfo that the breadth of the wheel fhall not be extravagantly great, to make its buckets contain as much water as would produce the power required from the wheel.

The lofs of water, at the lower part of the wheel, will very much depend upon the proportion of water which is poured into each bucket. It is evident, that if the buckets, of whatever form they are made, were totally filled when at the top of the wheel, they muft begin to fpill the water immediately when they departed from that pofition. But, on the other hand, if only a part of the content of each bucket is filled with water, then it will bear a greater degree of inclination, and be a longer time before the water will begin to fpill from the bucket. This is a reafon for making large buckets, and filling only a part of their contents. In practice a medium muft be ftruck between thefe contending circumftances, and the wheel will act to advantage.

It has been propofed to apply another bend to the partition-boards of each bucket which fhall be beyond the inclined board that we have defcribed, and fhall be concentric with the rim of the wheel, in the fame manner as is reprefented in Mr. Buchanan's wheel, *fig.* 5. It is true that this form would retain the water from fpilling for a longer time, and thus be an advantage; but it is not favourable for admitting the water into the buckets when at the top of the wheel.

The inclined boards, when made as we have defcribed, may be exactly in the line of the ftream of water, which iffues from the fpout when it paffes beneath fuch ftream; and in this way, if the edge of the inclined board is made thin, there will be as little fplafhing of the water as poffible. But by the addition of another part to the edge of the partition, which is concentric to the circle of the wheel, the ftream of water cannot be made to proceed exactly in the line

line of the partition, and will therefore ſplaſh the water. The ſplaſhing may appear immaterial, but it is in reality very prejudicial, becauſe the broken water fills the mouth of the bucket, and prevents the air from getting out readily, and it is for this reaſon that it is very neceſſary to allow ſo much of the fall above the height of the wheel, as will make the water run into the buckets, with a little greater velocity than the motion of the wheel.

Dr. Robinſon, in the Encyclopædia Britannica, deſcribed a plan for the buckets of an overſhot wheel, which was invented by Mr. Robert Burns, millwright, and executed by him at a cotton-mill in Scotland: it is ſhewn in *fig.* 5. *Plate* II. *Water-wheels*. In this way, the wheel has two ranks of buckets, one within the other. The buckets conſiſt of a partition A B, in the direction of a radius of the wheel, which is joined to another B C, inclined to that, and alſo to a third C D, which is concentric with the rim of the wheel.

The bucket is divided into two, by a partition L M, alſo concentric with the rim of the wheel, and ſo placed as to make the inner and outer portions of the bucket nearly of equal capacity. It is evident, without any farther reaſoning, that this partition will enable the double bucket to retain its water much longer than the ſingle one could. When they are filled only one-third, they retain the whole water at eighteen degrees from the bottom of the wheel, and they retain half of the water at eleven degrees. The only objection is, that they do not admit the water quite ſo freely as buckets of the common conſtruction.

This ariſes from the air, which muſt find its way out to admit the water, but is obſtructed by the entering water, and occaſions a great ſputtering at the entry. This may be entirely prevented, by making the ſpout conſiderably narrower than the wheel, and will leave room at the two ends of the buckets for the eſcape of the air. It was found in practice, that a ſlow moving wheel, allowed one half of the water to get into the inner buckets, eſpecially when the partitions which form the inner buckets, did not altogether reach the radius drawn through the lip D of the outer bucket. The doctor conſiders this as a very great improvement of the bucket-wheel; and when the wheel is made of a liberal breadth, ſo that the water may be very ſhallow in the buckets, it ſeems to carry the performance as far as it can go. Mr. Burns made the firſt trial on a wheel of twenty-four feet diameter, and its performance is manifeſtly ſuperior to that of the wheel which it replaced, and which was a very good one. It has alſo another valuable property. When the ſupply of water is very ſcanty, a proper adjuſtment of the ſtream of water iſſuing from the ſpout, will direct almoſt the whole of the water into the outer buckets; which, by placing it at a greater diſtance from the axis, makes ſome addition to its mechanical energy.

IV. *Concerning the proper Velocity of the Circumference of an overſhot Wheel, in order to produce the greateſt Effect.*—If a body of water is let fall freely from the ſurface of the water in the upper reſervoir to the bottom of the deſcent, it will take a certain time in falling; and in this caſe, the whole action of gravity will be ſpent in giving the water a certain velocity. But if this water in falling is intended to act upon ſome machine, ſo as to produce a mechanical effect, the falling water muſt be retarded, becauſe a part of the action of gravity is then ſpent in producing the effect, and the remainder only will give motion to the falling water, which motion it will retain, after it has quitted the machine. On this principle, the ſlower a body deſcends the greater portion of the action of its gravity can be applied to produce mechanical effect, and in conſequence the greater that effect will be.

If a quantity of water falls from a ſtream, into each bucket of an overſhot-wheel, it is there retained until the wheel, by moving round, diſcharges it. Now, the ſlower the wheel moves, the more water each bucket will receive, becauſe it remains a longer time beneath the ſpout, ſo that what is loſt in the ſpeed with which the wheel moves, is gained by the preſſure of a greater quantity of water acting in the buckets at once; and if conſidered only in this light, the mechanical power of an overſhot-wheel to produce effects will be equal, whether it moves quick or ſlow. The popular reaſoning adduced to prove this has been of the following kind. Suppoſe that a wheel has thirty buckets, and that four cubic feet of water are delivered in a ſecond on the top of the wheel, and diſcharged, without any loſs by the way, at a certain height from the bottom of the wheel.

It is clear that this ſtream will ſupply the ſame quantity, whatever is the rate of the wheel's motion; and the buckets muſt be of a ſufficient capacity to hold all the water which falls into them when the wheel moves very ſlow. Suppoſe this wheel employed to raiſe a weight of any kind, for inſtance to draw a baſket of coals out of a deep pit or mine, and that the rope winds upon a barrel of ſuch ſize that the baſket will be drawn up with the ſame velocity as the water in the buckets deſcends. Suppoſe, further, that the wheel will make four revolutions in a minute, or one turn in fifteen ſeconds, when the load or weight in the baſket which forms the reſiſtance to the motion of the machine is one-third of the load of water contained in the buckets of the wheel.

Now, during the time of one revolution, ſixty cubic feet of water will have flowed into the thirty buckets, and each have received two cubic feet. In this caſe, the baſket may contain a weight equal to twenty cubic feet of water, which weight will be drawn up a height equal to one circumference of the wheel, during one turn of the wheel, or in fifteen ſeconds of time.

Now ſuppoſe the machine ſo loaded, by making the baſket more capacious, that the wheel can only make two turns in a minute, or one turn in thirty ſeconds, then each deſcending bucket of the wheel will receive four cubic feet of water. If the baſket contained a double weight, *viz.* equal to forty cubic feet, the effect produced by the machine would be the ſame as before, becauſe the velocity is only one half; but we find in practice, that it will raiſe more than in this proportion when it moves ſlower, for if we attend to what we have juſt obſerved of the falling body, we find that ſo much of the action of gravity as is employed in giving motion and velocity to the wheel and water therein, muſt be ſubtracted from its preſſure upon the buckets. The product made by multiplying the number of cubic inches of water which act on the wheel at once by its velocity, will be the ſame in all caſes; yet, as each cubic inch, when the velocity is greater, preſſes more lightly upon the buckets than when the velocity is leſs, the power of the water to produce effects will be greater in the leſs velocity than in the greater. This leads us to the general rule, that the leſs the velocity of the wheel, the greater will be the effect produced by any given quantity, and fall of water.

A confirmation of this doctrine, together with the limits it is ſubject to in practice, is a matter of experiment and obſervation which has been ably decided by Mr. Smeaton. The velocity of the wheel ſhould not be diminiſhed, further than what will produce ſome ſolid advantage in point of power; becauſe, as the motion is ſlower, the buckets muſt be made larger, that the increaſe of their weight may compenſate

penſate for the ſlowneſs of their motion. The wheel being thus more loaded with water, the ſtreſs upon every part of the work will be increaſed in proportion.

The beſt rule for practice will be, to make the velocity of the circumference a little more than three feet in a ſecond.

Experience confirms, that this velocity of three feet in a ſecond, is applicable to the greateſt overſhot wheels as well as the ſmalleſt; and all other parts of the work being properly adapted to this velocity, the fall of a given quantity of water, will produce very nearly the greateſt effect poſſible. But it is alſo certain from experience, that large wheels may deviate further from this rule before they will loſe their power, by a given aliquot part of the whole, than ſmall ones can be admitted to do; for inſtance, a wheel of twenty-four feet high may move at the rate of ſix feet *per* ſecond, without loſing any conſiderable part of its power. This may perhaps be accounted for, when we conſider how ſmall a proportion of the whole fall is requiſite to give the water the proper velocity which the wheel ought to have; whilſt in a ſmaller wheel, the ſame height muſt be allowed for that purpoſe, and conſequently, a greater proportion of the whole height. On the other hand, Mr. Smeaton tells us, that he had ſeen a wheel of thirty-three feet diameter that moved very ſteadily and well, with a velocity but little exceeding two feet *per* ſecond.

There is a natural wiſh to ſee a machine move briſkly; it has the appearance of activity: but a very ſlow motion always looks as if the machine was overloaded. For this reaſon, mill-wrights have always yielded ſlowly, and with reluctance, to the advice of Mr. Smeaton, but they have yielded; and we now ſee them adopting maxims of conſtruction more agreeable to ſound theory, that is, making their wheels of great breadth, and loading them with a great deal of work. The reluctance to adopt this ſyſtem did not ariſe ſolely from prejudice, but from a real inconvenience attending the ſlow motion of the wheel when the reſiſtance which is oppoſed to its motion, and which is the cauſe that it moves ſlowly, is not uniform in the different parts of a revolution.

In all machines, there are ſmall inequalities of action which are unavoidable; and in ſome machines very great inequalities ariſe, from the intermitting motions of cranks, ſtampers, and other parts which move unequally or reciprocally. When a water-wheel is employed to give motion to ſuch machines, it may be ſo reſiſted or loaded, as to be nearly in equilibrio with its work, in the moſt favourable poſition of the parts of the machine; but when theſe change into a leſs favourable poſition, the machine may ſtop the wheel altogether, or at all events hobble, and work very irregularly. And for the ſame reaſon that a water-wheel accommodates its motion very quickly to the reſiſtance it is to overcome, ſo all tendency to irregular motion is increaſed. A wheel, when its load is increaſed, moves more ſlowly, and receives more water into each bucket; thereby taking to itſelf a weight of water equal to overcome its load, and on the other hand by moving quicker, it takes leſs water into each bucket when the load is diminiſhed. But theſe changes do not take place inſtantaneouſly, becauſe it can be only in the moment that each bucket paſſes beneath the ſtream, that the ſhare of water it ſhall have, will be influenced by the rate of the wheel's motion. When a bucket is once filled it continues with that charge until it arrives at the bottom of the wheel.

This ſelf-regulating property of the wheel can only apply in caſes of ſmall and permanent changes of reſiſtance, for it always comes too late to correct ſudden and conſiderable changes in the reſiſtance; then it acts in the contrary direction. Suppoſe, for inſtance, an overſhot wheel is employed to work a ſingle pump by means of a crank, the reſiſtance of this machine will be continually varying; it will be nothing during one-half of the period of the revolution when the pump is not drawing any water, and during the other half it will be in a conſtant ſtate of increaſe and diminution. Now, during the time this wheel has nothing to do, it will turn round very quickly, and therefore each bucket will receive very little water; conſequently, when the wheel comes to be reſiſted, the wheel will have ſo little water in its buckets, that it will perhaps be quite ſtopped: in this caſe, the bucket beneath the ſpout will receive water until it is quite full, and then the water will run over and fill ſo many of the buckets beneath it, as to put the wheel in motion ſlowly; in conſequence, the ſucceeding buckets will receive a large ſhare of water during the half revolution when the pump makes its ſtroke; but when this is finiſhed, and the reſiſtance ceaſes, the wheel being well loaded with water, will in conſequence move very rapidly for a half revolution, and its buckets will receive very little water.

This is indeed an extreme caſe of irregular reſiſtance, and muſt be remedied by applying two pumps inſtead of one, or a balance-weight, or a fly-wheel; but the ſame principle will apply in caſe of ſmaller irregularities. In all caſes, the reſiſtance muſt be reduced to a great degree of uniformity, before a water-wheel can be applied to it with advantage, particularly if the wheel is intended to move ſlowly, with a view of obtaining the greateſt power, the irregularities will then have more ſerious conſequences.

A little more velocity enables the machine to overcome thoſe increaſed reſiſtances by its *inertia*, or the great quantity of motion inherent in it. Great machines poſſeſs this advantage in a ſuperior degree, and will conſequently work ſteadily with a ſmaller velocity. In all caſes, the machine muſt have ſo much moving matter in it as is ſufficient to overcome the irregularities, and regulate the motion of the wheel. If this is not already found in the machine, as in the mill-ſtones of a corn-mill for inſtance, the weight muſt be placed in the water-wheel itſelf, or in a fly-wheel applied for the purpoſe.

Mr. Buchanan meaſured the quantity of water which a cotton-mill required, when going at its common velocity; and when going at half that velocity. The reſult was, that the laſt required juſt half the quantity of water which the firſt did. In the experiments, the quantities of water were calculated from the depth of water and apertures of the ſluices.

From which experiments, he inferred that the quantity of water neceſſary to be employed in giving different degrees of velocity to a cotton-mill, muſt be nearly as the velocity. The water from the cotton-mill on which he made the obſervation, falls a little below it, into a perpendicular-ſided pond, which ſerves as a dam for a corn-mill. By meaſuring the time which the water took to riſe at a certain height in that pond, he determined the expenditure of water when the corn-mill moved at its common velocity; and alſo when it moved at nearly half that velocity.

The reſult of theſe experiments approached very nearly to the former, and all the differences could be accounted for, by a ſmall degree of leakage, which took place at the ſluices on the lower end of the pond; and the time being greater when the mill moved ſlower, the leakage would of courſe be greater.

In

In thefe experiments, the motion of the water-wheel being exactly proportioned to the quantity of water expended, the load upon the wheel muft have been equal when it moved quick or flow, that is to fay, the buckets muft have been equally filled when the wheel moved at its ordinary motion, or at half that motion.

The effect, therefore, of letting more water on a wheel when the refiftance continues the fame, is not to lodge a greater quantity in each of the buckets, but to fupply the fame quantity to each bucket when the wheel is in a greater motion.

The greateft velocity that the circumference of an overfhot wheel can acquire, depends jointly upon the diameter or height of the wheel, and the velocity of falling bodies; for it is plain, that the velocity of the circumference can never be greater, than to defcribe a femicircumference, in the time that a body let fall from the top of the wheel would defcend through its diameter, nor indeed quite fo great; as a body defcending through the fame perpendicular fpace cannot perform its courfe in fo fmall a time, when paffing through a femicircle, as would be done in a perpendicular line. Thus, if a wheel is fixteen feet one inch diameter, a body will fall through the line of its diameter in one fecond: this wheel, therefore, can never arrive at a velocity equal to the making one turn in two feconds. An overfhot wheel can never come near this velocity, for when it acquires a certain fpeed the greateft part of the water is prevented from entering the buckets; and the reft, at a certain point of its defcent, is thrown out again by the centrifugal force. The velocity, when this action will begin to take place, depends in a great degree upon the form of the buckets as well as other circumftances; fo that the utmoft velocity that an overfhot wheel may be capable of is not to be determined generally; and indeed the knowledge of it is not at all neceffary in practice, becaufe a wheel, in fuch cafe, would be incapable of producing any mechanical effect.

V. *On the proper Load for an overfhot Wheel, in order that it may produce a maximum Effect.*—The maximum load or refiftance for an overfhot wheel, is that which will reduce the circumference of the wheel to its proper velocity, of three or three and a half feet *per* fecond; and this will be known, by dividing the effect it ought to produce in a given time, by the fpace intended to be defcribed by the circumference of the wheel in the fame time; the quotient will be the refiftance to be overcome at the circumference of the wheel, and is equal to the load required, the friction and refiftance of the machinery included.

VI. *On the greateft Load that an overfhot Wheel can overcome.*—The greateft load an overfhot wheel can overcome depends upon the magnitude of the buckets; and the refiftance which will ftop the wheel, muft be equal to the effort of all the buckets in one femicircumference, when quite filled with water.

The ftructure of the buckets being given, the quantity of this effort may be affigned, but is not of much importance in practice, as in this cafe alfo, the wheel lofes its power; for though the water makes the utmoft exertion of gravity upon the wheel, yet, being prevented by a counterbalance from moving at all, it is not capable of producing any mechanical effect, according to our definition. An overfhot wheel, generally ceafes to be ufeful before it is loaded to that pitch, for when it meets with fuch a refiftance as to diminifh its velocity to a certain degree, its motion becomes irregular; yet this never happens until the velocity of the circumference is reduced to lefs than two feet *per* fecond, where the refiftance is equable, as appears not only from the preceding fpecimen, but from experiments on larger wheels.

VII. *Conftruction of the Pentrough for fupplying the Water to overfhot Wheels.*—We have hitherto fpoken of the ftream of water, as if it iffued from a fpout nearly in an horizontal direction, or with only fo much inclination as will make the line of the ftream correfpond with the direction of the oblique part of the bucket-board. This is the ancient, and ftill the common way; Mr. Smeaton's, which is a much better, is fhewn in *fig.* 2. *Plate* I. *Water-wheels.* G reprefents the pentrough through which the water flows, and F F ftrong crofs-beams on which it is fupported; the wheel is fituated very clofe beneath the bottom of the trough, as the figure fhews. E E are two arms of the wheel, which are put together, as fhewn in *fig.* 7. D B is the wooden rim of the wheel; the narrow circle beyond this is the fection of the fole planking, and on the outfide of this the bucket-boards are fixed as the figure fhews; one of the bottom boards, *b*, of the trough at the end is inclined, and an opening is left between that end and the other boards of the bottom, to let the water pafs through; this opening is clofed by a fliding fhuttle, *c*, which is fitted to the bottom of the trough, and can be moved backwards and forwards by a rod, *d*, and lever, *e*, which is fixed into a ftrong axis *f*; this axis has a long lever on the end, which, being moved by the miller, draws the fhuttle along the bottom of the trough, and increafes or diminifhes the aperture through which the water iffues. The extreme edge of the fhuttle is cut inclined, to make it correfpond with the inclined part *b*, and by this means it opens a parallel paffage for the water to run through, and this caufes the water to be delivered in a regular and even fheet; and to contribute to this the edges of the aperture where the water quits it, are rendered fharp by iron plates; the fhuttle is made tight where it lies upon the bottom of the trough by leather, fo as to avoid any leakage when the fhuttle is clofed. When the wheel is of confiderable breadth, the weight of the water might bend down the middle of the trough until it touched the wheel; to prevent this, a ftrong beam, O, is placed acrofs the trough, and the trough is fufpended from this by iron bolts which pafs through grooves in the fhuttle, fo that they do not interfere with the motion of the fhuttle.

Fig. 3. of the fame plate is an overfhot wheel, for which Mr. Nouaille took a patent in 1813; he recommends that the water-wheel be made the full height of the fall of water, and that the water be applied upon the wheel at 53 degrees from the vertex. The pentrough is made nearly on the fame plan as Mr. Smeaton's. O R is the trough, *h g* the end inclined in the direction in which the water is intended to be directed, *f* the fhuttle, fliding horizontally on the bottom of the trough, *c d e* the lever for drawing the fhuttle, to which motion is given by a regulating fcrew *a* and nut *b*.

Fig. 9. *Plate* II. *Water-wheels*, is the method of laying on water, which has for feveral years been in common ufe in Yorkfhire and the north of England. In this the water is not applied quite at the top of the wheel, but nearly in the fame pofition as the laft defcribed; but the advantages of this wheel over all others is, that the water can be delivered at a greater or lefs height, according to the height at which the water ftands in the trough; but in all the preceding methods if the water is fubject to variations of height, as all rivers are, then the wheel muft be diminifhed, fo that in the loweft ftate of the water it will ftand a fufficient depth above the orifice in the bottom of the trough to iffue with a velocity rather greater than the motion of the wheel. In this cafe, when the water rifes to its ufual height, or above it, the increafe of fall thus obtained is very little advantage to the wheel; the improved wheel

wheel can at all times take the utmoſt fall of the water, even when its height varies from three to four feet. A A is the pentrough made of caſt-iron ; the end of it is formed by a grating of broad flat iron bars, which are inclined in the proper poſition to direct the water through them into the buckets of the wheel. The ſpaces between the bars are ſhut up by a large ſheet of leather, which is made faſt to the bottom of the iron trough at *a*, and is applied againſt the bars ; and the preſſure of the water keeps it in cloſe contact with the bars, ſo as to prevent any leakage. This is the real ſhuttle, and to open it ſo as to give the required ſtream of water to the wheel, the upper edge of the leather is wrapped round a ſmaller roller *b* ; the pivots at the ends of this roller are received in the lower ends of two racks, which are made to ſlide up and down by the action of two pinions fixed upon a common axis which extends acroſs the trough ; this axis being turned, raiſes up or lowers down the roller, and the leather ſhuttle winds upon it as it deſcends, or unwinds from it as it aſcends, ſo as to open more of the ſpaces between the bars, or cloſe them as it is required. In order to make the roller take up the leather, and always draw it tight, a ſtrap of leather is wound round the extreme ends of the rollers, beyond the part where the leather ſhuttle rolls upon it. Theſe ſtraps are carried above water and applied on wheels, which wind them up with a very conſiderable tenſion by the action of a band and weight wrapped on the circumference of a wheel, which is on the end of the axis of thoſe wheels.

The water runs over the upper ſide of the roller, and flows through the ſpaces between the grating into the buckets of the wheel ; the deſcent of the water paſſing through the bars, and afterwards in falling before it ſtrikes the bottom of the bucket, is found fully ſufficient to produce the neceſſary velocity of the water, for a fall of four inches produces a velocity of more than four feet *per* ſecond.

We recommend this as the beſt method of applying the water, as we ſee in all other forms that a much greater portion of the fall is given up in order to make the water flow into the wheel ; not that any ſuch depth as is commonly given is at all neceſſary, but the aperture in the trough muſt be placed ſo low that the water will run through it in the very loweſt ſtates of the water, otherwiſe the wheel muſt ſtop at ſuch times.

On the Manner of framing Water-wheels.—The weight of every wheel muſt be ſupported by its axis, which therefore demands the firſt conſideration. If the axis is to be of wood it ſhould be made of a tree of hard and durable wood, of a length and ſize proportioned to the ſize and weight of the wheel ; into each end a gudgeon or centre ſhould be fixed for the wheel to turn upon. There are two methods of fixing the gudgeon into a wooden axis ; one is, by forming the gudgeon with a croſs, which is let into the end of the tree, and faſtened by ſcrews, and the wood is compreſſed round the croſs by two or three iron hoops, fitted on the end of the tree and wedged ; this is explained in the article MILL-*Work*. The other method is, to make a ſtrong iron box in a piece with the gudgeon, into which box the end of the tree is received and ſecured by wedges. The box being of an octagon ſhape, and the wood being cut to the ſame figure, it cannot ſlip round within the box.

Of late years it has been uſual to make the great axis of water-wheels of caſt-iron, which is a very good plan, provided the axis is made of ſufficient dimenſions. This was firſt practiſed by Mr. Smeaton, but he was rather unfortunate, as ſeveral of them broke after having been many years in uſe : he then employed hollow tubes of caſt-iron of large dimenſions and conſiderable thickneſs of metal. Even now that the ſtrength of caſt-iron is better underſtood, it is not uncommon for the axis of a water-wheel to break, particularly in cold and froſty weather, and for this reaſon ſome millwrights uſe wrought iron, but the hollow tube is ſo much ſtronger, as to be very ſecure from accident.

In an iron axis it is adviſeable to make the bearings of the axis cloſe to the ſides of the water-wheel, and leave the ends of the axis projecting beyond the bearings, in order to attach the cog-wheel, by which the power of the wheel is to be communicated to other machinery. This diminiſhes the length of the axis between the bearings, and renders it much ſtronger ; wooden axes muſt have the gudgeons at the extreme ends.

The next point to be conſidered is, the beſt means of affixing the arms of the wheel firmly to the axis. If the arms are of wood, and the axis alſo, the moſt obvious plan is to mortiſe the arms into the axis ; but this is the worſt method that can be adopted, becauſe the axis is much weakened, and the water being admitted into the centre of the tree cauſes it ſoon to decay, nor can an arm be eaſily replaced without taking all the wheel to pieces.

A better way is to uſe eight timbers for the arms, and put them together ſo as to interſect each other at right angles, (as is ſhewn in *fig.* 7. *Plate* I.) leaving a ſquare opening in the centre for the reception of the axis, which is made up to a ſquare by adding pieces of wood to it, and the wheel is faſtened on by wedges. The only objection to this is, that the arms are weakened by interſecting each other, and they ſupport the circular rim of the wheel in unequal ſegments.

In Mr. Buchanan's water-wheel, which we have before deſcribed in *figs.* 4 and 5, *Plate* I. *Water-wheels*, is a particular conſtruction of the arms formed by thin planks of wood. He ſtates that this plan is applicable to any kind of water-wheel ; and ſince 1790, when he firſt conſtructed a wheel with arms on that principle, a conſiderable number of large wheels have been erected in Scotland on the ſame plan. It is evident that arms, ſuch as are commonly fixed in mortiſes in the axis, are weakeſt in one direction, and that commonly in the direction of the ſtrain. To remedy this defect the feather-pieces F F are applied all round, having their broadeſt ends towards the centre of the wheel, and being at right angles to the breadth of the principal arms. In order to unite them ſtrongly to the principal arms, and connect the whole more firmly together, a ring of iron, R, is applied on each ſide ; blocks of wood being put in the vacant ſpaces between, and the keys or wedges, K K, bind the whole cloſe to the axis.

The very beſt method of uniting the arms to the axis is to have a caſt-iron centre-piece, or ſtrong hoop, to fit on the wooden axis with a broad projecting flanch round it, againſt the flat ſurface of which the arms of the wheel are applied, and the intervals between them filled up by wooden blocks or wedges ; the arms and blocks are firmly bound to the iron flanch by iron rings applied to the arms on the oppoſite ſide to the flanch, with ſcrew bolts to go through the whole. This ſame plan is applicable to an iron axis, and will be more clearly underſtood by a reference to the article MILL, and *Plate* XXXIV. *Mechanics* ; but it is there deſcribed that the broad circular flanch to ſcrew the arms againſt, is caſt in the ſame piece with the axis. This was Mr. Smeaton's original plan, but the flanch ſhould be made in a ſeparate piece, and faſtened on the axis with wedges ; for if caſt in the ſame piece, the contraction of the metal contained in the flanch when cooling, renders the metal of the axis ſpongy at the part where it joins to the flanch, and cauſes them to break at that part. Sometimes the caſt-iron centre-piece is made with a

diſtinct

diſtinct cell to receive each arm, and they are faſtened into the cells by wedges and ſcrew-bolts, but a flat flanch with the intervals filled up by blocks is more ſimple and ſecure. Modern wheels are very frequently made with caſt-iron arms, which in this caſe are attached to the axis by a ſimilar centre-piece.

The circular rims of water-wheels are commonly made of wood, put together in two or three thickneſſes, the joinings of one ring not coinciding with thoſe of the other, and 8 or 10 ſegments in each thickneſs, according to the ſize of the wheel; the thickneſſes are united together by rivets. The arms are attached to the ring by notching them in, and ſecuring them by bolts. Caſt-iron rings are now generally uſed, and with great advantage, becauſe the neceſſary mortiſes can be made in iron, without weakening the ring; but the ſtrength of a wooden ring is greatly impaired by the mortiſes through it.

The number of rings in a wheel depend upon its breadth; when the wheel is four feet wide, two rings will ſupport the float-boards or buckets, but the rings ſhould not be more than five feet aſunder, or the floats may bend and yield; for want of a ſufficient ſupport each ring is framed with its ſet of arms, ſo that every one derives its ſtrength from the axis. When a wheel is of great breadth, the whole will be very much ſtrengthened, by applying oblique braces, extending from the centre-pieces of the outſide rings to the circumference of the middle ring, by firmly attaching theſe oblique braces to the arms of all the rings which they intercept; they form truſs-frames which prevent the wheel and the axis from bending by its weight: this is particularly uſeful in wide overſhot wheels.

In breaſt and underſhot wheels the float-boards are nailed to pieces of wood called ſtarts, which are fixed into the mortiſes in the rings, and project outwards for that purpoſe.

In overſhot-wheels, the rings of the wheels are covered by boards laid parallel to the axis, well jointed together, and ſpiked down to the rings like the boards of a floor to the joiſts. This boarding forms a cloſe cylinder, which is called the ſole of the wheel, and is the foundation for the buckets. When the rings of the wheel are of iron, holes are left in the caſtings in the edge of the rings, at regular diſtances round the circumference, and theſe are filled up with plugs of wood, into which the nails can be driven to faſten on the boarding of the ſole. The ſole of the wheel is ſometimes made of iron plates rivetted together, and rivetted alſo to the rings of the wheel.

At the ends of the ſole-boards, two circular rings of wood or iron, called ſhrouds, are fitted on perpendicularly to the ſole to form the ends of the buckets; and it is uſual, if the wheel is wide, to apply a ſhrouding over each ring of the wheel, and then the buckets are divided into lengths of about four or five feet. In the flat ſurfaces of the ſhroudings, grooves are made for the reception of the ends of the bucket-boards. It is uſual to make the firſt board, which is in the direction of a radius, of wood, and the outſide one is generally made of iron plate; but ſometimes the whole are made of plate iron, and both parts of the buckets are then bent up out of one piece, and the ends of the plate; and alſo that part of the edge which is to apply to the ſole, is turned ſquare to lie flat againſt the ſole and the ſhrouding, ſo that rivets and nails may unite all together, and make water-tight joints.

When the ſhrouding is of caſt-iron, it is made to ſerve inſtead of the rings of the wheel, becauſe it has ſufficient ſtrength to ſerve both purpoſes: the arms of the wheel are in this caſe applied flat againſt the ring of ſhrouding, and bolted to it.

The breaſt-wheel, *fig.* 3. *Plate* II. *Water-wheels*, at Meſſrs. Strutt's works, which we have already noticed, is deſerving of further notice from the manner of putting it together. The rings of the wheel are made of caſt-iron, and the float-boards are included between the rings in the manner of an overſhot wheel, but the arms are only of wrought iron, being made of ſmall round iron rods, which are very light, and have little ſtrength to reſiſt bending; but as they are all tied in from the centre, the ring cannot deviate from its true circular figure, and to ſuſtain the wheel ſideways, oblique bars are extended from the centre-pieces at each end of the axis, and are united to the circular ring in the middle of its breadth, which is 15 feet. We have ſeen two overſhot-wheels of 24 feet diameter, and 9 feet broad, made in the ſame way. It is plain that in this conſtruction the axis of the wheel can do no office but to ſupport the weight of the wheel; for though theſe arms are ſufficiently ſtrong for that purpoſe, they can have little ſtrength by way of levers to tranſmit the force of the circular motion of the rim of the wheel to the axis; but the power is tranſmitted in a better way than from the axis, *viz.* by a ring of cogs ſcrewed to the circular rim of the wheel, and working in a pinion which conveys the motion to the mill. There is another ſimilar ring of cogs at the other ſide of the wheel, which works into a pinion fixed on the ſame ſhaft, by this means nearly all the ſtrain is taken from the axis of the water-wheel; for the pinion is placed on the deſcending ſide of the wheel, ſo that the weight of the water acting on the float-boards is immediately tranſmitted to the pinions by the ſtrength of the rings of the wheel.

This method of tranſmitting the power is alſo applied to other wheels than thoſe which are made with ſlight arms like the above; the ring of cogs is ſometimes placed in the middle of the breadth of the wheel, and then acts upon one pinion, but it is much better to place it at one ſide or both ſides, if the wheel is very broad, becauſe the circle of the teeth may then be made rather leſs than the diameter of the rings of the wheel, and the ſide of the ring being cloſely fitted to the ſtone-work of the race, the water may be excluded from the cogs.

It is obvious that of the various conſtructions of water-wheels, that is the ſtrongeſt which communicates its motion by means of a ring of cogs immediately attached to its rim, where the power of the water is alſo applied, the leaſt poſſible ſtrain being thus thrown on its arms and axis.

The only objection to this plan is, that as the teeth of the cog-wheel are in moſt caſes conſtantly wet, which prevents the greaſe from adhering, the uſual mode of occaſionally greaſing the cogs is of little or no uſe, and the dirt in the water grinds away the teeth; or, were the water even free from dirt, there would be much unneceſſary friction and waſte of power.

Greaſing Machine for the Cog-Wheel of a Water-Wheel.— Mr. Buchanan mentions two water-wheels of this kind, in which the rings of the teeth were wearing very faſt, and knowing the trouble and expence of renewing them, he was ſolicitous to diſcover ſome means of rendering them more durable. The only way which preſented itſelf was by ſome contrivance to keep them well greaſed.

This he did by a machine ſhewn in *fig.* 8. *Plate* I. *Water-wheels*; it is nothing more than a kind of pinion, with one or more of its teeth made hollow to contain the greaſy ſubſtance, and the metal plate of which the hollow cog is compoſed is perforated with ſmall holes, for exudating the greaſe through thoſe parts which come in contact with the teeth of the wheel.

Fig. 8. is a ſection of the greaſing machine; A B repreſents part of the ring of teeth on the circumference of the water-

water-wheel. The greafing-pinion which works in thefe teeth is mounted on an axis, as is clearly fhewn.

N O a retarding lever, of which N is the fulcrum, and O a weight to make it prefs on the axis of the greafing-pinion, fo as to caufe a refiftance, and make the cogs of the wheel prefs forcibly on the cogs of the pinion.

G H I K, the hollow teeth for containing the greafe; they are made of copper-plate or iron; and to make the perforated fides of the greafing leaves come in clofe contact with the face of the teeth of the wheel, the lever N O, with a fmall weight on it, acts on a pulley fixed on the axle of the pinion, and ferves to retain it.

E F, &c. the folid teeth of the pinion, made of wood; there are fliders which open for admitting the greafe into the hollow teeth at their ends.

The number of leaves in the greafer fhould be fuch, that thofe containing the greafe fhall apply themfelves in the courfe of feveral revolutions of the wheel to each of its teeth. Mr. Buchanan found a greafer of 12 leaves, 4 of which contained greafe, had this effect upon a wheel of 304 teeth; and one of 13 leaves, with one tooth only filled with greafe, ferved a wheel of 168 teeth.

It is beft to ufe a mixture of tallow, oil, and black lead for greafing, made of a confiftency to feed regularly, and frefhened about twice in a week.

Conftruction of a Breaft-Wheel of very great Width.—At Meffrs. Strutt's works is a very powerful breaft-wheel, made of the extraordinary width of 40 feet, and it deferves our notice from the manner of framing it together; its diameter is only 12½ feet, and it is made without any axis, or rather the axis is hollow, and fo large that the float-boards are fixed immediately upon it. It is made like a very long cafk, 48 feet long, compofed of 32 ftaves of fix inches thicknefs, bound together by hoops like an ordinary cafk; it is five feet in diameter at one end and fix feet at the other, and in the middle 7 feet 2 inches; the fmall end is made up folid for three feet in length, and the gudgeon is fixed in this folid part; the larger end is folid for four feet from the end, and on this part the large cog-wheel is fixed to communicate the motion to the mill; it is 14 feet diameter, and has 120 cogs, whilft the water-wheel is only 12½ feet diameter to the outfide of the floats. The floats are fupported by 10 circular rings, which are fixed on the outfide of the axis or cafk, at four feet diftance from each other, and the float-boards are fixed between thefe rings, 24 floats being arranged in each circle; but the floats in the different fpaces are not made to line with each other, becaufe if the water was to ftrike upon the whole length of 40 feet of float-board at once, it would give a fenfible fhock to the water-wheel, and work the mill irregularly; hence the floats between all the different rings are placed oppofite to the intervals between the floats in the adjoining fpaces, by which means the water acts on the floats in rapid fucceffion, fo that the ftroke upon any one float is imperceptible.

The float-boards are not made to touch the central-barrel or axis within two inches, in order to leave fpace for the air to efcape. The float-boards in the middle of the wheel are 2 feet 4 inches wide, and at the ends are wider. This wheel has two fhuttles, one above the other, like the breaft-wheel before defcribed in *fig.* 3, and the fame dimenfions; for the wheel is placed in the fame mill, but is adapted to work when the tail-water rifes in time of floods to fuch a height as to prevent the other wheel from working.

A very large overfhot Wheel.—The largeft overfhot water-wheel of which we have heard, is that at Mr. Crawfhaw's iron-works at Cyfarthfa, near Merthyr Tidvil, in South Wales: it is ufed to blow air into three of the large blaft furnaces for fmelting iron; the water-wheel is fifty feet in diameter and fix feet wide: it is chiefly made of caft iron, and has 156 buckets. The axis is a hollow tube, and is ftrengthened by twenty-four pieces of timber applied round it. On each end of the axis is a cog-wheel of twenty-three feet diameter, which turns a pinion. On the axis of thefe are two cranks, and a fly-wheel twenty-two feet diameter, and twelve tons weight; each of the cranks gives motion to a lever, like that of a large fteam-engine, and works the pifton of a blowing cylinder or air-pump 52½ inches in diameter, and five feet ftroke, which blows air into the furnace, both when the pifton goes up and down. The work on the other fide being the fame, it actuates in the whole four of thefe double cylinders; the wheel makes about two and a half turns *per* minute, and each cylinder makes ten ftrokes. It is called Æolus, and was built in 1800 under the direction of Mr. Watkin George.

At Aberdare, in South Wales, is an immenfe double water-wheel, confifting of two wheels of forty feet in diameter, placed one above the other like the figure 8, (fee our article CANAL,) the water from the upper one actuating the lower one, and both being connected together by cog-wheels on their refpective rings. We underftand this machine has not anfwered, and we only mention it as an attempt to occupy a fall of water of eighty feet; in fuch cafes, the *Preffure-engine*, defcribed under that article, is a better method, particularly if the work will admit of a reciprocating motion.

Chain of Buckets.—This is applicable in many fituations where there is a confiderable fall of water. This fketch was taken from one in Scotland ufed to give motion to a thrafhing-mill; the *fig.* 6. *Plate* I. is fo obvious as to need little explanation. The buckets C, D, G, H, &c. muft be connected by feveral chains to avoid the danger of breaking, and united into an endlefs chain, which is extended over two wheels A and B, the upper one being the axis which is to communicate motion to the mill-work; E is the fpout to fupply the water. The principal advantage of this plan is, that no water is loft by running out of the buckets before they arrive at the loweft part, as is the cafe with the wheel. Another is, that the buckets being fufpended over the wheel A of fmall diameter, it may be made to revolve more quickly than a wheel of large diameter, and without increafing the velocity of the defcending buckets beyond what is proper for them. This faves wheel-work when the machine is to be employed, as in a thrafhing machine to produce a rapid motion. On the other hand, the friction of the chain in folding over the wheel at the top, and feizing its cogs, will be very confiderable; thefe cogs muft enter the fpaces in the open links between the buckets, to prevent the chain flipping upon the upper wheel. We think this machine might be much improved by contriving it fo, that the chain would pafs through the centre of gravity of each bucket, whereas in the prefent form, the weight of each bucket tends to give the chain an extra bend.

The *Chain-Pump reverfed* has been propofed as a fubftitute for a water-wheel when the fall is very great, and we think it would anfwer the purpofe with fome chance of fuccefs. It would have an advantage over the chain-pump when employed for raifing water, in the facility of applying cup leathers to the piftons on the chain, in the fame way as other pumps, which leathers expand themfelves to the infide of the barrel, and are kept perfectly tight by the preffure of the water. In the chain-pump fuch leathers cannot be employed, becaufe the edges of the leather-cups would turn down and ftop the motion, when the cups were drawn upwards into the barrel. It is the defective mode of leathering the piftons of the chain-pump which occafions its great friction. In the motion of a machine of this kind the piſtons would deſcend into the barrel, and might therefore be leathered with cups like other pumps, ſo as to be quite tight without immoderate friction. This machine was propoſed by a Mr. Cooper in 1784, who obtained a patent for it, and Dr. Robiſon has again propoſed it with recommendation.

Mechaniſm for equalizing the Motion of Water-Wheels.— When a part of the machinery of a mill is ſuddenly detached from the firſt mover, or ſuddenly connected with it, the load of the machine is either increaſed or diminiſhed; and the moving power remaining the ſame, an alteration in the velocity of the whole will take place; it will move faſter or ſlower. Every machine has a certain velocity, at which it will work with greater advantage than at any other ſpeed; hence the change of velocity ariſing from the above cauſe, is in all caſes a diſadvantage, and in delicate operations exceedingly hurtful. In the caſe of a cotton mill, for inſtance, which is calculated to move the ſpindles at a certain rate, if from any cauſe the velocity is much increaſed, a loſs of work immediately takes place, and an increaſe of waſte from the breaking of the threads, &c.; on the other hand, there muſt be an evident loſs from the machinery moving too ſlow. In ſteam-engines this evil is remedied by a contrivance called a governor, which we have already deſcribed in our article STEAM-*Engine.*

Governors are ſometimes applied to water-wheels, and made on various conſtructions. Smith-bellows have been applied to that uſe, the upper board riſing and falling on any augmentation or diminution of the velocity of the lower board, which received its motion from the mill, and forced air into the ſpace beneath the upper board; from this ſpace the air was permitted to eſcape by a pipe with a cock. If the lower board worked faſter than the air could eſcape, the upper board would riſe, but if it moved ſlower, then the board would ſink; and this riſing and falling was applied to regulate the ſhuttle of the water-wheel, not by the force of the bellows alone, but the bellows were made to throw the wheel-work of the mill into action, either to raiſe or lower the ſhuttle.

Of late years a new kind of water-wheel governor has been introduced, the principles of which are nearly the ſame as the governor of a ſteam-engine. It has a revolving pendulum, which receives its motion from the mill, and in proportion as the machinery moves faſter or ſlower, the centrifugal force acts with greater or leſs force upon the balls of the governor, making them approach to, or recede from, the perpendicular axis. This raiſes or depreſſes an iron croſs, which ſlides upon the perpendicular axis of the revolving pendulum, and by acting on a lever, is made to engage the ſluice with a train of wheel-work, which is kept in conſtant motion by the power of the water-wheel. When this train is connected with the ſluice, it operates upon it ſo as to enlarge or leſſen the paſſage of the water to the water-wheel, and by augmenting or leſſening the quantity of water falling on the wheel, increaſes or diminiſhes its ſpeed.

This ſluice is made on the principle of the throttle-valve of ſteam-engines. In order that it may be moved by a ſmall power, it is poiſed on an axis of motion paſſing through the middle of the ſluice. When it is turned edgeways to the ſtream of water, it makes no obſtruction; but if it is turned perpendicularly, it cloſes the paſſage of water, or by placing it more or leſs obliquely, it alters the area of the paſſage for the water.

The axis on which the ſluice turns, if horizontal, ſhould be one-third of the height of the ſluice from the bottom, in order that the preſſure of the water above the centre may balance that below.

So long as the machinery is moving at a proper velocity, this wheel-work of the ſluice apparatus is not connected with the ſluice, and it remains at reſt. But if the mill goes too ſlow, the croſs is depreſſed, and ſtriking the lever in an oppoſite direction, connects the ſluice with a different part or train of wheel-work, which has a motion in a contrary direction to the former, and ſo produces a contrary effect on the ſluice.

The train of wheel-work is ſo calculated, as to reduce the action on the ſluice to a very ſlow motion, and it is found, from experience, that this is neceſſary. Where the area of the aperture is too ſuddenly changed, the effect on the water-wheel would be too violent. See a more complete deſcription of this contrivance in Vol. XXIII. MILL-*Work.*

On the Conſtruction of the Wheel-race and Water-courſe.— The wheel-race ſhould always be built in a ſubſtantial manner with maſonry, and if the ſtones are ſet in Roman cement, it will be much better than common mortar. The earth behind the maſonry ſhould be very ſolid, and if it is not naturally ſo, it ſhould be very hard rammed and puddled, to prevent percolation of the water. This applies more particularly to breaſt-wheels, in which the water of the dam or reſervoir is uſually immediately behind the wall or breaſt in which the wheel works, a ſloping apron of earth being laid from the wall in the dam to prevent the water leaking. The wall of the breaſt ſhould have pile planking (ſee CANAL) driven beneath, to prevent the water from getting beneath, becauſe that might blow up the foundation of the race. The ſtones of the race are hewn to a mould, and laid in their places with great care; but afterwards when the ſide walls are finiſhed, and the axis of the wheel placed in its bearings, a gauge is attached to it and ſwept round in the curve, and by this the breaſt is dreſſed ſmooth, and hewn to an exact arch of a circle: the ſide walls in like manner are hewn flat and true at the place where the float-boards are to work. It is uſual to make the ſpace between the ſide walls two inches narrower at each ſide, in the circular part where the floats act, than in the other parts.

In ſome old mills the breaſt is made of wood planking, but this method has ſo little durability that it cannot be recommended. In modern mills, the breaſt is lined with a caſt-iron plate, but we do not approve of this, becauſe it is next to impoſſible to prevent ſome ſmall leakage of water through the maſonry, and this water being confined behind the iron breaſt cannot eſcape, but its hydroſtatic preſſure to force up the iron is enormous; and if the water can ever inſinuate itſelf behind, the whole ſurface of the plate rarely fails to break it, if not to blow it up altogether. This is beſt guarded againſt by making deep ribs projecting from the back of the plate, and bedding them with great care in the maſonry; theſe not only ſtrengthen the plate, but alſo cut off the communication of the water, ſo that it cannot act upon larger ſurfaces at once, than the ſtrength and weight of the plate can reſiſt. Stone is undoubtedly the beſt material for a breaſting. In overſhot-wheels the loſs of water, by running out of the buckets as they approach the bottom of the wheel, may be conſiderably diminiſhed by accurately forming a ſweep, or caſing round the lower portion of the wheel, ſo as to prevent the immediate eſcape of the water, and cauſing it to act in the manner of a breaſt-wheel, which has been already deſcribed. While this improvement remains in good condition, and the wheel works truly, it produces a very ſenſible effect; but it is frequently objected to, becauſe a ſtick or a ſtone falling into the wheel would be liable to tear off part of its ſhrouding, and damage the buckets; and again, a hard froſt frequently binds all faſt, and totally prevents the poſſibility of working during its conti-

 nuance;

nuance; but we do not think the latter a great objection, for the water is not more liable to freeze there than in the buckets or on the shuttle, and may be prevented by the same means, *viz.* by keeping the wheel always in motion; a very small stream of water left running all night will be sufficient. Mr. Smeaton always used such sweeps, and with very good effect; it is certainly preferable to any intricate work in the form of the buckets.

On setting out Water-courses and Dams.—The most ancient mills were undershot-wheels placed in the current of an open river, the building containing the mill being set upon piles in the river. It would soon be observed that the power of the mill would be greatly increased, if all the water of the river was concentrated to the wheel, by making an obstruction across the river which penned up the water to a required height; and also to form a pool or reservoir of water. A sluice or shuttle would then become necessary to regulate the admission of water to the wheel, and other sluices would be necessary to allow the water to escape in times of floods; for though in ordinary times the water would run over the top of the obstruction or dam, yet a very great body of water running over might carry away the whole work, by washing away the earth at the foot of the dam, and then overturning it into the excavation. This is an accident which frequently happens to mills so situated, and the danger is so obvious, that most water-mills are now removed to the side of the river, and a channel is dug from the river to the mill to supply it with water, and another to return the water from the mill to the river. The difference of level between these two channels is the fall of water to work the mill, and this is kept up by means of a weir or dam entirely across the river; but the water can run freely over this dam in case of floods, without at all affecting the mill, because the entrance to the channel of supply is regulated by sluices and side walls.

The dam should be erected across the river at a broad part, where it will pen up the water so as to form a large pond or reservoir, which is called the mill-pond or dam-head. This reservoir is useful to gather the water which comes down the river in the night, and reserve it for the next day's consumption; or for such mills as do not work incessantly, but which require more water, when they do work, than the ordinary stream of the river can supply in the same time. The larger the surface of the pond is, the more efficient it will be; but depth will not compensate for the want of surface, because as the surface sinks, when the water is drawn off, the fall or descent of the water, and consequently the power of the water, diminishes.

The dam for a large river should be constructed with the utmost solidity; wood framing is very commonly used, but masonry is preferable. Great care must be taken, by driving pile planking under the dam, to intercept all leakage of the water beneath the ground under the dam, as that loosens the earth, and destroys the foundation imperceptibly; when a violent flood may overthrow the whole. It is a common practice to place the dam obliquely across the river, with a view of obtaining a greater length of wall for the water to run over, and consequently prevent its rising to so great a height, in order to give vent to the water of a flood. But this is very objectionable, because the current of water constantly running over the dam, always acts upon the shore or bank of the river at one point, and will in time wear it away, if not prevented by expensive works. This difficulty is obviated, by making the dam in two lengths which meet in an angle >, the vertex pointing up the stream. In this way the currents of water, coming from the two opposite parts of the dam, strike together, and spend their force upon each other, without injuring any part. A still better form is a segment of a circle, which has the additional advantage of strength, because if the abutments at the banks of the river are firm, the whole dam becomes like the arch of a bridge laid down horizontally. This was the form generally used by Mr. Smeaton.

The foot of the dam where the water runs down should be a regular slope, with a curve, so as to lead the water down regularly; and this part should be evenly paved with stone, or planked, to prevent the water from tearing it up, when it moves with a great velocity.

When the fall is considerable, it may be divided into more than one dam; and if the lower dam is made to pen the water upon the foot of the higher dam, then the water running over the higher dam will strike into the water, and lose its force. There is nothing can so soon exhaust the force of rapid currents of water as to fall into other water, because its mechanical force is expended in changing the figure of the water (see *circular weir* in our article CANAL); but when it falls upon stone or wood, its force is not taken away, but only reflected to some other part of the channel, and may be made to act upon such a great extent of surface as to do no very striking injury at any one time, but by degrees it wears away the banks, and requires constant repairs: for it is demonstrable that, as much of the force of the water as is not carried away by the rapid motion with which it flows, after passing the dam, must be expended either in changing the figure of the water, or in washing away the banks, or in the friction of the water running over the bottom.

The cotton-works of Messrs. Strutt at Belper, in Derbyshire, are on a large scale, and the most complete we have ever seen, in their dams and water-works. The mills are turned by the water of the river Derwent, which is very subject to floods. The great weir is a semicircle, built of very substantial masonry, and provided with a pool of water below it, into which the water falls. On one side of the weir are three sluices, each 20 feet wide, which are drawn up in floods, and allow the water to pass sideways into the same pool; and on the opposite side is another such sluice, 22 feet wide. The water is retained in the lower pool by some obstruction which it experiences in running beneath the arches of a bridge; but the principal fall of the water is broken by falling into the water of the pool, beneath the great semicircular weir.

The water which is drawn off from the mill-dam above the weir passes through three sluices, 20 feet wide each, and is then distributed by different channels to the mills, which are situated at the side of the river, and quite secure from all floods. There are six large water-wheels; one of them, which is 40 feet in breadth, we have mentioned, from the ingenuity of its construction; and another which is made in two breadths, of 15 feet each, we have also described. They are all breast-wheels. The iron-works of Messrs. Walker at Rotherham, in Yorkshire, are very good specimens of water-works; as also the Carron works in Scotland.

The largest works for overshot-mills are in Russia, at Colpino, near St. Petersburgh, on the river Neva. They were erected principally under the direction of Mr. Gascoigne of the Carron works in Scotland, and have been greatly improved by the present director, who is an engineer of his school. An immense dam of granite is built across the river to pen up the water, until it makes a large reservoir. The waste and flood waters do not run over this dam, but are conducted out of the reservoir by a semicircular branch of the river, and run over a great weir to join the original course of the river below the works. The mills

mills are ſituated in the valley below the great dam, the water being conveyed to the wheels by channels coming through the dam, and conveyed away into a large tail baſon, which is the original courſe of the river. The wheels, which are very numerous, are all 22 feet diameter. They are placed in ſeveral different mills, for rolling and forging iron and copper, boring guns, making anchors, &c. Theſe mills are arranged on the ſides of the tail baſon, which is navigable to bring the boats up to them. There are alſo two large ſaw-mills at the end of the ſemicircular channel.

Theſe works are very complete, owing to the excellent execution of the dam and water-works; but it is not a good plan to place the mills beneath the dam, becauſe if it ſhould fail, or the water pour over it by an extraordinary flood, the mills and buildings below would be in danger of being carried away; whereas, on the other conſtruction, the mills, being placed at a diſtance from the river, are perfectly ſafe, and would not be injured if the dam ſhould be wholly carried away. This is not a fault imputable to the gentlemen we have mentioned, as the foundations of theſe works were commenced in the time of Peter the Great, and too far advanced to admit of altering the plan radically, when the empreſs Catherine invited Mr. Gaſcoigne to Ruſſia, in 1786, to enlarge them to their preſent magnitude.

On the Diſtribution of the different Falls of Water in Rivers.—In erecting a mill, care muſt be taken to place it ſo that it ſhall not be impeded by flood-waters, except when they riſe to exceſs. When the water below will not run off freely, but ſtands penned up in the wheel-race, ſo that the wheel muſt work or row in it, the wheel is ſaid to be tailed, or to be in back water or tail water.

Upon moſt rivers in this country all the falls of water are fully occupied, and at every mill there is a weir, which pens up the water as high as the mill above can ſuffer it to ſtand without inconvenience. Each miller is anxious to obtain the greateſt poſſible fall, and he can at any time augment the fall, by raiſing the ſurface of his weir; but as this may produce an inconvenience to the mill above, in preventing the water from running freely away from its wheel, it is a conſtant ſource of diſpute and litigation. A mill may be ſubjected to tail-water by the concurrence of ſo many circumſtances, that it is frequently very difficult to know where to ſeek the beſt remedy, whether the miller ought to raiſe his wheel higher and diminiſh his own fall, or inſiſt upon a diminution of his neighbour's below him by lowering his weir.

The following rule is that which Mr. Smeaton conſtantly followed, in placing ſucceſſive dams upon rivers, whether for the erection of mills or for navigation. In flat countries, where the falls of water are ſmall, and conſequently tail or back water is moſt troubleſome, thoſe dams muſt be ſo built, that no one ſhall pen the water into the wheel-race of the mill next above it, when the river is in its ordinary ſummer's ſtate. The ſame rule we have found generally ſubſiſting in ancient mills.

This rule is founded upon reaſon; for if the erection of a dam does not affect the mill above by tail-water, in dry ſeaſons, when water is the moſt ſcarce, it can do no material injury at any other time. Every mill that is well and properly conſtructed will clear itſelf of a conſiderable depth of tail-water, provided it has at the time an increaſe of the height of water in the mill-dam or head, and an unlimited quantity of water to draw upon the wheel; for if floods produce tail-water, they alſo increaſe the head water, and afford a ſuperior quantity to be expended. This is the proper means by which a number of mills on the ſame river are to be cleared of back-water, as far as is conſiſtent with the mutual enjoyment of their ſeveral falls of water. This alone is a very ſufficient ſecurity againſt any one being injured. Common breaſt-mills will bear two feet of tail-water, when there is an increaſe of head, and plenty of water to be drawn upon the wheel, without prejudice to their performance; but mills well conſtructed, with ſlow moving wheels, will bear three and even four feet and upwards of tail-water. Mr. Smeaton mentions having ſeen an inſtance of ſix feet; and it is a common thing in level countries, where tail-water is moſt annoying, to lay the wheels from ſix to twelve inches below the water's level of the pond below, in order to increaſe the fall of water; and, if judiciouſly applied, is attended with good effect, as it increaſes the diameter of the wheel, and though it muſt always work in that depth of tail-water, it will perform full as well, becauſe the water ought always to run off from the bottom of the wheel, in the ſame direction as the wheel turns.

The law reſpecting mill property is by no means ſettled, but is greatly influenced by the cuſtom of the mills upon any river or in any diſtrict; ſome few points however are eſtabliſhed. Every one has a right to that fall which the water has, in running through his own grounds, and may make what uſe he pleaſes of the deſcent of the water, provided that he does not divert the water, at the tail of his eſtate, into any other channel, or that he does not pen up the water higher than the level at which it has always entered into his land; he has alſo a right to inſiſt that the miller below ſhall let the water depart from his grounds, at the ſame level at which it has always been uſed to do. The knowledge of this is very neceſſary, becauſe a miller very frequently finds himſelf ſeriouſly injured, when he is not entitled to any redreſs. It ſcarcely ever happens that any conſiderable improvements or alteration in mills can be made, without producing diſputes among the parties intereſted. Suppoſe, for inſtance, that there are two ancient mills upon a river, with an unoccupied deſcent in running over the lands between them, the proprietor of this land, by deepening the channel and erecting a weir, may bring all the fall into one place and erect a mill, without infringing the conditions we have laid down; but ſtill the miller below him may be conſiderably injured: for in the original ſtate the river, in running down with a regular and eaſy ſlope, from the upper mill to the lower, held a great quantity of water, which was a *corps de reſerve* for the miller below, and tended to regulate his ſupply. If the upper mill ſtopped working, the water contained in the river would ſtill run down to him, and ſo long as that laſted he could continue to work, perhaps until the upper mill began to work again, and thus he would ſuffer no interruption. The erection of an intermediate mill cuts off this reſource, and he will be obliged to ſtop working very ſoon after the new mill ſtops working; and further, he is obliged to work when the new mill is at work, or elſe the water poured down will run over his mill-dam and be waſted; but, in the former inſtance, the water would have come down leſs ſuddenly, and he might be able to ſet to work before the whole of the water had eſcaped over his weir.

In ſuch a caſe the lower miller may be inclined to appeal to the law, but he will find that he has no right to prevent his neighbour above from uſing the water in the ſame manner as he does himſelf, and if he finds any alteration in his own mill, it is for want of a capacious mill-pond to reſerve the water. In the original ſtate the channel of the river in his neighbour's ground above ſerved him in ſome meaſure as a mill-dam, by retaining the water for a given time, though it would not retain it permanently. The advantage of this he had enjoyed for a long time, when it was no inconvenience to his neighbour, but had acquired no right to demand

demand that his neighbour's property ſhould be ſacrificed for his convenience, but he muſt relieve himſelf by making an artificial pond for his own mill.

The ſame queſtion ariſes when any mill is altered or enlarged, ſo as to conſume the water faſter than the river brings it down, for ſuch a mill can only work for ſhort intervals, and muſt then ſtop that the water may accumulate in the dam until there is a ſufficient quantity to ſet to work again. This is the ſyſtem of copper-mills and rolling-mills, for during the time that the iron or copper is heating in the furnace, the mill is ſtopped, and the water gathered in the dam; but when the metal is ready, it is ſet to work with all the power of the water penned up. This is very prejudicial to a mill below, particularly if it is a corn-mill, which cannot conſume the water faſter than the regular ſupply of the river, and ſometimes alſo to mills above by frequently tailing their water.

Much uſeful information on theſe points will be found in Smeaton's Reports, 3 vols. 4to. 1813.

We have not, in the preceding article, entered into any of the mathematical inveſtigations upon the ſubject of water-wheels, becauſe we find few of them founded on experiment; but thoſe who wiſh to purſue this ſubject farther may conſult the following authors, which Dr. Young points out in his catalogue.

WATER, *Column of*, fignifies fo much of the mafs of water which is contained in a pipe, or any other veffel, as preffes againft any plane furface; which furface is called the bafe of the column.

All columns of water are confidered as if they were vertical prifms, of the fame fize and figure as the bafe, *i. e.* the furface upon which they prefs, and as high as the greateft height to which the water rifes in the pipe or other veffel.

This is demonftrable in hydroftatics, (fee FLUID,) and alfo that fluids prefs equally in all directions, fo that the preffure againft a vertical or inclined plane is the fame as againft an horizontal plane, provided that the planes are of the fame extent, and that the water which preffes upon them rifes to an equal height above them. This will be true whether the fize of the veffel which contains the water is greater or lefs than the furface upon which the preffure is exerted; the preffure will be neither more nor lefs than the weight of a perpendicular column or prifm of water, having a horizontal bafe, equal and fimilar to the plane or bafe upon which the preffure is exerted; and an altitude equal to the level of the furface of the water above the bafe.

Rule to find the Preffure or Weight of any Column of Water in Pounds Avoirdupois.—If the bafe of the column is of a circular figure, fuch as the pifton of a pump, take the diameter in inches, and alfo the perpendicular height of the furface of the water above the bafe of the column in feet; then fquare the diameter in inches, to obtain the area of the bafe in circular inches, and multiply this by the decimal .341 or by .34, this gives the weight of one foot in height of the column; laftly, multiply by the number of feet in the altitude of the column, and the refult is the weight of the whole column of water in pounds avoirdupois, or, what is equivalent, the preffure exerted by the water upon the bafe or plane againft which it acts.

If the bafe of the column is fquare or rectangular, it will be more convenient to find its area in fquare inches, and then the conftant decimal is .434.

The reafon of thefe rules is, that a cylindrical column of rain-water, of 1 inch in diameter and 1 foot high, weighs .3408853 lbs. avoirdupois; and a fquare prifm, 1 inch fquare, and 1 foot high, weighs .4340277 lbs. avoirdupois; the other multiplications are only to find how many of fuch cylinders or prifms are contained in the whole column.

Example 1.—It is required to find the weight which bears upon the pifton or bucket of a pump, whofe barrel is 9 inches diameter withinfide, and the height of the furface of the water above the pifton 67 feet. Diameter $9 \times 9 = 81$ circular inches of area $\times$ .341 lbs. $= 27.62$ lbs., which is the weight of every foot in height $\times$ 67 feet $= 1850.54$ lbs. which is the weight that bears upon the pifton, and which muft be overcome to draw it up.

Example 2.—It is required to find the weight which bears upon a rectangular valve, which is 7 inches by 5 inches, and the water rifes 67 feet above it. $7 \times 5 = 35$ fquare inches of furface $\times$ .434 lbs. $= 15.2$ lbs. for every foot of altitude $\times$ 67 feet $= 1018$ lbs.; the weight refting upon the valve.

Note.—In pumps it generally happens that there is a column of water contained in the pipe, beneath the pifton or valve, and is fufpended therefrom, becaufe the preffure of the atmofphere is taken off from fuch column by the valve or pifton, and the preffure of the atmofphere upon the furrounding water forces the water up the pipe until it touches the pifton, provided the height is not more than 33 feet. In all fuch cafes, the height of the column depending beneath the valve or pifton muft be added to the height of the column above the pifton, becaufe it is fo much additional burthen or preffure.

Rule to find the Preffure which any Column of Water exerts upon each fquare Inch or circular Inch of its Bafe, in Pounds Avoirdupois.—Multiply the height of the column in feet by .434, for the preffure on each fquare inch of the bafe, or by .34 lbs. for each circular inch.

In large works it is more convenient to take the area of the bafe in fquare feet, in which cafe the multiplier will be 62.5 lbs.; or, if it is circular feet, 49,0875 lbs.

Example.—A tank to contain water, ten feet deep, is lined with vertical walls of mafonry, each ftone of which is one foot fquare in its vertical face; required the preffure which

which will be exerted upon each ftone of the mafonry to thruft it outwards.

Depth beneath the Surface in Feet.	Preffure on each Stone, or on every fquare Foot, in Pounds.
1	62.5
2	125
3	187.5
4	250
5	312.5
6	375.
7	437.5
8	500
9	562.5
10	625.

The length and width of the tank does not influence the preffure upon each ftone ; becaufe, following our firft propofition, we are only to regard the magnitude of the plane againft which the water acts, and the depth at which it is fituated beneath the furface. But in all cafes when the plain is not horizontal, the depth of the water will be greater upon fome parts of the plane than upon others. The depths muft therefore be taken from the *centre of preffure* of the plane ; fee that article in Vol. VII.

The knowledge of the centre of preffure is required, in order to apply this calculation to wooden veffels, fuch as the large backs ufed by brewers ; or to find the preffure againft the gates of a fluice or lock, or in any other cafe where the wood planks, or the ftones of the mafonry are fo united together into one mafs, that the whole fide of the veffel muft be removed together. If the plane againft which the water acts rifes up as high as the furface of the water, and is of a rectangular figure ; that is, if all its horizontal dimenfions, whether taken at the bottom of the veffel or at the top, are equal, then the centre of preffure is fituated at $\frac{2}{3}$ds of the greateft depth beneath the furface.

Example.—A wooden vat is 18 feet long, and contains water 6 feet deep ; required the force which the water exerts againft the fide of the vat to force it outwards. Two-thirds of 6 feet is 4 feet, which is the depth of the centre of preffure : $4 \times 62.5 = 250$ lbs. is the mean preffure upon each fquare foot of the plane, 18 feet long $\times$ 6 feet deep $= 108$ fquare feet of area $\times$ 250 lbs. 27,000 lbs., which is the force exerted againft the fide of the veffel, and muft be refifted by the ftrength of the materials.

On the Means of meafuring or guaging the Quantity of running Water.—The ancients feem to have had no other meafure of running water than that uncertain and fallacious one, which depended wholly on the perpendicular fection of a ftream, without confidering the velocity of the motion. The firft who opened a way to the truth was Benedict Caftelli, an Italian, and friend of Galileo. He firft fhewed that the quantity of water, flowing through a given fection of a ftream, is proportional to the celerity with which the water is carried through that fection. This obfervation engaged philofophers to ftudy the doctrine of the motion of fluids with much diligence, and after Caftelli's time there was fcarcely any mathematicians who did not endeavour to add fomething thereto, either by experiments or by reafoning and argument.

But few of them, until the illuftrious fir Ifaac Newton, had any fuccefs, becaufe of the exceeding difficulty of the fubject.

Thofe who ftudied the theory laid down fuch theorems as were found to be falfe, when brought to the teft of experiments, and thofe who laboured in making experiments frequently omitted to obferve fome minute circumftances, the importance of which they had not yet perceived. Hence they differed greatly from one another, and almoft all of them erred from the real meafure.

The theory of hydraulics has never been carried to a very high degree of perfection upon mathematical foundation alone, nor has it hitherto, even with the affiftance of experiment, been rendered of much practical utility. Newton began the inveftigation of the motions of fluids on true principles. Daniel Bernouilli added much valuable matter to Newton's propofitions, both from calculation and experiment. D'Alembert, and many later authors, have exercifed their analytical talents in inquiries of a fimilar nature.

Dr. Robifon obferves that thefe, and other mathematicians of the firft order, feem to have contented themfelves with fuch views as allowed them to entertain themfelves with elegant applications of calculus. They rarely had any opportunity of doing more, for want of a knowledge of facts, but they have made excellent ufe of the few which have been given them.

It requires much labour, great variety of opportunities, and great expence, to learn the multiplicity of things which are combined, even in the fimpleft cafes of water in motion. Thefe advantages feldom fall to the lot of a mathematician, and he is without blame when he enjoys the pleafures within his reach, and cultivates the fcience of geometry in its moft abftracted form. Here he makes a progrefs which is the boaft of human reafon, being almoft infured from every error, by the intellectual fimplicity of his fubject. But were we to turn our attention to material objects, we know neither the fize and fhape of the elementary particles of water, nor the laws which nature has prefcribed for their action. We cannot, therefore, prefume to forefee their effects, calculate their exertions, or direct their actions, with any reafonable expectations of certainty.

A different and more practical mode of attaining hydraulic knowledge, has been attempted by a diftinct clafs of inveftigators. Thefe have begun from experiment alone, and have laborioufly deduced, from very ample obfervations of the actual refults of various particular cafes, the general laws by which the phenomena appear to be regulated, or at leaft the formulas by which the effect of new combinations may be predicted. But it muft be confeffed, that thefe formulas, however accurate, are almoft too intricate to be retained in the memory, or to be very eafily applied to calculations from particular data.

There are two gentlemen whofe labours in this refpect deferve very particular notice, profeffor Michelotti, at Turin, and abbé Boffut, at Paris. The firft made a prodigious number of experiments, both on the motion of water through pipes and in open canals. The experiments of Boffut are alfo of both kinds, and though on a much fmaller fcale than thofe of Michelotti, they feem to deferve equal confidence. The chevalier de Buat, who has taken up this matter where the abbé Boffut left it, has profecuted his experiments with great affiduity and fingular fuccefs.

Mr. Eytelwein, a gentleman honoured with feveral employments and titles relative to the public architecture of the Pruffian dominions, made a tranflation of Buat's works into German, with important additions of his own; and he alfo publifhed "Handbuch der Mechanik und der Hydraulik," Berlin, 1801. In this compendium of mechanics and hydraulics, he has collected the principal facts that have been afcertained, as well by his own experiments as by thofe of former authors, efpecially fuch as are the moft capable of practical application. He appears to have done this in fo judicious a manner, as to make his book a moft valuable

abftract

abstract of every thing that can be deduced from theory, respecting natural and artificial hydraulics. The elegant concisenefs of his manner deserves so much the more praise, as his countrymen too often make a merit of prolixity.

In our article Discharge, we have given the general principles of the motion of spouting fluids; and under River the theory of water running in rivers. The object of the present article will be to lay down such rules as may be immediately applicable to the use of the engineer.

In all cases of gauging streams, the quantity which flows, in any given time, is obtained by measuring the area of the aperture, or channel, through which the water flows, and finding the velocity with which the water moves through that aperture. To find the area of the aperture is a simple operation of mensuration, but to ascertain the velocity is not so easy. There are two different methods of determining the velocity. The first is, by observing the rate of motion of the surface, either by means of small light bodies thrown into the stream, or by employing instruments adapted to measure the rate at which the stream moves. This method is only applicable in cases of open canals and rivers, where the water flows with a slow motion. The other method is more general, and is applicable to the greatest velocities; because it is derived from calculation, according to the depth of water, or height of column, which urges the flowing water, and occasions its motion.

To measure the Quantity of Water running in a River or Canal. First Method.—Choose a part of the channel where the banks are of a determinate figure, and where they continue of the same breadth and depth for a length of ten, twenty, or thirty feet, the longer the better, and the more regular the banks are, the better the observations will be. Measure the breadth and the depth, or other dimensions which may be necessary, to find the area, or section of the passage, through which the water flows. Take these measures at several different points, and if there is any difference at different places, find the area at each place, and take a mean between them.

Then proceed to find the velocity of the motion, by throwing in a cork, or other light body, and observing, by a stop-watch, or pendulum, what number of seconds it takes to flow through a given length of the channel; for instance, the length of ten, twenty, or fifty feet, which was chosen in the first instance for the experiment, and marked out by stretching two strings, parallel across the river. This trial must be repeated several times, and as the instant when the floating body arrives at the last string, can be very exactly noted, this method admits of considerable exactness. A mean of the different results must be taken for the true velocity.

It is true that this only gives the velocity of the water at the surface, and the water moves with different velocities at different depths, beneath the surface; (instead of a single light body to float upon the surface of the water), we are recommended to employ a cylindrical rod of wood, of a length something less than the depth of the water: this is to be ballasted by a weight at the lower end, so that it will swim just upright in standing water, and with the upper end of the stick about an inch above water. By using this, instead of a single cork, we are supposed to attain the mean velocity of the stream at its different depths, instead of the velocity of the surface.

Instead of a cylinder of wood, three or four apples, strung together by a string, will answer the purpose very well, the lower ones being loaded by putting nails in them till they are rather heavier than water, so that the apples, when put into standing water, will hang in a perpendicular line. Goosberries are very nearly the weight of water, and may be employed singly, to shew its velocity at different depths.

Example.—A canal measured eight feet in width, and four feet in depth, the sides being perpendicular; then the area of the section is thirty-two square feet. It was found, by experiments with three apples, that the current ran through a space of fifteen feet in five seconds, in another experiment six seconds, and in a third four seconds and a half. What is the quantity of water passing through this canal?

The mean of all these is five seconds and one-sixth, during which the water moved fifteen feet. Now as five seconds and one-sixth is to fifteen feet, so is sixty seconds to a hundred and seventy-four feet, which the stream flows in the space of a minute. Then thirty-two square feet (the area), multiplied by 174 feet, gives 5568 cubic feet, which is the quantity of water flowing through the canal every minute.

This is the method recommended by Desaguliers, and if carefully executed, and the trials frequently repeated, is tolerably exact. Several authors have supposed this method might be much improved, by employing some instrument to shew the velocity of the stream by inspection. There are many ingenious inventions for this purpose.

Stream-Measurers.—M. Pitot invented a stream-measurer of a simple construction, to find the velocity of any part of a stream. This instrument is composed of two long tubes of glass open at both ends, and placed in a perpendicular direction in the stream of water: one of these tubes is cylindrical throughout and straight; but the other has its lowest extremity bent nearly at right angles, so as to form a horizontal branch, which gradually enlarges like a funnel, or the mouth of a trumpet; both these tubes are fixed to the side of a triangular prism of wood, with the lengths of the tubes parallel to the length of the prism, and their lower extremities both on the same level; the horizontal branch of the tube is carried through the prism, so that the end of the trumpet-mouth opens in one of the angles of the prism. The upright parts of the tubes stand one beside the other, and are let into grooves in the prism, so as to be tolerably well preserved from accidents. The face of the prism in which these tubes stand, is graduated on the edges close by the sides of them into divisions of inches and lines.

To use this instrument, it is placed perpendicularly in the water in such a manner, that the opening of the trumpet-mouth at the bottom of one of the tubes, shall be completely opposed to the direction of the current, in order that the water may pass freely through the funnel up into the perpendicular tube. Then by observing to what height the water rises in each tube, it will he found to rise higher in the tube with the trumpet-mouth than the other, and the quantity of this difference will be the height due to the velocity of the stream.

It is manifest that the water will rise in the straight cylindrical tube to the same height as the surface of the stream: this is by the hydrostatic pressure. But the water of the current entering by the funnel into the other tube, will be compelled to rise above that surface to some certain height, at which height it will be sustained by the impulse of the moving fluid; that is, the momentum or impulse of the stream will be in equilibrio with the column of water sustained in one tube above the surface of that in the other. In estimating the velocity by means of this instrument, we must have recourse to the following rules: if the height of the column sustained by the stream, or the difference of heights in the two tubes be taken in feet, the velocity of the

the

the ftream *per* fecond in feet will be 6.5 times the fquare root of the height.

If the height be meafured in inches, then the velocity in feet *per* fecond will be 1.88 times the fquare root of the height, nearly. It will be eafy to put the funnel into the moft rapid part of the ftream, by moving it about to different places, until the difference of altitude in the two tubes becomes the greateft. In fome cafes, it will happen that the immerfion of the inftrument will produce a little eddy in the water, and thus difturb the accuracy of the obfervation; but keeping the inftrument immerfed only a few feconds will correct this. The wind alfo would affect the accuracy of the experiments; it is therefore advifeable to make them when there is little or no wind.

By means of this inftrument, the velocity of water at various depths in a canal or river may be found with tolerable accuracy, and a mean of the whole drawn. Where great accuracy is not required, the bent tube with the funnel at bottom will alone be fufficient, becaufe the furface of the water will be indicated with tolerable precifion, by that part of the prifmatic frame for the tube which has been moiftened by the immerfion.

M. Pitot likewife propofed that a fimilar inftrument fhould be ufed inftead of a log, to determine the rate at which a fhip fails. For this purpofe, in the middle of a veffel, or as near as can be to the centre of its ofcillations, place two tubes of metal of three or four lines in diameter, one of them being ftraight, and the other bent at bottom and enlarged into a conical funnel. The lower ends of both are to dip into the water in which the veffel fails, and there will be no evil to apprehend from orifices fo minute. Into thefe metallic tubes, two others are clofely fitted at a convenient height for the obfervations. The water will rife, in the firft of thefe tubes, up to its level on the outfide of the fhip; and in the fecond, up to a certain height, which will indicate as above the velocity of the veffel. For the funnel being turned towards the prow of the fhip, it will, in confequence of the motion, be affected in like manner, as if it were plunged into the ftream of a running water. The actual velocity of the veffel is found by the fame rules as that of the current. This method has been repropofed in this country, without any acknowledgments to M. Pitot. We do not, however, recommend its adoption on board a fhip; for, notwithftanding its theoretical ingenuity, it is liable to many fources of error in practice, and would not, it is probable, furnifh more accurate meafures of a fhip's way, than thofe deduced from the common log.

In the practical ufe of M. Pitot's inftrument, a great difficulty is experienced from the ofcillations of the water in the tubes, which it is not eafy to prevent, and a mean height of the ofcillating water muft be taken.

M. Du Buat made trials of the inftrument, and found it could not be trufted for any other purpofes than to give the ratios of different velocities. He found the inftrument was better without the ftraight tube, and he employed only one tube with its lower end turned horizontally, in the direction of the ftream, it was made of tinned plate inftead of glafs, and fufficiently large to admit a float to fhew the height of the water in the tube. Inftead of making the end of the tube an open trumpet-mouth, he ufed to clofe it by a flat plate, with a fmall perforation in the centre to admit the water through it, or in fome cafes feveral fmall perforations. In this way, the water will rife in the tube, juft the fame as if it was open; but the ofcillations of the column will be avoided, or greatly diminifhed.

The hydraulic quadrant has been recommended by feveral authors, for meafuring the velocity of water.

It confifts of a fmall quadrant with a divided arch, and having two threads moving round its centre. One of thefe is fhort, and carries a plummet which always hangs in air, and ferves to place the quadrant in its true pofition. The other thread is longer, and carries a weight whofe fpecific gravity is greater than that of water, and which plunges more or lefs deep in the current as the thread is lengthened. The inftrument is held over the water, fo that the plummet of the long thread hangs in the water, and the force of the current will remove it from the perpendicular, whilft the angular diftance from the other thread, which is a vertical line can be afcertained by the divifions on the arch of the quadrant; the quantity of this deviation from the perpendicular is the meafure of the force, and confequently of the velocity of the current. Boffut has fhewn, that the force of the current is as the tangent of the angle which one thread makes with the other, and gives directions for ufing this inftrument to try a current at different depths.

Dr. Brewfter, in his edition of Fergufon's lectures, recommends a fmall and light wheel, like an underfhot waterwheel, with float-boards on its circumference. It is provided with an apparatus to afcertain and record the number of turns it makes, and is held in the ftream, fo that the water may act upon the float-boards to turn it round; and from the number of turns it makes in any given time, the velocity of the ftream may be computed. He directs the wheel to be made of the lighteft materials, and about ten or twelve inches in diameter: it is furnifhed with fourteen or fixteen float-boards. The centre of the wheel is perforated with a hole, and tapped to receive a delicate fcrew or wire, which forms the axis upon which it revolves, with as little friction as poffible. At each end of the fcrew or axis, is a handle to hold it by, and to fupport the wheel; and to one of thefe handles an index is fixed, pointing to divifions on the circumference of the wheel, which confift of 100 parts. This index fhews the aliquot parts of a revolution, whilft the number of threads which the wheel advances on the fcrew fhews the number of whole turns it makes.

To prepare this inftrument for ufe, the wheel muft be turned round upon the fcrew until it arrives quite at one end of it, and till the index points to zero of the divifions on the rim of the wheel; then hold the axis or fcrew horizontally by the two handles, fo that the floats dip in the water and turn the wheel round upon the fcrew.

By means of a ftop-watch, or a pendulum, find how many revolutions of the wheel are performed in a given time, a minute, for inftance. Multiply the mean circumference of the wheel, *i. e.* the circumference deduced from the mean radius, meafured from the centre of impulfion upon the float-boards to the centre of the wheel, by the number of revolutions, and the product will be the number of feet which the water moves through in the given time. On account of the friction of the fcrew, the refiftance of the air, and the weight of the wheel, its circumference, will move with a velocity a little lefs than that of the ftream; but the diminution arifing from thefe caufes, may be eftimated with fufficient precifion for all the purpofes of the practical mechanic.

This, we think, is one of the beft ftream-meafurers, becaufe it will give a correct meafure of the motion at the furface of the water; but it will not give the velocities at the different depths beneath the furface, nor do we know any machine which will effectually anfwer that purpofe.

By means of this inftrument, we can obtain the velocity of the furface with greater accuracy than perhaps by any other means; but to afcertain the quantity of water which fhall ſhall be diſcharged, we muſt know the mean velocity of the water.

Ratio between the mean Velocity of running Water and the Velocity of the Top and Bottom of a Channel.—M. Du Buat ſtates, that the ſuperficial velocity of a ſtream of water always bears a certain relation to the mean velocity, ſo that we can derive one from the other by an arithmetical rule.

From a great number of experiments, he diſcovered the following laws: 1ſt, That the velocity at the ſurface in the middle of the ſtream, (in ſlow motions,) is to the velocity at the bottom of the ſtream, in a ratio of conſiderable inequality. 2d, This ratio diminiſhes as the velocity increaſes, and in very great velocities approaches to the ratio of equality. 3d, What was moſt remarkable, was, that neither the magnitude of the channel, nor its ſlope, had any influence in changing this proportion, whilſt the mean velocity remained the ſame. Whether the ſtream ran in a channel with the bottom covered with pebbles, or coarſe ſand, the proportions between the two velocities was, as nearly as poſſible, the ſame as when it ran in a ſmooth channel. 4th, If the velocity at the ſurface in the middle of the ſtream be conſtant, the velocity at the bottom will be alſo conſtant, and will not be affected by the depth of water or magnitude of the ſtream. In ſome experiments, the depth was thrice the width, and in others the width was thrice the depth. This changed the proportion of the magnitude of the ſection, to the magnitude of the rubbing part, but made no change in the ratio between the velocities at the top and bottom.

The place of the mean velocity in the ſection of the ſtream could not be diſcovered with any preciſion. In moderate velocities, it was not more than one-fourth or one-fifth of the depth diſtant from the bottom. In very great velocities, it was ſenſibly higher, but never in the middle of the depth.

In all caſes he computed the mean velocity by meaſuring the quantities of water diſcharged in a given time. His method of meaſuring the bottom velocity was ſimple, and probably juſt; he threw in a gooſeberry, as nearly as poſſible of the ſame ſpecific gravity with the water; it was carried along the bottom without touching it. We have already obſerved, that the ratio between the velocity at the ſurface in the middle, and the velocity at the bottom, diminiſhed as the mean velocity was increaſed. This variation he was enabled to expreſs in a very ſimple manner, ſo as to be eaſily remembered, and to enable us to find any one of them from having obſerved another.

Dr. Robiſon ſtates, that if we take unity from the ſquare root of the ſuperficial velocity, in the middle of the ſtream, expreſſed in inches *per* ſecond, the ſquare of the remainder is the velocity at the bottom; and the mean velocity is the half ſum of theſe two. Thus, if the velocity of the ſurface in the middle of the ſtream be twenty-five inches *per* ſecond, its ſquare root is five; from which if we take unity, there remains four. The ſquare of this, or 16, is the velocity at the bottom, and $\frac{25 + 16}{2}$, or $20\frac{1}{2}$, is the mean velocity.

This is a very curious and moſt uſeful piece of information. The velocity of the ſurface in the middle of the ſtream, is the eaſieſt meaſured of all, by any light ſmall body floating down it, or by a ſtream-meaſurer; and the mean velocity is the one which regulates the diſcharge, and all the moſt important conſequences.

Dr. Robiſon gives the following table of theſe three velocities, which will ſave the trouble of calculation in ſome of the moſt frequent queſtions of hydraulics.

Velocity in Inches *per* Second.			Velocity in Inches *per* Second.

The knowledge of the velocity at the bottom is of uſe to an engineer, to enable him to judge of the action of a ſtream on its bed. Every kind of ſoil will bear a certain velocity without changing the form of the channel. A greater velocity would enable the water to tear it up, and a ſmaller velocity would permit the depoſition of more moveable mate-

rials

rials from above. It is not enough, then, for the permanency of a river, that the accelerating forces are ſo adjuſted to the ſize and figure of its channel, that the current may acquire an uniform velocity, and ceaſe to accelerate. It muſt alſo be in equilibrio with the tenacity of the channel.

It appears from obſervation, that a velocity of three inches *per* ſecond at the bottom, will juſt begin to work upon fine clay fit for pottery, and however firm and compact it may be, it will tear it up. Yet no beds are more ſtable than clay, when the velocities do not exceed this, for the water ſoon takes away the impalpable particles of the ſuperficial clay, leaving the particles of ſand ſticking by their lower half in the reſt of the clay, which they now protect, making a very permanent bottom, if the ſtream does not bring down gravel or coarſe ſand, which will rub off this very thin cruſt, and allow another layer to be worn off. A velocity of ſix inches *per* ſecond, will lift fine ſand; eight inches will lift ſand as coarſe as linſeed; twelve inches will ſweep along fine gravel; twenty-four inches will roll along rounded pebbles an inch in diameter; and it requires three feet *per* ſecond at the bottom to ſweep along ſhivered angular ſtones of the ſize of an egg.

Dr. Young gives an excellent ſimple rule for the ſame object, which is only a trifle different from Dr. Robiſon's; he ſtates, that from a mean of all the beſt experiments, he found that, if the ſquare root of the mean velocity of any ſtream (running in an uniform open channel) be added to ſuch mean velocity, it will give the ſuperficial or top velocity in the middle; or if deducted therefrom, it will leave the bottom velocity: whence we have deduced the following practical rule, *viz*.

1. Having found the top velocity, expreſſed in any convenient meaſure, which will correſpond with the reſult required.

To find the bottom velocity, add the conſtant number .25 (or $\frac{1}{4}$) to the top velocity; extract the ſquare root of the ſum, and double it; again add 1 to the top velocity, and from the ſum deduct the double root before found: the remainder is the bottom velocity of the ſtream.

2. To find the mean velocity from the top velocity, add the conſtant number .5, (or $\frac{1}{2}$) to the top velocity, and from their ſum deduct the ſquare root found in the firſt rule: the remainder is the mean velocity.

Or, 3. To find the mean velocity from the bottom velocity, add the conſtant number .25, (or $\frac{1}{4}$) to the bottom velocity, and extract the ſquare root of the ſum; then to this ſquare root add the bottom velocity, and the conſtant number, .5, and their ſum is the mean velocity.

Theſe are true in all caſes, provided the top and bottom velocities are related to each other, as Dr. Young ſtates. For example, Mr. Watt obſerved the ſurface of the water in an open canal to move with a velocity of 17 inches *per* ſecond: What was the bottom velocity?

By our firſt rule $17 + .25 = 17.25$, of which extract the ſquare root; it is 4.15; twice this is 8.3. Again, to the top velocity 17 add $1 = 18$, and deduct 8.3, it leaves 9.7 for the bottom velocity. Mr. Watt obſerved the bottom velocity to be 10 inches *per* ſecond.

2. To find the mean velocity, add .5 to the top velocity 17, it gives 17.5; deduct 4.18, and we get 13.32 inches *per* ſecond for the mean velocity.

3. If we take Mr. Watt's obſervation of the bottom velocity of 10 inches *per* ſecond, inſtead of the top; then to find the mean velocity $10 + .25 = 10.25$, of which the ſquare root is 3.201; and $10 + .5 = 10.5$; add theſe together, thus $(3.201 + 10.5) = 13.701$ inches *per* ſecond for the mean velocity; which only exceeds that deduced from the top velocity by little more than ⅓d of an inch in a ſecond.

By the aid of this rule, and the wheel ſtream-meaſurer before deſcribed, great accuracy may be obtained. Care muſt be taken to apply the wheel in the centre of the ſtream, on the ſurface, or rather at that place where the velocity of the ſurface is found to be the greateſt.

Second Method of meaſuring the Flowing of Water in an open Canal.—When a river flows with an uniform motion, and is neither accelerated nor retarded by the action of gravitation, it is obvious that the whole weight of the water muſt be employed in overcoming the friction of the water againſt the bottom and ſides.

The principal part of this friction is as the ſquare of the velocity, and the friction is nearly the ſame at all depths: for profeſſor Robiſon found, that the flow of the fluid through a bent tube was not increaſed by increaſing the preſſure againſt the ſides, being nearly the ſame when the bended part of the tube was ſituated horizontally, as when vertically, the ſame difference of level being preſerved.

The quantity of friction will, however, vary, according to the ſurface of the fluid which is in contact with the ſolid, in proportion to the whole quantity of fluid; that is, the friction for any given quantity of water will be, as the ſurface of the bottom and ſides of a river directly, and as the whole quantity of water in the river inverſely; thus, ſuppoſing the whole quantity of water to be ſpread on a horizontal ſurface equal to the bottom and ſides of the river, the friction is inverſely as the depth at which the river would then ſtand. This is called the hydraulic mean depth.

If the inclination or ſlope of the ſurface of water in a river varies, the deſcending weight, or the force that urges the particles down the inclined plane, will vary as the height of the fall in a given diſtance; conſequently, the friction, which is equal to the deſcending weight, muſt vary as the fall; and the velocity being as the ſquare root of the friction, muſt alſo be as the ſquare root of the fall. Suppoſing the hydraulic mean depth to be increaſed or diminiſhed, the inclination remaining the ſame, the friction would be diminiſhed or increaſed in the ſame ratio; and, therefore, in order to preſerve its equality with the deſcending weight, the friction muſt be increaſed or diminiſhed, by increaſing the velocity in the ratio of its ſquare to the hydraulic mean depth; that is, increaſing the velocity in the ratio of the ſquare root of the hydraulic mean depth.

Mr. Eytelwein's Rule is, that the velocity of a ſtream will be in the joint proportion of the ſquare root of the hydraulic mean depth, and the ſquare root of the fall in a given diſtance; or as a mean proportional between theſe two quantities.

Taking two Engliſh miles for a given length upon a ſtream, we muſt find a mean proportional between its hydraulic mean depth and its fall in two miles in inches, and inquire what relation this bears to the velocity in a particular caſe. We may thence expect to determine it in any other. According to Mr. Eytelwein's formula, this mean proportional is $\frac{11}{10}$ths of the velocity in a ſecond in inches.

In order to examine the accuracy of this rule, we may take an example, which could not have been known to Mr. Eytelwein. Mr. Watt obſerved, that in a canal 18 feet wide above, and 7 below, and 4 feet deep, having a fall of 4 inches in a mile, the velocity was 17 inches *per* ſecond at the ſurface, 14 in the middle, and 10 at the bottom. The mean velocity may be called $13\frac{3}{4}$ inches, in a ſecond. Now to find the hydraulic mean depth, we muſt divide the area of the

the fection $\left(\frac{18+7}{2} \times 4\right) = 50$ fquare feet, by the breadth of the bottom and length of the floping fides added together; whence we have $\frac{50}{20.6}$, or 29.13 inches: and the fall in two miles being 8 inches, we have $\sqrt{(8 \times 29.13)} = 15.26$ for the mean proportional; $\frac{10}{11}$ths of which is 13.9, agreeing nearly with Mr. Watt's obfervation. Profeffor Robifon has deduced from Buat's elaborate theorems 12.568 inches for the velocity, which is confiderably lefs accurate.

For another example we may take the river Po, which falls one foot in two miles, where its mean depth is 29 feet, and its velocity is obferved to be about 55 inches in a fecond. Our rule gives 58, which is perhaps as near as the degree of accuracy of the data will allow.

On the whole, we have ample reafon to be fatisfied with the unexpected coincidence of fo fimple a theorem with obfervation; and in order to find the velocity of a river from its fall, or the fall from its velocity, we have only to recollect that the velocity in inches *per* fecond is $\frac{10}{11}$ths of a mean proportional between the hydraulic mean depth and the fall in two Englifh miles in inches. This is, however, only true of a ftraight river flowing through an equable channel.

For the flope of the banks of a river or canal, Mr. Eytelwein recommends, that the breadth at the bottom fhould be $\frac{2}{3}$ds of the depth, and at the furface $\frac{10}{3}$ds; the banks will then be in general capable of retaining their form. The area of fuch a fection, is twice the fquare of the depth, and the hydraulic mean depth $\frac{2}{3}$ds of the actual depth.

M. Du Buat's Rule.—In our article RIVER, we have given the theorem of M. Du Buat for calculating the motion of water in a river or other regular channel, or through pipes. It has been obferved by the late Dr. Robifon, that the comparifon of the chevalier Du Buat's calculations with his experiments is very fatisfactory; that it exhibits a beautiful fpecimen of the means of expreffing the general refult of an extenfive feries of obfervations in an analytical formula; and that it does honour to the penetration, fkill, and addrefs of M. Du Buat, and of M. De St. Honore, who affifted him in the conftruction of his expreffions.

Dr. Young's Rule.—Dr. Young juftly remarks, in an excellent paper in the Philofophical Tranfactions for 1808, that the form of Du Buat's expreffions is not fo convenient for practice as they might have been rendered; and are liable to great objections, in particular cafes: for when the pipe is extremely narrow, or extremely long, they become completely erroneous. Dr. Young has, therefore, fubftituted for the formulæ of M. Du Buat others of a totally different nature; and he profeffes to have followed Du Buat only, in his general mode of confidering a part of the preffure, or of the height of a given fall, as employed in overcoming the friction of the pipe, through which the water flows out of it; a principle which, if not of his original invention, was certainly firft publifhed by him, and reduced into a practicable form. We find Mr. Smeaton ufed it in conftructing his MS. tables. By comparing the experiments which Du Buat has collected, with fome of Gerftner's, and fome of his own, Dr. Young difcovered a formula, which appears to agree fully as well as Du Buat's, with the experiments from which his rules were deduced, and at the fame time accords better with Gerftner's experiments; and which formula extends to all the extreme cafes with equal accuracy. It feems to reprefent more fimply the actual operation of the forces concerned; and it is direct in its application to practice, without the neceffity of any fucceffive approximations.

He began by examining the velocity of the water difcharged through pipes of a given diameter, with different degrees of preffure; and found that the friction could not be reprefented by any fingle power of the velocity, although it frequently approached to the proportion of that power of the velocity, of which the exponent is 1.8; but that it appeared to confift of two parts, the one varying fimply as the velocity, the other as its fquare. The proportion of thefe parts to each other muft, however, be confidered as different, in pipes of different diameters; the firft part being lefs perceptible in very large pipes, or in rivers, but becoming greater than the fecond in very minute tubes; while the fecond alfo becomes greater, for each given portion of the internal furface of the pipe, as the diameter is diminifhed.

If, with Dr. Young, we exprefs all the meafures in Englifh inches, calling the height employed in overcoming the friction f, the velocity in a fecond v, the diameter of the pipe d, and its length l; we may make $f = a\frac{l}{d}v^2 + 2c\frac{l}{d}v$: for it is obvious, that the friction muft be directly as the length of the pipe; and fince the preffure is proportional to the area of the fection, and the furface producing the friction to its circumference or diameter, the relative magnitude of the friction muft alfo be inverfely as the diameter, or nearly fo, as Du Buat has juftly obferved.

We fhall then find, that a muft be $.0000001\left(413 + \frac{75}{d} - \frac{1440}{d+12.8} - \frac{180}{d+.355}\right)$, and c muft be $.0000001\left(\frac{900dd}{dd+1136} + \frac{1}{\sqrt{d}}\left(1085 + \frac{13.21}{d} + \frac{1.0563}{dd}\right)\right)$.

Hence it is not difficult to calculate the velocity for any given pipe, open canal or river, with any given column of water: for the height required for producing the velocity, including friction, is, according to Du Buat, $\frac{v^2}{510}$; or rather, as it appears from almoft all the experiments which the doctor compared, $\frac{v^2}{586}$; and the whole height h is, therefore, equal to $f + \frac{v^2}{586}$, or $h = \left(\frac{al}{d} + \frac{1}{586}\right)v^2 + \frac{2cl}{d}v$; and affuming $b = \frac{1}{al \div d + .00171}$, and alfo affuming $e = \frac{bcl}{d}$, we have $v^2 + 2ev = bh$; whence, $v = \sqrt{(bh + e^2)} - e$; which is a general theorem.

In order to adapt this formula to the cafe of rivers, we muft make l (the length) infinite; by which b becomes $\frac{d}{al}$, and $bh = \frac{d}{a} \times \frac{h}{l} = \frac{ds}{a}$; s being the *fine* of the inclination of the water's furface, and $d = 4$ times the hydraulic mean depth. The hydraulic mean depth is the area of the fection of the moving water, divided by as much of the circumference of that area, as the water touches. And fince e is here $= \frac{c}{a}v = \frac{\sqrt{(ads + c^2)} - c}{a}$; and in moft rivers, v becomes nearly $\sqrt{(20000\,ds)}$.

Another ufeful rule by Dr. Young, is to find the fuperficial velocity of the water in a river by adding to the mean velocity

velocity of a river its ſquare root; this gives the velocity at the ſurface; and by ſubtracting the ſame ſquare root, we get the velocity at the bottom.

N. B. $2.618 - \sqrt{2.618} = 1$, and $.382 + \sqrt{.382} = 1$; which it may be uſeful to remember, with reference to this laſt rule.

Dr. Young made a compariſon of his general theorem, as above, with forty experiments extracted from the collection which ſerved as a baſis for Du Buat's calculations; and he found that the mean error of his formula is $\frac{1}{34}$th of the whole velocity, and that of his own $\frac{1}{36}$th only. But, omitting the four experiments, in which the ſuperficial velocity only of a river was obſerved, and in which he calculated the mean velocity by Du Buat's rules, the mean error of the remaining 36 is but $\frac{1}{35}$th, according to Dr. Young's mode of calculation, and $\frac{1}{37}$th according to M. Du Buat's; ſo that, on the whole, the accuracy of the two formulæ may be conſidered as preciſely equal with reſpect to theſe experiments.

In the ſix experiments which Du Buat has wholly rejected, the mean error of his formula is about $\frac{1}{24}$th, and that of Dr. Young's $\frac{1}{35}$th. In fifteen of Gerſtner's experiments, the mean error of Du Buat's rule is $\frac{1}{3}$d, that of Dr. Young's $\frac{1}{4}$th; and in the three experiments which Dr. Young made with very fine tubes, the error of his own rules is $\frac{1}{15}$th of the whole; while in ſuch caſes Du Buat's formulæ completely fail.

It would be uſeleſs to ſeek for a much greater degree of accuracy, unleſs it were probable that the errors of the experiments themſelves were leſs than thoſe of the calculations. But if a ſufficient number of extremely accurate and frequently repeated experiments could be obtained, it would be very poſſible to adapt Dr. Young's formula ſtill more correctly to their reſults.

In order to facilitate the computation, Dr. Young made tables of the co-efficients a and c for 44 different values of a, both in French and Engliſh inches, which may be ſeen in the Philoſophical Tranſactions for 1808; but inſtead of inſerting them, we ſhall give a far more extended table, which we have carefully deduced from Dr. Young's formula and table, and put it in a form more directly applicable to practice.

Let d repreſent four times the hydraulic mean depth of an open canal.

Note.—The hydraulic mean depth is the area of the ſection through which the water runs, divided by ſo much of the circumference of that ſection as is touched by the water.

Note alſo.—In caſe of cloſe pipes running a full bore of water, the diameter of the pipe is four times the hydraulic mean depth.

s repreſents the ſine of the inclination of the water's ſurface; that is, the height of the head or riſe, divided by the length or diſtance of the ſlope in which ſuch riſe takes place.

v, the mean velocity *per* ſecond, in inches.

The other ſymbols uſed in the theorem are ſhewn at the head of the different columns of the Table.

Dr. Thomas

Dr. Thomas Young's Theorem, with a new and enlarged Table deduced therefrom, exprefsly for our Work, for calculating the Velocity of Water flowing in Rivers, Channels, or Pipes.

THEOREM. The mean Velocity *per* Second, in inches or v, is $= \sqrt{\left(\frac{d}{a}s + \frac{c^2}{a^2}\right)} - \frac{c}{a}$.

d	$\frac{d}{a}$	$\frac{c^2}{a^2}$	$\frac{c}{a}$	d	$\frac{d}{a}$	$\frac{c^2}{a^2}$	$\frac{c}{a}$

To

Uſe of the Table.—To render this theorem uſeful to thoſe who are not familiar with the uſe of algebraic expreſſions, we ſhall give an example of the manner of calculating a ſtream of water, all the operations being performed by common arithmetic, with the help of the preceding Table.

1. If it is a ſtream of water running in an uniform channel, take a ſufficient number of dimenſions of the tranſverſe ſection of the channel, and by the rules of menſuration calculate *the area* of its croſs ſection in ſquare feet. Calculate alſo, how much of the *circumference* of ſuch croſs ſection is touched by the water, not including its level top.

Then divide the area in ſquare feet by that portion of the circumference in feet, in order to obtain the *hydraulic mean depth;* this muſt be multiplied by 12, to reduce it to inches. Multiply the quotient by 4, and the reſult is d, the number which is to be ſought in the firſt column of the preceding Table.

If it is a circular pipe of uniform bore, running full of water, its internal diameter, taken in inches, is already equal to four times the hydraulic mean depth, without any computation; and accordingly the diameter of the pipe in inches is to be ſought for in column 1.

2. By a ſpirit-level or otherwiſe, aſcertain the perpendicular fall or difference of level, between any two diſtant points on the ſurface of the water, if it is an open ſtream, and find the diſtance between theſe points of levelling, by meaſuring upon a parallel to the ſurface of the ſtream. Theſe may be taken in any convenient meaſures; but the fall and the diſtance muſt be reduced to the ſame meaſures: then divide the fall by the diſtance, and the quotient is s, or a decimal number, which is the *ſine* of the inclination of the ſtream.

If it be a cloſe pipe, the perpendicular fall muſt be the difference of level between the ſurface of the reſervoir and the place of diſcharge; divide this by the length of the pipe.

3. Having found d, in column 1 of the Table, take out the number oppoſite to it in the ſecond column, entitled $\frac{d}{a}$ (that is, d divided by a), and multiply this tabular number by the decimal number s.

Note.—It will ſometimes happen that the exact amount of d is not to be found in column 1, but it will fall between two of the numbers therein; then take out the leaſt of thoſe numbers before d, and find how much is to be added thereto, by the following rule: Take the difference of the two numbers in col. 1. between which d falls; alſo the difference of the numbers oppoſite to them in col. 2.; alſo take the difference between the number d, and the leaſt of the two numbers between which it falls. Now, by the Rule of Three, ſay, as the whole difference of the two numbers in col. 1. is to the ſame in col. 2., ſo is the difference between d and the number above it in col. 1. to a fourth number, which is the proportional part to be added to the number of col. 2. before d.

4. Take out the tabular number from col. 3. which is entitled $\frac{c^2}{a^2}$; (that is, the ſquare of c divided by the ſquare of a).

But here *note*, in caſe of calculating a proportional part, (as directed in the laſt rule,) it is not always to be added (as in col. 2.); but ſometimes, on the contrary, it is to be ſubtracted, accordingly as the numbers in that part of col. 3. are increaſing or decreaſing; and for greater eaſe of diſcovering this, a * is placed oppoſite 14, and between 200 and 300 of col. 1., to ſhew the places where theſe changes take place, from decreaſe to increaſe, and the contrary.

5. Multiply s, the reſult of the ſecond operation, and $\frac{d}{a}$, the reſult of the third operation, together, and to the product add $\frac{c^2}{a^2}$, as found by the fourth operation: then extract the ſquare root of this ſum.

6. Take out $\frac{c}{a}$ from col. 4., and apply the proportional part as before, if neceſſary; deduct this number $\frac{c}{a}$ from the ſquare root laſt found, and the remainder or reſult is the *mean velocity* of the ſtream in *inches per ſecond*, which was required.

Should this reſult be afterwards wanted in *feet per minute*, the numbers laſt obtained muſt be multiplied by 60, and divided by 12; or rather, multiplied at once by 5, which is the ſame thing.

To obtain *the quantity* of water diſcharged in a minute, multiply *the area* of the ſection of the ſtream by *the velocity* now found; taking care, if the area is in ſquare feet, to expreſs the velocity of the water in feet; or if the area is in ſquare inches, the velocity muſt be expreſſed in inches, and the product or reſult will be in cubic feet or cubic inches, accordingly.

Example 1.—The Academy of Sciences at Paris were occupied, during ſeveral months, with an examination of a plan propoſed by M. Parcieux, for bringing the water of Yevette into Paris; and, after the moſt mature conſideration, gave in a report of the quantity of water which M. De Parcieux's aqueduct would yield. Their report was afterwards found erroneous in the proportion of at leaſt 2 to 5; for when the waters were brought in, they exceed the report in this proportion. Indeed, long after the giving in the report, M. Perronet, the moſt celebrated engineer in France, affirmed, that the dimenſions propoſed were much greater than were neceſſary; and ſaid that an aqueduct of $5\frac{1}{2}$ feet wide, and $3\frac{1}{2}$ deep, with a ſlope of 15 inches in a thouſand fathoms, would have a velocity of 12 or 13 inches *per* ſecond, and would bring all the water furniſhed by the propoſed ſources. The great diminution of expence occaſioned by the alteration, encouraged the community to undertake the work. It was accordingly begun, and partly executed. The water was found to run with a velocity of near 19 inches, when it was $3\frac{1}{2}$ feet deep.

M. Perronet founded his computation on his own experience alone, acknowledging that he had no theory to inſtruct him.

Let us examine this caſe by our theorem.

Firſt, The area of the ſection is 3.5 feet deep $\times$ by 5.5 feet wide $= 19.25$ ſquare feet.—The circumference which the water touches, conſiſts of the two ſides of 3.5 feet each, added to 5.5 feet, the bottom $= 12.5$ feet. The area 19.25 ſquare feet divided by 12.5 feet gives 1.54 feet, for the hydraulic mean depth $\times\ 12 = 18.48$ inches; four times this is $d = 73.92$, which we are to ſeek in the firſt column of the table; and may take 74.

Secondly, To find s, take the fall 15 inches, or 1.33 feet, and divide it by the diſtance, 1000 fathoms, or 6000 feet; the reſult is .00022, for s, or the ſine of the inclination.

Take out from the table the numbers correſponding to 74.

d	$\frac{d}{a}$	$\frac{c^2}{a^2}$	$\frac{c}{a}$
74	1875000	4.872	2.207

We

We now have all the neceſſary quantities for making the calculation thus: multiply $\frac{d}{a} = 1875000$ by $s = .00022$, and we have 416.25. To this add $\frac{c^2}{a^2} = 4.872$, and it makes 421.122, of which extract the ſquare root, and it is 20.52; deduct $\frac{c}{a} = 2.207$ from this, and it leaves 18.313 inches *per* ſecond for the mean velocity of the water.

This agrees pretty well with the obſervation of 19 inches, and Dr. Robiſon made very nearly the ſame reſult by a different mode of calculation.

The velocity of 18.313 inches *per* ſecond × 5 gives 91.56 feet *per* minute, and again multiplied by 19.25 ſquare feet, (the area of the ſection,) gives 1761.6 cubic feet of water which flow through this canal every minute.

This example is comparatively eaſy, becauſe the table affords the numbers required; but in ſome caſes the exact numbers cannot be found in the table, we ſhall therefore give another example.

Example 2.—Mr. Watt meaſured a canal in the neighbourhood of Birmingham, which was 18 feet wide at the ſurface of the water, 7 feet wide at the bottom, and 4 feet deep. The water had a declivity of four inches in a mile;—required the velocity with which the water moved, and the quantity which the canal afforded.

To have a complete knowledge of the ſection, find the length of each ſloping ſide, thus take the projection of the top width over the bottom width on each ſide, that is, half the difference between the top and bottom width $(18 - 7) \div 2 = 5.5$ feet: now the ſquare of 5.5 is 30.25, and the ſquare of 4 feet the depth is 16, the ſum of the two is $(30.25 + 16 =)$ 46.25; and the ſquare root of this is 6.8, the length of each ſloping ſide.

Firſt, To find the area and the hydraulic mean depth.—The mean between the widths of the top and bottom is $(18 + 7) \div 2$ 12.5 × 4 feet deep = 50 ſquare feet for the area of the ſection. To find the circumference which the water touches, add the two ſloping ſides, each 6.8 feet, to 7 feet, the width of the bottom, and it makes 20.6 feet.

The area, 50 ſquare feet, divided by 20.6 feet, gives 2.4272 feet = 29.126 inches for the hydraulic mean depth; 4 times this is 116.504, which is d, and muſt be found in the firſt column of the table. The neareſt which can there be found is 100 inches.

Secondly, The fall is 4 inches in the diſtance of a mile, = 63360 inches, divide 4 by 63360, and it gives .00006313 for s, the ſine of the inclination.

Thirdly, The value of $\frac{d}{a}$, in the ſecond column, oppoſite to 100 in the firſt column, is 2501000, to which ſomething muſt be added for the 16.5 inches. To find this quantity, take the difference between the adjacent numbers in column two, *viz.* 2501000 and 4950000 = 2449000, and, laſtly, the difference between 100 and 116.5 = 16.5; then ſay, as 100 is to 2449000, ſo is 16.5 to 404085, which number is to be added to 2501000, = 2905085, which is $\frac{d}{a}$ for 116.5.

Fourthly, The value of $\frac{c^2}{a^2}$, in column third oppoſite to 100, is 5.272, to which add .0043, as found by a rule of proportion ſimilar to the above, and it gives 5.276, which is $\frac{c^2}{a^2}$ for 116.5.

Fifthly, Multiply $s = .00006313$ by 2905085, and it gives 183.395; add $\frac{c^2}{a^2}$, or 5.276, as found by the preceding operation, and it gives 188.671; and the ſquare root of this number is 13.736.

Sixthly, The value of $\frac{c}{a}$, in column fourth, is 2.296 for 100, or for 116.5 it is 2.297; deduct this from 13.736, the reſult of the laſt operation, and we have 11.439, which is the velocity of the ſtream in inches *per* ſecond, and this × 5 = 57.195 feet *per* minute. To find the quantity, multiply the velocity, 57.19 feet *per* minute, by 50 ſquare feet the area, and we ſhall have 285.97 cubic feet, which quantity will flow every minute through this canal.

The velocity here found is conſiderably ſmaller than what was obſerved by Mr. Watt; he found the velocity at the ſurface 17 inches *per* ſecond, and at the bottom 10 inches, the mean velocity we have already calculated at 13.32.

Dr. Robiſon, in the Encyclopædia Britannica, gives a calculation of this ſame caſe by Du Buat's formula, which we have given in the article River. He makes the velocity 11.85 feet *per* ſecond, which differs ſo little from our computation, that the two theorems may be conſidered equally accurate; but both appear, by Mr. Watt's obſervation, to be rather too ſmall in very ſmall declivities of rivers and canals. This is not ſurpriſing when we conſider, that the experiments, which are the foundation of both theſe formulæ, were made on ſmall canals; but for this reaſon, we may expect they will be more accurate when applied to ſmaller channels, ſuch as mill-courſes, aqueducts, &c.

In taking obſervations to apply this method of calculation to practice, it muſt be recollected that it always proceeds on the ſuppoſition, that the canal is of a regular width and depth, and of an uniform ſlope throughout. If this is not the caſe, the canal muſt be conſidered in different portions, and each calculated ſeparately. We think greater accuracy will be attained by meaſuring and carefully levelling 100 yards in which the width and depth are quite regular, than by taking a mile in length, if there are any irregularities in the dimenſions, or in the ſlope in that diſtance.

On the other hand, the theorem cannot apply at all, unleſs the length of the channel is ſuch, that the water in it will arrive at an uniform motion without any acceleration of the motion, as it proceeds down. In ſhort and rapidly inclined channels, the water accelerates in conſequence of deſcending further down the fall; but when the canal is long, the velocity arrives at a certain point, and then the friction prevents any farther acceleration; in this caſe, the theorem applies. We ſhall not err ſenſibly in uſing this theorem for canals of 30 yards in length, or leſs, if the fall is ſmall.

Method of gauging the Water running through cloſe Pipes.—Dr. Young's theorem and our table, apply with equal, perhaps greater accuracy, to the caſe of cloſe pipes than to open canals.

All that is neceſſary is, to meaſure the internal diameter of the pipe in inches, the length of the pipe, and the difference of the level between the water in the reſervoir and the place at which the water is diſcharged, and proceed as in the former inſtance; but to render it more clear we ſhall give two examples.

Example 1.—The city of Edinburgh is ſupplied with water,

water, from ſprings at Comiſton, which is a conſiderable diſtance; this is conveyed by two pipes, the firſt of which was laid in 1720, under the direction of Deſaguliers. Dr. Robiſon mentions one of them, which is 5 inches diameter, 14,637 feet in length; the reſervoir at Comiſton is forty-four feet higher than the reſervoir on the Caſtle-Hill, in the town of Edinburgh.

Firſt, to find the ſine of the inclination, or s, divide the fall 44 feet by 14,637, and it gives .00301, which is s.

Now take five inches, the diameter of the pipe in col. 1., and oppoſite to it in col. 2. find $\frac{d}{a} = 159700$, which multiply by .00301, gives 479.1; to this add $\frac{c^2}{a^2} = 2.624$ taken from the third column, and the ſum is 481.724.

Extract the ſquare root of this, and it is 21.948, from which deduct $\frac{c}{a}$, or 1.620, taken from col. 4., and the reſult is 20.328, which is the velocity in inches *per* ſecond, and this × by 5 = 101.64 feet *per* minute.

To find the quantity, find the area of the ſection of the pipe in ſquare feet, by dividing the ſquare of the diameter 25 by 183.3, and it gives .1364 ſquare feet, and this × by 101.64 feet velocity, gives 13.86 cubic feet *per* minute for the diſcharge from the pipe.

Dr. Robiſon's calculation of this ſame caſe by Du Buat's formula, gives a velocity of 20.08 inches *per* ſecond.

In Mr. Smeaton's Reports, we find the other pipe ſtated at four and a half inches bore, and that it yielded 160 Scots pints *per* minute, each 103.4 cubic inches = 9.58 cubic feet. Mr. Smeaton's own calculation was 159 pints.

Example 2.—Mr. Smeaton ſtates, that this pipe was improved by obtaining an increaſe of fall, making it 51 feet, and that it then yielded 200 Scots pints = 11.98 cubic feet *per* minute, the bore being $4\frac{1}{2}$ inches, and the length 14,637 feet as before. Mr. Smeaton's calculation was 173 pints = 10.36 cubic feet *per* minute. What would it be by Dr. Young's theorem? *viz.* velocity = $\sqrt{\left(\frac{d}{a} \times s + \frac{c^2}{a^2}\right)} - \frac{c}{a}$.

To find s, divide the fall 51 feet by the length 14,637 feet; it gives .003484.

To find $\frac{d}{a}$, anſwering to 4.5 inches in col. 1., take half the difference between the numbers in the ſecond col. oppoſite to 4 and 5, and add it to the number anſwering to 4; thus, $\frac{d}{a}$ for 4 is 131560, and $\frac{d}{a}$ for 5 is 159700, difference 28200, which ÷ 2 = 14100, and this × 131500 = 145600, which is $\frac{d}{a}$ for 4.5. Multiply this 145600 by s, or .003484, and it is = 507.67: to this add $\frac{c^2}{a^2}$.

To find $\frac{c^2}{a^2}$ for 4.5, take half the difference between the numbers in the third column for 4 and 5, which is .869, and ſubtract it from 4.363, the number anſwering to 4; the reſult is 3.494, which is $\frac{c^2}{a^2}$ for 4.5; this added to 507.67 is 511.164.

The ſquare root of that number is 22.609, from which deduct $\frac{c}{a}$, = 1.854, and it leaves 20.755, which is the velocity *per* ſecond in inches.

(*Note.* $\frac{c}{a}$ is found by ſubtracting half the difference between the numbers for 4 and 5 in the fourth column, from the number anſwering to 4.)

20.755 inches *per* ſecond × 5 = 103.775 feet *per* minute, for the velocity. The area of the pipe is 4.5 × 4.5 = 20.25 circular inches, which ÷ by 183.3, the circular inches in a ſquare foot, is = .1104 ſquare feet for the area of the pipe. Multiply this by 103.775 feet *per* minute, and we get 11.46 cubic feet *per* minute for the diſcharge, which agrees very nearly with the experiment.

Dr. Brewſter, in his Encyclopædia, has calculated this ſame pipe, except that he ſtates it 300 feet longer; he makes the velocity by Du Buat's theorem 20.385 inches *per* ſecond, and ſays that on an average of five years, from 1738 to 1742, its maximum diſcharge was 11.3 cubic feet *per* minute; he has alſo calculated the ſame caſe by five different formulæ; thus,

	Scot's Pints *per* Minute.	Cubic Feet *per* Minute.
The quantity of water actually diſcharged	200 189.4	11.968 11.333
Calculated by Eytelwein's formula	189.77	11.355
Calculated by Girard's formula	188.26	11.265
Calculated by Du Buat's formula	188.13	11.257
Calculated by M. Prony's ſimple formula	192.32	11.502
Calculated by M. Prony's table	180.7	10.813
To which we may add Mr. Smeaton's calculation	173.	10.352
And by Dr. Young's theorem	191.5	11.459

It is ſatisfactory to find the reſults of ſo many different proceſſes agree ſo nearly, and gives us great confidence in the truth of the principles. There is in this caſe ſo little difference amongſt theorems that any one may be taken; but we think it needleſs to enter into farther particulars, as the one which we have given effects all that can be deſired, and by the help of the table, is the moſt ready in the application.

We ſhall only add Mr. Smeaton's table on the friction of water running through pipes, which we find in his manuſcript papers, and which he computed from his own obſervations alone, without knowing the experiments on which the other theorems are founded. They will give rather leſs than the theorems, and perhaps may approach more nearly to actual practice, in which pipes are not laid with the ſame care, to avoid roughneſs withinſide and ſudden bends, as when prepared purpoſely for experiments; we may conſider the theorems as the maximum diſcharge, and Mr. Smeaton's table as the fair average of practice.

Uſe of the Table.—Find the velocity of the water *per* minute in feet and decimals in the firſt column, or in feet *per* ſecond in the next column, and on the ſame line underneath the diameter of the bore in inches, you will find the perpendicular height of a column of water in inches and 10ths, neceſſary to overcome the friction of that pipe for 100 feet in length, and obtain the given velocity.

Mr.

Mr. Smeaton's TABLE for shewing the Friction of Water in Pipes; the Bore of the Pipe being given, and the Velocity of the Water therein; the Column or Height of Head necessary to overcome the Friction, and produce that Velocity, is shewn by this Table for 100 Feet in Length.

Velocity.		Bore of the Pipes in Inches.										
		½	¾	1	1¼	1½	1¾	2	2¼	2½	3	3½
In Feet *per* Minute.	In Feet *per* Second.	Depths of Water necessary to overcome the Friction of the Water in a Pipe 100 feet long, and produce the Velocities marked in the two first Columns.

		Bore of the Pipes in Inches.									

We

We have fearched in Mr. Smeaton's papers for the experiments by which this table was made, and we find an inveftigation, from the experiments of M. Couplet, as recorded by Belidor, on the flow of water through a large pipe at Verfailles. From thefe he deduced the following rule, to find the height of column in inches, correfponding with the velocities in inches *per* fecond, through a pipe of any diameter given in inches, and 100 feet long.

$$\frac{48 \times (\text{velocity}) + \text{velocity}^2}{52.66 \times (\text{diameter})} = \text{depth of column};$$

or, ftill more nearly, taking 47.873 for the conftant number inftead of 48.

It appears that he found this rule did not agree with his own obfervations; and, in confequence, he made the following experiments himfelf with a pipe of $1\frac{1}{4}$ inch bore and 100 feet in length; and we believe he arranged them into the table, by projecting and drawing a curve, at leaft we find that was his ufual method in like cafes.

Velocity *per* Second.	Depth of the Column.	
	By the Table.	By Experiment.
Inches.	Inches.	Inches.
$6\frac{1}{2}$	2.1	2.0
$7\frac{3}{4}$	3.0	2.8
$8\frac{3}{4}$	3.7	3.8
10	4.7	4.8
$11\frac{1}{2}$	6.2	6.2
13.4	7.9	7.8
$15\frac{1}{2}$	10.4	10.7
$18\frac{1}{4}$	14.7	14.5
21	18.3	18.1
$23\frac{3}{4}$	22.7	23.0
27	28.4	27.6
$28\frac{1}{4}$	30.8	30.5
$29\frac{3}{4}$	33.8	34.3
$30\frac{1}{4}$	34.8	35.6
35.5	47.2	47.0
$43\frac{3}{4}$	71.2	71.0

This is ufeful information, becaufe it fhews what part of the table may be depended upon. He affumed, that the depth of the column in pipes of other dimenfions, was as the length of the pipe directly, and as the diameters inverfely.

The form of this table renders it immediately applicable to a great variety of purpofes; for inftance, an engine is required to pump water to a height of 60 feet; but the water muft pafs through 1800 feet of horizontal pipe of 5 inches bore, and with a velocity of 140 feet *per* minute. The table fhews, that for every 100 feet of this pipe the friction will be equal to a column of 7.6 inches; multiply this by 18.6, and we find the whole friction will be 141.36 inches, this added to 60 feet makes 71.78 feet for the real column which the pump muft overcome.

Rules for meafuring the Quantity of Water flowing through Sluices or Apertures.—In this, like the former inftances, we muft multiply the area of the aperture by the velocity with which the water rufhes through it.

Sir Ifaac Newton, in his Principia, book ii. theo. 8. prob. 36. has demonftrated, that the velocity of water, flowing through holes in the bottom or fide of a veffel, ought to be equal to the velocity which a heavy body would acquire, in falling through a fpace equal to the diftance between the furface of the water and the place where it is difcharged.

Hence, at the depth of $16\frac{1}{12}$ feet, a ftream of $32\frac{1}{6}$ feet in length, ought to flow out in a fecond of time. And from the laws of falling bodies, it follows, that as the fquare root of $16\frac{1}{12}$ is to the velocity of the ftream flowing out at that depth, fo is the fquare root of any other depth to the velocity of that depth.

Hence, the velocity of water flowing out of a horizontal aperture, in the bottom of a ciftern or refervoir, is as the fquare root of the height, or the depth of water above the aperture.

That is, the preffure, and confequently the depth, is as the fquare of the velocity; for the quantity flowing out in any given time is as the velocity, and the force required to produce a velocity in a certain quantity of matter in a given time, is alfo as that velocity; therefore, the force muft be as the fquare of the velocity.

The propofition is fully confirmed by Boffut's and Michelotti's experiment; the proportional velocities, with a preffure of 1, 4, and 9 feet, being 2722, 5436, and 8135, inftead of 2722, 5444, and 8166; very inconfiderable differences.

There is another mode of confidering this propofition, which is a very good approximation. Suppofe a very thin cylindrical plate of water, like a wafer, fituated in the orifice; and fuppofe a conftant fucceffion of fuch plates to be put in motion, one at every inftant, by means of the preffure of the whole cylinder ftanding upon it; let all the gravitating force of the column be employed in generating the velocity of each fmall cylindrical plate, (neglecting the motion of the cylinder itfelf,) this plate would be urged by a force as much greater than its own weight, as the column is higher than itfelf, and this through a fpace fhorter in the fame proportion than the height of the column. But where the forces are inverfely as the fpaces defcribed, the final velocities are equal: therefore, the velocity of the water flowing out muft be equal to that of a heavy body falling from the height of the head of water.

This velocity may be found very nearly by the rule which we have before given in underfhot water-wheels, or by extracting the fquare root of the depth in feet, and multiplying it by 481.2: the product is the velocity *per* minute in feet.

In practice it is more convenient to take the depth in inches, inftead of feet; then to obtain the velocity in feet *per* minute.

Extract the fquare root of the depth in inches, and multiply it by 138.88: the product is the velocity in feet *per* minute.

As this rule is the foundation of all calculations for velocities, when friction is not confidered, it is conftantly wanted: we fhall, therefore, give a table, calculated by Mr. Smeaton from the above rule, fhewing the theoretic velocities correfponding with different depths.

A Table

A Table ſhewing the Velocity in Feet *per* Minute, or *per* Second, with which Water ſhould iſſue from an Aperture at any given Depth beneath the Surface, from ¼ Inch to 20 Feet, calculated according to the Theory of falling Bodies.

If

If we were to calculate the expence or difcharge for any orifice by this table, we fhould in every inftance find it much greater than nature really gives us.

It muft be recollected, that this table is not calculated from experiment, but from the theory of falling bodies, which makes no allowance for the lofs of velocity, which arifes from the friction of the particles of water againft the edges of the aperture, and againft the neighbouring particles of water which are not put in motion.

Sir Ifaac Newton, in making experiments, found the velocity thus determined to be too great, which in one cafe he corrected. The friction againft the fides of the aperture, and the oblique direction of the particles of water before they reach the aperture, both tend to diminifh the velocity of the ftream; and if thefe caufes could be removed, efpecially the latter, the Newtonian theory would be confirmed by experiment, or rather experiment would exactly agree with theory.

For, if we fuppofe water running into the top of a cylindrical tube, and that there is no attraction or friction between the particles of water and the interior of the tube, the velocity of the water, or of each of the particles at the bottom, would be the fame, or equal to that which they would have acquired in falling through the fame fpace without the tube, towards the earth.

Hence, to obtain the true velocity, under different circumftances, we muft correct the computed velocity by experiments.

It is ftated in fome elementary works on hydroftatics, that the velocity of the water at the orifice is only equal to that which a heavy body would acquire by falling through half the height of the fluid above the orifice. This was firft maintained by fir Ifaac Newton, who found that the diameter of the ftream is contracted, after it has quitted the orifice; and at the fmalleft part, the diameter was to that of the orifice as 21 to 25. The area, therefore, of the one was to the area of the other as 21^2 to 25^2, which is nearly the ratio of 1 to the fquare root of 2. By meafuring the quantity of water difcharged in a given time, and alfo the area of the vena contracta, fir Ifaac found, that the velocity at the vena contracta was that which was due to the whole altitude of the fluid above the orifice. He, therefore, concluded, that fince the velocity of the orifice was to that at the vena contracta as 1 to the fquare root of 2, the velocity in the vena contracta was that which was due to the whole altitude of the fluid; and that the velocity at the orifice muft be that which is due to one half that altitude, becaufe the velocities are as the fquare roots of the heights. From this, fir Ifaac ftated the actual velocity of flowing water to be $\frac{707}{1000}$, or .707 of the theoretic velocities.

But the real quantity of the reduction varies in different cafes, according to the nature of the aperture: hence, it is neceffary to confider all different forms of apertures, and make a different allowance for each cafe. To do this, the circumftances of the aperture muft be carefully examined.

A, *fig.* 8. *Plate* II. *Water-works*, explains the manner in which the filaments of water may be fuppofed to move, when a ftream flows through an aperture in a thin plate.

B fhews the motion, when a tube of about two diameters in length is added to the orifice, and when the water flows through the tube with a full ftream. This does not always happen in fo fhort a pipe, and never in one that is fhorter; but the water will frequently detach itfelf from the fides of the pipe, and flow through it with a contracted jet.

C fhews the motion, when the pipe projects into the infide of the veffel. In this cafe, it is difficult to make the tube flow full.

D reprefents a mouth-piece fitted to the hole, and formed agreeably to that fhape which a jet would affume of itfelf. In this cafe all contraction is avoided, becaufe the mouth of this pipe may be confidered as the real orifice; and nothing now diminifhes the difcharge but a trifling friction of the fides.

When water iffues through a hole in a thin plate, the lateral columns, preffing into the hole from all fides, caufe the iffuing filaments to converge to the axis of the jet, and contract its dimenfions after it has quitted the hole, and at a little diftance from the hole; and it is in this place of greateft contraction that the water acquires that velocity which we affume as equal to that acquired by falling from the furface: therefore, that our computed difcharge may beft agree with obfervation, it muft be calculated on the fuppofition that the orifice is diminifhed to the fize of this fmalleft fection. But the contraction is fubject to variations, of which the reafons are not apparent.

The following are the meafures of the contracted vein, as afcertained by different authors; the area of the aperture being 1000, the area of the contracted vein at the fmalleft will be as follows:

Sir Ifaac Newton - - -	707
Poleni - - - - - -	714
Greateft found by Boffut - -	667
Mean of fix experiments by Boffut	664
Loweft found by Boffut - -	666
Bernouilli - - - - - -	641
Michelotti - - - -	641
Du Buat - - - - - -	666
Venturi - - - - -	636
Eytelwein - - - - - -	642

The meafures given by Boffut were taken by a pair of fpherical compaffes, with which he meafured directly the diameter of the contracted vein, which he found to preferve the fame diameter for fome lines. The altitude of the water in the refervoir which Boffut ufed was 12 feet 6 inches. He meafured the vena contracta alfo, when the water iffued by vertical orifices placed 4 feet 3 inches below the furface of the fluid, and he obtained the very fame refults. The ratio between the area of the orifice and the area of the vena contracta appears from the above, to be by no means conftant. It undergoes perceptible variations, by varying the form and pofition of the orifice, the thicknefs of the plate in which the orifice is made, the form of the veffel, and the velocity of the iffuing fluid.

The dimenfions of the fmalleft fection of the contracted vein are at all times difficult to be afcertained with precifion. It is, therefore, much more convenient to compute from the real dimenfions of the orifice, and to correct this computed difcharge by means of an actual comparifon of the computed and effective difcharges, in a feries of experiments made in fituations refembling thofe cafes which moft frequently occur in practice.

We have made a collection of experiments by various authors, and from them we have deduced the following rule for the real velocity with which water iffues from an aperture in a thin plate.

Rule.—Meafure the depth of the centre of the orifice beneath the furface of the water in the refervoir in inches, extract its fquare root, and multiply it by the conftant number 85.87: the product is the velocity in feet *per* minute.

If the velocity, as marked in the preceding table, is multiplied by .618, the fame refult will be obtained. For the contraction of the ftream or vein of water, running out of a fimple orifice in a thin plate, reduces the area of its fection,

at

at the diſtance of about half its diameter from the orifice, from 1 to .665, according to the mean different ſtatements above quoted: hence the diameter is reduced to .815.

The quantity of water diſcharged is very nearly, but not quite, ſufficient to fill this ſection with the velocity due, or correſponding to the height. For finding accurately the quantity diſcharged, the area of the orifice muſt be ſuppoſed to be further diminiſhed to .619 on account of friction.

In regard to the accuracy of this rule, we muſt refer to the following table, which contains the reſults of 35 experiments, and alſo the calculation for each. We have been obliged to reject about 12 other experiments, becauſe they would not accord with the theorem; but in nearly all of them, the velocity was greater than the rule, and thoſe which are leſs we have preſerved. This was done, becauſe we ſuſpect that many of the caſes were not apertures in thin plates; but in wood planks of conſiderable thickneſs, ſuch as ſluices, the diſcharge would then be greater than our rule ſuppoſes, and ſuch caſes ſhould be claſſed with another deſcription of aperture.

Table of Experiments on the Efflux of Water from Apertures on thin Plates.

Authors.	Depth in Inches of the Centre of the Orifice beneath the Surface.	Velocity of the effluent Water *per* Minute in Feet.	Velocity calculated, by multiplying the Square Root of the Depth by 85.87.	Deſcription of the Aperture.

Theſe are the reſults of the diſcharge through orifices in a thin plate. If we apply to the orifice the ſhorteſt cylindrical pipe, that will cauſe the ſtream to adhere every where to its ſides, we ſhall find that its length muſt be twice its diameter. The diſcharge through ſuch a tube will be about $\frac{13}{16}$ths of the full quantity, and the velocity may be found by multiplying the full velocities marked in our firſt Table by .8125.

The greateſt diminution of velocity is produced by inſerting the pipe ſo as to project within the inſide of the reſervoir; probably becauſe of the greater interference of the motions of the particles approaching its orifice in all directions: in this caſe, the velocity is reduced nearly to half of the full velocity.

It was one great aim of the experiments of Michelotti and Boſſut to determine the effects of contraction in different caſes. Michelotti, after carefully obſerving the form and dimenſions of the natural jet, made various mouth-pieces reſembling

ſembling it, till he obtained one which produced the ſmalleſt diminution of the computed diſcharge, or till the diſcharge computed for the area of its ſmaller end approached the neareſt to the effective diſcharge. And he at laſt obtained one, which gave a diſcharge of 983, when the natural diſcharge would have been 1000. This piece was formed by the revolution of a trochoid round the axis of the jet, and the dimenſions were as follow:

Diameter of the outer orifice	= 36
——— inner orifice	= 46
Length of the axis	= 96

Eytelwein ſtates that a conical tube, approaching to the figure of the contraction of the ſtream, procured a diſcharge equal to .92 of the full velocity; and when its edges were rounded off, of .98, calculating on its leaſt ſection.

Venturi has aſſerted, that the diſcharge of a cylindrical pipe may be increaſed by the addition of a conical tube at the end of it nearly in the ratio of 5 to 2. (See his experiments in our article DISCHARGE.) But Mr. Eytelwein finds this aſſertion ſomewhat too ſtrong, and obſerves, that when the pipe is already very long, ſcarcely any effect is produced by the addition of ſuch a tube. He made a number of experiments with different pipes, where the ſtandard of compariſon was the time of filling a given veſſel out of a large reſervoir, which was not always kept full, becauſe it was difficult to avoid agitation in repleniſhing it; but this circumſtance was rendered indifferent to the reſults of the experiments by the application of an ingenious theorem. They prove that a compound conical pipe may increaſe the diſcharge to twice and a half as much as through a ſimple orifice, or to more than half as much more as would fill the whole ſection with the velocity due to the height; but where a conſiderable length of pipe intervenes, the additional orifice appears to have little or no effect.

The reſults of the inveſtigations of Boſſut, Michelotti, and Eytelwein, agree in a very ſatisfactory manner reſpecting the diminution of the diſcharge in different caſes; and we have arranged them in the following Table, which we recommend to engineers, as affording all the neceſſary information to calculate the diſcharge from ſluices and orifices.

Deſcription of the Aperture through which the Water flows. *Note.*—In taking the meaſure for the depth of the column which produces the velocity, we may in general take it from the ſurface of the water to the centre of the aperture; but if the aperture is in a perpendicular plane, and of a height greater than one-fourth of the whole depth, then the velocity muſt be found for the top of the aperture and alſo for the bottom of the aperture, and the mean of both taken for the mean velocity of the water.	Ratio between the real velocity and the theoretic velocity, or that which is due to the whole Depth, as ſhewn by our firſt Table.	To find the Velocity of the iſſuing Water. *Rule.*—Extract the Square Root of the Depth, (meaſured from the Centre of the Orifice to the Surface of the Water,) and multiply by ſome One of the following Numbers, according to the Circumſtances of the Caſe.				To find the Number of Cubic Feet of Water which flow *per* Minute through each Square Inch of the Area.	
		I. When it is required to know the Velocity in Feet *per* Second.		II. When it is required to know the Velocity in Feet *per* Minute.

For the whole velocity due to the height according to the theorems for falling bodies -	1.000	8.019	2.3148	481.14	138.888	3.349	.9645

To apply thefe rules for gauging fluices, the following meafures muft be taken. 1. The perpendicular depth of the bottom of the aperture beneath the furface of the water. 2. The perpendicular depth of the top of the aperture. 3. The horizontal width of the opening. Then, taking the difference between the two firft meafures leaves the height of the opening.

Note.—If the aperture is not in a vertical plane, but inclined, as is frequently the cafe in mill-fluices, then the width of the opening muft be meafured on the flope; but the depths muft always be taken perpendicularly beneath the furface of the water.

To make the calculation, find the mean velocity of the effluent water, by calculating the velocity due to the depth of the top of the aperture, and alfo for the bottom of the aperture, and take a mean of the two.

Note.—When the height of the aperture is lefs than one-fourth of the whole depth, then the velocity due to the depth of the centre of the aperture will be very near the truth.

Having found the mean velocity in feet, multiply it by the number of fquare feet in the area of the aperture, and it will give the quantity difcharged, in cubic feet.

Example 1.—A fluice, which is four feet wide, is opened or drawn feven inches, and the depth of water above the centre of the orifice is ten feet. The edges of the fluice are cut fharp, fo that the borders of the orifice are like a thin plate. What is the velocity and difcharge *per* minute in cubic feet?

The fquare root of 10 is 3.162, which × 297.45 from the table, gives 940.6 feet *per* minute, for the mean velocity of the water.

The area of the aperture is 4 feet, which × 7 inches, = 28 ÷ 12 = 2.333 fquare feet, for the area of the aperture; therefore, multiply 940.6 by 2.333, and we have 2194 cubic feet *per* minute, for the quantity difcharged.

If the depth had been expreffed in inches, it would have been 120. The fquare root of this is 10.95, and this multiplied by 85.87, gives 940.6 feet *per* minute for the velocity, as before. In like manner, the table gives the proper multipliers for finding the velocity in feet *per* fecond, if it is required.

If it was only required to obtain the quantity difcharged, we may proceed more directly, thus. The depth is 10 feet, and the fquare root is 3.162, × by 2.065, the number taken from the laft column but one of the table, and we have 6.529 cubic feet, which are difcharged *per* minute from every fquare inch of the aperture. The aperture is 48 inches, this × 7 = 336 fquare inches, this × 6.529 = 2194 cubic feet difcharged as before.

If the depth had been 120 inches, then the fquare root of that number = 10.95, and this × .5963, the number in the laft column gives 6.529, as the laft.

Another method is, to calculate the theoretic difcharge, and then make a proper reduction, by multiplying by the decimal number in the firft column. Thus, by our firft table of velocities, 120 inches deep = 1521.8 feet *per* minute, this × by 2.333 fquare feet, the area of the aperture gives 3550 cubic feet *per* minute for the theoretic difcharge.

The firft column of the prefent table fhews that the real difcharge is only .618 of the theoretic difcharge; therefore, multiply 3550 cubic feet by .618 = 2194 cubic feet for the real difcharge, as in all the former cafes.

This latter method is very convenient, becaufe we can apply a different correction in different cafes, according to difcretion, and the table of velocities facilitates the calculation very much.

Example 2.—A flour-mill was worked by the water which ran through a fhuttle four feet wide, the depth to the bottom of the aperture was 22 inches, and the fhuttle was drawn up one inch and one-quarter, fo that the depth to the top of the aperture was 20.75 inches; what is the expenditure *per* minute?

The full velocity due to 22 inches depth is by the table } 651.6 feet *per* minute.
Ditto - - for $20\frac{3}{4}$ 632.7

2)1284.3

642.15 mean velocity *per* min.

Note.—As 20.75 is not to be found in the table, take $20\frac{1}{2}$ = 628.8, and add to it half the difference between $20\frac{1}{2}$ and 21, *viz.* 3.9 = 632.7 feet *per* minute velocity for 20.75, as above.

The area of the aperture 48 inches, × 1.25 inches = 60 fquare inches, ÷ 144 = .4166 fquare feet. Multiply this by the velocity = 642.15 feet, and it gives 267.5 cubic feet *per* minute difcharged according to theory.

To reduce this to the practical difcharge, multiply by fome of the numbers in the firft column of the Table oppofite, according to the nature of the aperture. The fluice was in a trough, nearly of its own dimenfions; fo that the bottom and fides nearly correfponded with the aperture; therefore, take .860, and × 267.5 gives 238 cubic feet *per* minute.

It is very convenient to an engineer to be able to calculate the difcharge of water by means of the flide-rule. This he may do by means of the two lines ufually marked C and D; C being a line of logarithms, and D a line fimilarly divided on a fcale twice as large. By means of thefe, the fquare root of any number can be extracted and multiplied by any number at one operation. To ufe it, find the multiplier which is to be ufed, upon the line D, and fet the flider fo that 10 upon C will correfpond with it; then feek for the depth upon C, and oppofite to it upon D, the required velocity will be found.

Thus,

Line on the flider marked C, depth in inches, 10

Line on the rule marked D, velocity in feet *per* minute, 85.8

And in like manner for any other multipliers: for inftance,

Line on the flider marked C, depth in inches 10

Line on the rule marked D, cubic feet *per* minute difcharged through a fquare inch, } .596

Mr. Eytelwein obferves, from Du Buat, that the difcharge through an orifice communicating between two refervoirs, and fituated beneath the furface of the water in the lower refervoir, is the fame as if the water run into the open air, taking the difference of level between the two furfaces, for the depth of the column; he calculates the difcharge when the water has to pafs through feveral orifices in the fides of as many refervoirs open above. In fuch cafes, where the orifices are fmall, the velocity in each may be confidered as generated by the difference of the heights in the two contiguous refervoirs; and the fquare root of the difference will therefore reprefent the velocity which muft be generated in the feveral orifices, inverfely as their refpective areas, fo that we may calculate from hence the heights of the different refervoirs when the orifices are given. Mr. Eytelwein alfo confiders the cafe of a lock, which is filled from a canal of an invariable height, and determines the time required, by comparing it with that of a veffel emptying itfelf by the preffure of the water that it contains, obferving, that the motion is retarded in both cafes in a fimilar manner, and he finds the calculation agree fufficiently well with experiments made on a large fcale.

Rules for meafuring the Quantity of Water which flows over a Weir, or through an Aperture in the Edge of a Board, the Stream being open at Top.—If we fuppofe water running in a regular fheet over the edge of a large ciftern or refervoir, or through a rectangular aperture made in the perpendicular wall or fide of the ciftern, but open at top, we may take the area of the aperture, and proceed to find the velocity by calculation.

When this fubject has been confidered theoretically, it has been affumed, that the furface of the water at the place where it runs through the aperture, is without motion, becaufe it ftands at the fame level with the ftagnant water in the refervoir, and that the velocity of the water at different depths will always be as the fquare root of the depth; that is, beginning at nothing at the furface, the velocity at different depths will increafe by that law.

We can find the velocity at the bottom of the aperture, or at any intermediate depth, by the rules and table we have already given; but what we require is the mean velocity of the whole fheet of water. We could obtain this nearly by calculating the velocities for a great number of different depths, increafing by regular intervals, and taking a mean of the whole; but we can effect the fame with exactnefs, if we take two-thirds of the velocity at the bottom, and confider it as the mean velocity of the whole body of water; or, the velocity due to four-ninths of the depth, will give the fame refult.

In practice we muft make allowance for lofs of motion by the friction of the water in paffing through the aperture, and alfo becaufe the water does not fill the aperture to the fame level as the ftagnant water in the refervoir. The motion of the water extends fome diftance into the refervoir, and the water will confequently have a floping furface from that part of the furface where the motion begins; the flope will continually increafe as the motion of the water accelerates, fo as to form a convex furface, which is a portion of a parabolic curve; hence the furface of the water where it is paffing through the aperture will be in rapid motion, inftead of being motionlefs as the theory fuppofes, and the furface will be much lower than the furface of the ftagnant water, fo that the aperture will only be half full of water; at leaft this is the affertion of M. Du Buat. But Dr. Robifon ftates, that he always found the depth of the water in the aperture about .715 of the whole depth from the bottom of the aperture to the level of the water in the refervoir.

M. Du Buat's theorem for the difcharge through an open aperture, when reduced to Englifh meafures, is this: having given the depth from the level furface of the water to the bottom of the aperture, and alfo the width of the aperture in inches, to find the difcharge in cubic inches *per* fecond.

Let it be remembered that 11.4491 cubic inches of water, or 11.5, will be difcharged in a fecond, through every inch in width of the aperture, when the bottom of it is exactly one inch beneath the level furface of the refervoir. To obtain the difcharge for any other depths, this number muft be multiplied by the fquare root of the cube of the depth in inches, and it will give the cubic inches difcharged *per* fecond through each inch in width of the aperture.

Example.—Suppofe the depth of the bottom of the aperture beneath the level furface of the water in the refervoir to be 4 inches. The cube of this is 64, the fquare root of which is 8; therefore, at that depth each inch in width will difcharge $8 \times 11.5 = 92$ cubic inches *per* fecond; if the width of the aperture was 3 feet, then 92×36 inches $= 3312$ cubic inches, or 1.917 cubic feet, which $\times$ 60 feconds $= 11.502$ cubic feet *per* minute.

Dr. Robifon gives the following table, which is rather greater than from the above theorem, and will be found very exact, when the aperture is made in a plank or board half an inch or an inch thick, and fo fituated that the fides and bottom of the refervoir do not correfpond with the edge of the aperture, to lead the particles of water in a current to the aperture.

Depth from the Bottom of the Aperture to the level Surface of the Water, in Inches.	Cubic Feet difcharged *per* Minute through each Inch of the Width of the Aperture.	
	In fmall Apertures of lefs than 18 Inches wide.	In larger Apertures than 18 Inches.
1	0.403124	0.428
2	1.140	1.211
3	2.095	2.226
4	3.225	3.427
5	4.507	4.789
6	5.925	6.295
7	7.466	7.933
8	9.122	9.692
9	10.884	11.564
10	12.748	13.535
11	14.707	15.632
12	16.758	17.805
13	18.895	20.076
14	21.117	22.437
15	23.419	24.883
16	25.800	27.413
17	28.258	30.024
18	30.786	32.710

In taking the depth, if it does not exceed four inches, it will not be exact enough to take proportional parts for the fractions of an inch. The following method is exact: if there be odd quarters of an inch, look in the table for as many inches as the depth contains quarters, and take the eighth part of the anfwer. Thus, for $3\frac{3}{4}$ inches take the eighth part of 23.419, which correfponds to 15 inches. This is 2.927.

If the aperture is not in the fide of a large refervoir, but in a running ftream, we muft augment the difcharge, by multiplying the fection by the velocity of the ftream. But this correction can feldom occur in practice, becaufe in this cafe the difcharge is previoufly known.

The amount of the allowance for friction and lofs of motion muft be different in different cafes, according to the kind of aperture, or board over which the water flows; but will always be very nearly the fame as the allowance, for lofs in an aperture or orifice of fimilar nature. For inftance, if the edges of the aperture through which the water runs be a thin plate, then we may find the velocity in feet *per* minute due to the whole depth from the bottom of the notch to the level furface of the water in the refervoir; multiply the fquare root of the depth in inches by 85.87, as we have

have before directed, and take two-thirds of the product for the mean velocity; this multiplied by the number of ſquare feet in the area of the ſection of the aperture, will give the cubic quantity of water which flows *per* minute in cubic feet. Note, in taking the area of the ſection, we muſt meaſure the whole depth from the level ſurface, and multiply it by the horizontal width of the aperture, and not ſimply the ſection of the water. This is becauſe, the theory upon which the rule is founded ſuppoſes the water in the aperture to have no velocity at the ſurface, and to be upon the level of the ſtanding water. Neither of theſe ſuppoſitions is true in reality, but the reſult is very nearly true, becauſe the ſection of the moving water is diminiſhed in proportion to the velocity which the water has at the ſurface, and in conſequence the errors of the two aſſumptions always correct each other.

We have therefore only to apply a correct theorem to obtain the velocity due to the whole depth, according to the nature of the aperture, and take two-thirds of the product. All the neceſſary information for this purpoſe may be taken from the table of multipliers laſt given, for the velocity of the diſcharge through apertures; or otherwiſe, if we take the velocity at the bottom, and multiply it by the depth, and take two-thirds of the product, we ſhall have the mean velocity. But to make the ſubject clear we ſhall give another table for this object.

Rules for obtaining the Velocities and Quantities of Water diſcharged through rectangular Apertures, which are open at Top.

Deſcription of the Aperture. *Note.*—The depths are ſuppoſed to be meaſured from the level ſurface of the water to the bottom of the aperture, in inches.	To find the mean Velocity of the Water running through the Aperture in Feet *per* Minute. *Rule.*—Multiply the Square Root of the Depth in Inches, by ſome one of the following Numbers, according to the Caſe.	To find the Number of Cubic Feet diſcharged *per* Minute through each Inch in Width of the Aperture. *Rule.*—Multiply the Square Root of the Cube of the Depth in Inches; by ſome One of the following Numbers, according to the Caſe.
For a ſmall aperture in one ſide of a large reſervoir, the bottom and ſides of which do not correſpond with the aperture, ſo as to lead the particles of water thereto in a ſtream; the edges of the aperture againſt which the water runs is ſuppoſed to be ſharp and made of thin plate; the aperture not to exceed 18 inches long and nine inches deep - - - - -	57·246	·39754
For an aperture under the ſame circumſtances as the former, but made in a plank with edges from half to one inch thick - -	58.0493	·40312
For an aperture of great breadth and more than nine inches deep, ſuch as the weir or dam in a river; it is ſuppoſed that the water runs over the edge of a plank or waſte board, one or two inches thick - - - - -	58.88	.40886
For an aperture of which the bottom is on a level with the bottom of the reſervoir, or for a weir which occupies the whole breadth of a river, and where the water flows over the top of a broad ſtone-wall ſo ſloped as to conduct the water to the paſſage -	88.92	.6174
For the full diſcharge according to theory, ſuppoſing no loſs from friction. Very large and deep weirs will come near to this -	92.592	.6430

When the aperture occupies nearly or the whole width of the reſervoir, there is no level ſurface of the water above the aperture, becauſe the water is continually running towards the aperture in a ſtream; ſuch is the caſe of a weir acroſs a river, or when water ſpouts out of the open end of a rectangular trough.

It is extremely difficult to meaſure the exact height of the water above the bottom of the aperture, for the curvature of the ſurface of the water will begin ſeveral feet up the ſtream before it arrives at the aperture; and there muſt be ſomething arbitrary in the meaſurement, becauſe the ſurface of the water, even where there is no curvature, is not horizontal but ſloping, when the water is in motion. In ſuch caſes, the depth muſt be taken beneath the inclined ſurface of the water, if we ſuppoſe the ſame prolonged until it reaches the aperture, which can eaſily be done, by ſtretching a line along the ſurface of the water ſo as to correſpond therewith, at the part above where the curvature commences.

We muſt alſo make ſome addition to the diſcharge, on account of the motion which the water poſſeſſes before it comes to the aperture; to do this with accuracy, we may meaſure the regular velocity of the ſtream, by throwing in floating bodies, and obſerving the diſtance they paſs through in a given time, taking care that we make this obſervation at a part of the channel, where the ſurface is in a regular motion and not in a ſtate of acceleration, becauſe what we want is the velocity of the water at that point where the curvature begins, in conſequence of the deſcent through the aperture. Now when the channel is not of an uniform breadth and depth, as in a mill-dam for inſtance, the velocity of every part of the ſtream is different, we ſhall then find difficulty in meaſuring

measuring the velocity by floating bodies, and muſt apply the wheel ſtream-meaſure before deſcribed; this will give the preciſe velocity of the ſurface at any given ſpot, and we ſhould chooſe that place where the curvature begins. The velocity ſo obtained we muſt add to the mean velocity, and find the diſcharge by multiplying the ſum by the area of the aperture.

Example.—Suppoſe the depth of the bottom of the aperture to be eight inches beneath the line of the ſurface of the water; that the width of the aperture is four feet, and that the aperture is in a thin plate with ſharp edges. Alſo that the ſtream is found by the wheel to move with a velocity of thirty feet *per* minute, at the place where the ſurface of water begins to deviate from its regular ſlope, and to aſſume a curvature.

Then take the numbers 57.246 from the firſt caſe in our laſt table, and multiply it by 2.83, which is the ſquare root of eight (the depth); thus $57.246 \times 2.83 = 162$ feet *per* minute, for the mean velocity of the water; to this add 30 feet for the previous motion $= 192$ feet *per* minute. The area of the aperture is 8 inches, or .66 feet $\times$ 4 feet $=$ 2.66 ſquare feet. Multiply 192 feet velocity by 2.66, and we have 510.72 cubic feet *per* minute, for the quantity diſcharged.

Water-Gauge for meaſuring the Quantity of Water afforded by any Spring or Brook.—The moſt accurate and convenient method for this purpoſe, is to conſtruct a temporary bank or dam to intercept the ſtream, and pen it up into a pond, then in the bank or dam fix a board with an aperture in it for the water to flow through. By meaſuring the width and depth of the aperture as before explained, the quantity can be calculated by the rules already given.

This is what Mr. Smeaton called the water-gauge, and is of moſt important uſe, to aſcertain the quantity of water which can be procured to ſupply a canal, or for a town, or a mill, or any other purpoſe: it is the neceſſary prelude for undertaking any ſuch kind of work, and all perſons employed in ſuch purſuits, ſhould underſtand the manner of fixing up a gauge, and making the neceſſary obſervations.

The dam muſt be of ſuch a height as to pen up the water into a tolerable large pond compared with the aperture, ſo that the ſurface of water ſhall have no ſenſible inclination or run towards the aperture; and to avoid this, the larger the pond is the better. The water muſt have ſo much fall down from the aperture, as to flow away in a clear ſtream perfectly free from all obſtruction of the water below; but it ſhould not ſpout out ſo as to fall far in the air.

The aperture ſhould be a rectangular notch cut in the edge of a broad plank; it will be beſt to make the length of the notch ſome even number of inches, as 6, 8, 12, or 24, and the depth correſpondent to the quantity expected to flow through the aperture.

We recommend that the edges of the aperture be cut ſharp, or even faced with a ſlip of metal plate, and then our firſt rule in the laſt table will apply with great accuracy. The more common practice is, to uſe a plank of one inch thick, and leave the edges of the aperture of that thickneſs, only rounding off the ſharp angles: in this caſe, the ſecond theorem in our table muſt be uſed; but this is leſs certain, becauſe the loſs of motion from reſiſtance will not bear a conſtant portion in different depths, for the thickneſs of the plank is a conſtant quantity, and therefore bears a different proportion to the quantity diſcharged, in every caſe of a different depth.

The accuracy of our rules, when applied to water-gauges, will appear from the following table.

Reſults of Thirteen Experiments on the Diſcharge of Water through an Aperture open at Top, made by Meſſrs. Smeaton and Brindley, and M. Du Buat.

Depth, in Inches, from the level Surface to the Bottom of the Notch, Inches.	Cubic Feet diſcharged *per* Minute, aſcertained by Obſervation,		Cubic Feet diſcharged *per* Minute by each Inch in Width, as aſcertained by Calculation,	
	the Notch being ſix Inches wide.	by each Inch in Width.	by the Number .403124.	by the Number .39754.
1.	2.75	.4583	.403	.397
1.25	3.68	.613	.56	.554
1.375	4.07	.678	.646	.64
1.625	5.1	.85	.83	.825
* 1.778	5.75	.958	.958	.94
2.312	8.63	1.438	1.42	1.40
3.125	12.9	2.15	2.22	2.2
* 3.2	13.9	2.316	2.3	2.26
* 4.665	24.4	4.066	4.05	4.90
5.	26.1	4.35	4.5	4.45
5.625	28.5	4.75	5.35	5.30
6.5	40.	6.66	6.7	6.57
* 6.753	42.6	7.083	7.06	7.

The two laſt columns of the table are deduced from calculation, and agree ſo well with the obſervations as to give every confidence in the rules. The laſt column is calculated on the ſuppoſition that the aperture is made in a thin plate; but the laſt column but one is according to Dr. Robiſon's number, and agrees more nearly with the truth. We believe that Mr. Smeaton's experiments were made on an aperture in a board one inch thick; the aperture was ſix inches wide. M. Du Buat's four experiments, denoted by * in the table, were in an aperture $18\frac{1}{4}$ inches wide, which we have reduced to ſix inches, in order to compare them with Mr. Smeaton's. In making this compariſon, we have not rejected any experiment, as we were obliged to do in the caſe of diſcharge through the apertures beneath the ſurface.

Self-regiſtering Water-Gauge.—When the produce of a ſpring or ſtream is required with great accuracy, the depth of the water flowing through the gauge muſt be taken very frequently during a whole ſeaſon, and a mean of all the reſults obtained. This would require the conſtant attendance of an intelligent perſon, and would be liable to miſtakes; but a ſmall machine may be made to ſhew the depth by inſpection, ſo that any careful perſon can keep the account. Thus, at the ſide of the water-gauge, fix up a wooden or tin cylinder or trunk, which is open at the bottom, ſo that the water can enter freely. In this trunk, or tube, let a float be placed, having a ſmall light rod attached to the float that will riſe up from it, and appear above the top of the trunk; this part muſt be divided into inches and tenths, and muſt have ſome index fixed to the trunk to read the diviſions by. This apparatus muſt be carefully adjuſted; in the firſt inſtance, by the perſon who fixes the gauge, ſo that its diviſions will correſpond with the depth of water meaſured very exactly in the way we have directed; then the float will ever after riſe and fall with the ſurface of the water, and will ſhew the depth without any neceſſity of referring to the original mode of meaſurement, unleſs it be to verify the adjuſtment. It is obvious that ſuch an apparatus muſt be fixed ſo, that it cannot be deranged either by deſign or accident. The tube

in

in which the float acts ſhould be in the ſtill water ſome feet above the plank in which the aperture is made, and have a proper box, or cover, which can be locked up, to ſecure the whole. The float ſhould be a hollow copper ball, or a glaſs bottle, becauſe wood or cork floats abſorb the water, and ſink deeper therein; and the rod of wood ſhould be well painted.

A ſtill more perfect water-gauge is obtained by a ſmall machine to keep the regiſter; for this purpoſe, let an eight-day clock of the ordinary conſtruction be fixed up in a kind of centry-box, or ſmall houſe, over the gauge; this is to be connected by wheel-work, with a cylindrical barrel, which is to be placed in a perpendicular direction, and made to turn round once in a week by the clock; a ſheet of paper is wrapped round the barrel, and faſtened upon it in the ſame manner as paper is faſtened on a drawing-board.

The perpendicular ſtem of the float muſt have a ſmall pencil attached to it, with a ſlight ſpring to cauſe it to bear againſt the paper on the circumference of the cylinder, ſo as to mark upon it: in this way the pencil marks, at a different part of the length of the cylinder whenever the float riſes or falls, and the cylinder turning regularly on its axis by means of the clock, cauſes theſe riſings and fallings to be marked on different parts of the ſheet of paper, ſo that when it is removed from the cylinder it will have a curved line traced upon it, which ſhews all the increments and decrements of riſe and fall, and affords an exact regiſter of the flow of water, which may be reduced to cubic meaſure, by our rules already given.

A different kind of water-gauge has been propoſed by M. De Baader: two large caſks or other veſſels are to be fixed ſide by ſide, in ſuch poſition, that the ſtream of water may be poured into either of them by a ſpout or trough. The ſpout is ſo contrived, as to turn the ſtream into one or other of the veſſels at pleaſure, with the greateſt eaſe, but the ſtream cannot run into both at once. In each veſſel is a large float which is connected with a perpendicular ſtem, ſo that the ſtem riſes or falls with the float, as the veſſels fill or empty; alſo at the bottom of each veſſel is a valve, or ſluice, to allow the water to run out from it, and the perpendicular ſtem from the float is provided with means to open this ſluice, whenever the veſſel is full of water, and the float riſes to the top, or to ſhut the ſluice whenever the veſſel is empty; and the ſame action turns the ſtream of ſupply from the veſſel which is full, into that which is empty. In this way, the two veſſels act alternately to receive the water, and meaſure it, for while the ſpout runs into one veſſel its float riſes until the veſſel is quite full; the float then turns the ſpout and ſtream into the other veſſel, which we ſuppoſe to be already empty, and at the ſame moment it will open the valve in the bottom of the full veſſel; the water then begins to run out of the full veſſel and to fill the other, which becoming full in turn, its float opens the valve in its bottom. In this way the machine continues to meaſure the water, and is provided with a ſmall counting machine to regiſter the number of reciprocations it has made.

We have now, as far as our limits will allow, given all the moſt uſeful and practical rules for meaſuring flowing water; and ſhall conclude by obſerving, that this is one of the moſt intricate and difficult ſubjects in hydraulics, and that no engineer can be fully competent to direct the execution of large works without ſtudying the ſubject much farther than we have been able to enter into it. Many untried caſes, and combinations of caſes, will continually ariſe, which cannot be decided by any previous knowledge. As a reſource for ſuch occaſions, he ſhould be well verſed in the theory of the ſubject, ſo as to modify the rules laid down for ſimple caſes, and adapt them to his particular caſe, as far as theory can aſſiſt him.

If he only purſues the rules laid down by others, without any knowledge of theory, and without entering into the reaſon and origin of the rules, his experience will not be of much avail, becauſe he will be unable to correct and improve the rules by his own obſervations, or if he attempts to do ſo, he may completely ſpoil them, by making them falſe in many caſes, in order to obtain truth in ſome one caſe.

To attain the knowledge to which we allude, the following authors may be conſulted.

Julius Frontinus, De Aquæductibus urbis Romæ Commentarius; written about the year 100, in the time of the emperors Nerva and Trajan. This contains all the knowledge of the ancients on this ſubject. It is printed in Grævii Theſaurus Antiquitatum Romanorum, vol. iv. 1630 and 1780. A new edition was alſo publiſhed.

Caſtelli, a diſciple of Galileo, Della Meſura dell' acque correnti, 1628.

Torricelli De Motu Gravium Naturaliter Accelerato, 1643. In this work we find the origin of the propoſition, that the velocities of iſſuing fluids are as the ſquare roots of the depths.

Raphel Fabrettus de Aquis et Aqueductibus veteris Romæ, 1679.

Marriotte, Traite du Mouvements des eaux, 1686. This work contains a great number of experiments on the motion of fluids, and particularly on jets of ſpouting fluids; but the reaſoning is frequently erroneous.

Guglielmini, La Meſura dell' acque correnti.—Alſo, Della Natura dell Fuimi, Bologn. 1697.

Guglielmini de Fluviis et Caſtellis Aquarum. Theſe contain a theory which has long ſince been exploded. He firſt attempted to apply the principles of falling bodies to the motion of waters in open canals and rivers.

Polenus, De Motu aquæ Mixto, Patav. 1697, 1718, 1723.

Parent Mem. Acad. Par. 1700.

Newton's Principia, 1687. This work contains the doctrine, that the velocity of a ſpouting fluid is equal to that which a heavy body acquires in falling through half the depth of the column; but which is not correct. And in the ſecond edition, 1713, Newton firſt points out the contracted vein, and the proportion of its area to that of the orifice to be, as .707 to 1.

Polenus De Caſtellis per quæ derivantur fluviorum aquæ, Padua, 1718. He ſtates the area of the contracted vein to be .571 of the area of the orifice, and he diſcovered, that more water is yielded by a cylindrical pipe than by a ſimple orifice.

Michelotti, De Separatione Fluidorum in Corpore Animale, 1719.

Dr. Jurin, "On the Motion of running Water," publiſhed in the Philoſophical Tranſactions for 1718 and 1722. Lowthorp's Abridgment, vol. vi. p. 341.

Raccolta De Autori che Trattano dell Moto dell' acque, 3 tom. 4to. Florence, 1723. This moſt valuable collection contains the writings of Archimedes, Albizi, Galileo, Caſtelli, Michelini, Borelli, Montanari, Viviani, Caſſini, Guglielmini, Grandi, Manfredi, Picard, and Narducci; and an account of the numberleſs works which have been carried on, in the imbankment of the river Po in Italy.

M. Couplet, Des Recherches ſur le Mouvement des eaux dans les tuyaux de conduit. Memoires de l'Acad. 1732. This is on the motion of water in pipes, and is given by Belidor in his Arch. Hydraulique.

Architecture Hydraulique ou l'Art de Conduire d'elever et de ménager les eaux pour les differens beſoins de la vie, in 4 vols. 4to. par M. Belidor, Commiſſaire Provincial d'Artillerie, Paris, 1739.

Daniel

Daniel Bernouilli, Hydrodynamica feu de viribus et motibus Fluidorum Commentarii, Strafbourg, 1738. He gives a beautiful mathematical theory.

John Bernouilli fupported the fame theory in his Hydraulica mine primum detecta et directè ex demonftrata ex principiis puré mechanicis.

Maclaurin, in his Fluxions, Edin. 1742, has followed the fame tract.

D'Alembert difputes the theory of Bernouilli in his Dynamics, 1743, and gives a new theory in his Traité de l'Equilibre et du Mouvement des Fluides, 1744, which he has farther improved in his Effai fur la Refiftance des Fluides, 1752.

Euler, in his Opufcules Mathematiques, has brought the theory of d'Alembert to perfection, 1752.

Lecchi Idroftatica efaminata ne fuoi principi e ftabilita nellæ fue regole della mefura delle acque correnti, 1765.

Nuova Raccolta di autori che trattano del moto dell' acque, 7 vols. Parma, 1766. This extenfive work contains the experiments and theorems of a vaft number of the preceding authors on the fubject of running waters, the courfes of rivers, &c. &c. and in a great meafure fuperfedes all the Italian books of older date.

Michelotti, Sperimenti Idrauliche, 1767 and 1774. — Alfo, Mem. Taurinens, 1788. This work contains a moft valuable feries of experiments made at Turin, fome of which we have quoted.

Silberfchlag Theorie des Fleuves avec l'art de batir dans leur eaux et de prevenir leur ravages, 1769. Tranflated from the German.

Boffut Traité Theorique et Experimental d'Hydrodynamique, 2 vols. 8vo. 1771, 1786, 1796.

Du Buat, engineer to the French king, Principes d'Hydraulique, 1779. His theory was firft founded on the experiments of Boffut and others; but in 1786 he gave another edition containing many experiments of his own, and that valuable theory of the motion of water in rivers, which we have given in our article River, and which has made the firft approach to accuracy. The honour of this difcovery is in part due to M. S. Honoré, an officer of engineers.

Dr. Robifon's Syftem of Mechanical Philofophy; and the articles Hydrodynamics, River, Resistance, and Water-*Works*, which he prepared for the Encyclopædia Britannica. Thefe are the moft valuable collection of experiments, theories, and practical rules of any in the Englifh language: the learned profeffor took the trouble to collect and arrange all the experiments of Boffut, Du Buat, and others, into one fyftem.

Water, *Weight of.* It is neceffary to afcertain the weight or abfolute gravity of fome known quantity or meafure of water with great precifion, becaufe we ufually exprefs the weight of different bodies by their fpecific gravity, that is, their relative weight to the weight of water. Hence, by knowing the weight of any required quantity of water, we may obtain the weight of the fame quantity of any other fubftance, by means of the fpecific gravity of fuch fubftance.

It is recorded in the Philofophical Tranfactions, N° 169, that fome gentlemen at Oxford, in 1685, determined the weight of a cubic foot of fpring-water to be 1000 ounces avoirdupois. It was not obferved at that time that the denfity of water would increafe or diminifh according to the temperature. By a recent experiment by Dr. Wollafton and Mr. Playfair, the cubic foot was found to weigh 1000 ounces, or $62\frac{1}{2}$ pounds avoirdupois, at the temperature of $56\frac{1}{2}$ degrees of Fahrenheit. This we have made the foundation of the following tables.

Tables of the Weights of different Quantities of diftilled Water, the Cubic Foot being affumed $62\frac{1}{2}$ Pounds Avoirdupois, or 1000 Ounces, which is the exact Weight, when at the Temperature of $56\frac{1}{2}°$ of Fahrenheit.

Thefe tables ferve to afcertain the weight of any required quantity of any fubftance whofe fpecific gravity is known. Thus by our tables of fpecific gravities, in the article Gravity, we find the proportion which the weight of any required fubftance bears to that of water. Then to obtain the weight in pounds avoirdupois of any given quantity of fuch fubftance, multiply the number which expreffed the fpecific gravity of the fubftance, by the number of pounds weight in the given quantity of water, as fhewn by the prefent tables, and we have the weight of the fubftance in queftion.

For example, it is required to know the weight of a piece of caft-iron, which contains feven cubic inches: the fpecific gravity of caft-iron, or its weight compared with that of water, is as 7.207 to 1; alfo by the above table we find 7 cubic inches of water weigh .253 pounds avoirdupois: now multiply 7.207 by .253 pounds, and we have 1.823371 pounds weight for 7 cubic inches of caft-iron.

What is the weight of a block of Portland-ftone, which is found by meafurement, to contain 9 cubic feet? The weight of 9 cubic feet of water is by the table 562.5 pounds, multiply this by 2.570, the fpecific gravity of Portland-ftone, and we have 1445.6250 pounds for the weight required.

What is the weight of a wrought iron bar, 1 inch fquare, and 10 feet long? The above table fhews that a prifm of water of that fize weighs 4.340 pounds, multiplied by 7.788, the fpecific gravity of bar iron, gives 33.7999.

In like manner, if it was a round bar of 1 inch diameter, and 3 feet long, the fame table fhews fuch a quantity of water weighs 1.0226 pounds; or, if it was a round plate of metal, 1 foot diameter, and 1 inch thick, the table fhews the weight of its bulk in water is 4.090 pounds.

The fourth, fifth, and fixth table is equally ufeful for commercial purpofes, to determine the weight of different quantities of liquids, as wine, oil, fpirits, &c.

Required the weight of an ale gallon of linfeed oil. The fpecific gravity of linfeed oil is .9403; the weight of an ale gallon of water is 10.1996 pounds, (as appears from the foregoing table,) multiply that number by .9403, and we have 9.5907, which is the weight of an ale gallon of linfeed oil.

What is the weight of a pipe of Bourdeaux wine? The weight of as much water is 1052.73 pounds, multiplied by .994, the fpecific gravity, gives 1046.41362 pounds.

On the conducting of Water from a Diftance for the Supply of Towns.—This is a fubject of the utmoft importance, and involves much curious inveftigation.

It frequently happens that the only fupply of frefh water for a town is from a diftant fpring, or that the quality of water which can be brought from a diftance is fo fuperior to the water on the fpot, as to induce the inhabitants to expend vaft fums in procuring good water. The Romans were famous for their works of this kind, and many ruins ftill remain as monuments of the enterprifing fpirit of that people; the moft celebrated of thefe we have mentioned in our article Aqueduct.

The works of modern times are more numerous, though on a lefs fcale; every great city has its water-works; of all others, London is the moft plentifully fupplied. The New River, which conducts water from Ware, in Hertfordfhire, is a great work, which was executed in the reign of James I.; fince that time a great many water-work companies have been eftablifhed, and moft of them draw their water from the river Thames by hydraulic machines. We believe that there are 16 large fteam-engines, befides the water-wheels at London-bridge, employed in this work, and almoft every ftreet has water-pipes laid in it.

The city of Paris is fupplied by the Canal de L'Ourcq, and by three fteam-engines; but the pipes are only laid to the palaces and public fountains, and in grand houfes.

Edinburgh is fupplied by water conveyed a vaft diftance from

from Comiston and Swanston, in leaden and iron pipes; but the supply is very inadequate to the size of the city.

When water is to be conveyed in an open canal, like the New River, the manner of setting out and executing the work is so nearly the same as for a navigable canal, that it is unnecessary to say more than we have already given in our article CANAL, except the rules for calculating the necessary slope or descent to produce the required velocity of the water; and the best theorem for this purpose we have already given in the preceding part of the present article.

We shall only add a few particulars of some of the largest modern aqueducts for conveying water.

Aqueducts.—Belidor states, in his Architecture Hydraulique, that one of the finest subterraneous aqueducts in France is that of Arcueil, which conducts the water from many collecting channels in a stone channel. It is situated in the countries of Rungis, Paret, and Coutin. This aqueduct is 14,920 yards in length, and is constructed in free-stone; it extends from the valley d'Arcueil to an elevated water-cistern, or chateau d'eau, which is at the Porte St. Jaques. The channel has an inclination of 6 inches in 400 yards, or 1 in 2400.

On each side of the water-course is a raised foot-path 19 inches wide, upon which a person can walk as far as the village d'Arcueil. The height of the passage from the bottom of the water-trough to the under side of the arch is $6\frac{1}{2}$ feet, except in some places where they have been obliged to make them less, in consequence of the high roads beneath which it passes.

Another subterraneous aqueduct of this kind is that of Rocquancourt, which conveys water to Versailles; it is 3623 yards in length, and in all the length has an inclination of only $3\frac{1}{2}$ feet, which was the utmost that could be given it. To construct this aqueduct, they were obliged in many places to dig to a depth of 30 yards, which rendered the execution of it very difficult. One hundred and fifty shafts were made in the length of this aqueduct. They were not made at equal distances, but only in such places as would facilitate the conveyance of materials; eighty of them were lined with stone, and the other seventy, which were not required to last longer than during the construction, were only lined with wood, and stopped up afterwards with a dome of masonry, and filled up with earth to the level of the surface.

This aqueduct cost 325,000 livres. From 1675 to 1678 it never yielded more than 6 pouces of water, and some times gave only 5, 4, 3, or even 2 pouces, according as the dry seasons were of greater or less duration. The pouce de fontainier is a measure of running water used by French engineers, which amounts to about .48 English cubic feet *per* minute; hence the 6 pouces would be 2.88 cubic feet *per* minute.

A pond was made in 1685 at the head of this aqueduct, to drain a country called Trou d'Enfer; and since then it has given 10 and 12 pouces, *i. e.* 4.8 and 5.76 cubic feet *per* minute.

When water is conducted in an open channel, it frequently becomes necessary to cross deep valleys; in this case, the channel must be supported on arches like a bridge. This was the object of those vast Roman aqueducts, of which we find the remains at Nimes, Arles, Frejus, &c. The greatest modern works of this kind are those constructed in the time of Louis XIV. to conduct water to Versailles and Marly. One of these is the aqueduct of Maintenon, for conveying the river Bure to Versailles: it consists of three courses of arches, raised one above the other, to support the water-course, which is a channel of stone, and on each side of it is a narrow path with a parapet, which renders it safe to walk along the side of the aqueduct when it requires cleaning or repairing.

In the Philosophical Transactions, it is stated that this aqueduct is 2560 fathoms in length, and consists of 242 arches; the span of each is $6\frac{1}{2}$ fathoms, and the thickness of each pillar to sustain the arches 4 fathoms. On the side of the valley next to Maintenon, there are thirty-three single arches, afterwards seventy-one double ones, (that is, having one arch upon another,) then forty-six treble ones; at this part the water-course is generally 216 feet 6 inches high from the ground up to the floor of the water channel; afterwards there are seventy-two double arches, then twenty single ones, which last reach to a mound of earth, which is raised 50 feet high above the ground for a great distance.

The general height from the ground up to the second arcade or row of arches is 16 fathoms; from the second row to the third or upper arcade 14 fathoms; in the upper arcade, the arches are double the number of those they stand upon; above this is 6 fathoms 6 inches more to the floor of the channel, which is at least 7 feet high besides the parapet.

The pillars at the ground are 8 fathoms thick, but with the slopes and shortenings, which are made in every story; the top where the channel runs is reduced to 20 feet broad. There is likewise at each pillar a buttress projecting one fathom, and two fathoms wide to strengthen the pillars.

There is another great aqueduct raised on arches in the Plaine de Bue, which conducts water to Versailles from the Plaine de Scale. This is built with two ranks of arches, and the lower ones are so much wider than the upper, as to afford room for a carriage-way across the valley about half as high up as the water-course. Drawings of these great works are given by Belidor.

It is difficult to determine the exact slope which should be given to a water-course, in order to conduct a given quantity of water; it can only be known by calculation according to the rules we have already given, and which are founded upon experience. Vitruvius recommended a slope of 1 foot fall in 200 feet in length; but Belidor says this is much more than is necessary, and that 1 foot fall in 3600 feet of length is quite sufficient, when the channel is straight without elbows, or sudden angles, or if the bends at such angles are by easy curves, so that the water is not retarded in changing its direction. He remarks, that the canal from the pool of Trappes, made by M. Picard to conduct the water to Versailles, had 9 inches slope in 1000 fathoms, or 1 foot fall in 7998 feet long. When the water was run into this, it took four hours to run 8526 yards, though it was urged by a pressure of 38.3 inches. Also that the aqueduct of Rocquancourt before mentioned has only 3 pieds fall in all its length, which is 1700 toises, that is, 1 foot fall in 3400 feet of length. Whence Belidor directs as a general rule to make the fall 1 inch in 100 yards, that is, 1 foot in 3600 feet, provided the bottom of the trough is of smooth stone, and not muddy. This is the least which can be allowed, and more may be given when the relative levels between the two places will admit of a more rapid descent.

On the Conveyance of Water in Pipes.—This is an object of great importance. The ancients conducted water in pipes only down hill; but never carried it up agaio, not knowing that water would rise to its own level; but we can conduct water to very great distances, and bring it from one mountain to another in pipes, which descend into the intermediate valleys and rise again, provided that the spring or place from which

which the water comes is ſomewhat higher than the other end where the water is to be delivered. The water would indeed ſhew itſelf at the ſame level at one end of the pipe as at the other, but it would not run out; and in all caſes with the ſame ſize pipe, the quantity of water given will increaſe in proportion as the receptacle at the diſcharge is below the ſpring at the other end of the pipe. Hence, if there is a great deal of water to be conveyed to a place ſituated but little lower than the level of the original ſpring, a very large pipe muſt be uſed to convey any given quantity. But the ſame quantity may be conveyed in a ſmaller pipe, and conſequently at leſs expence, if the reſervoir is much below the original level.

If the diſtance is great, the length of the pipes will conſiderably diminiſh the quantity of water brought through them, in conſequence of the friction of the water againſt the ſides of the pipes; this cannot be prevented, and we muſt make the bore of the pipe larger, in proportion to the length, if the water be in ſuch quantity and ſo much wanted as to make it worth the expence. The rules for calculating the proper ſize of pipes we have already given.

Deſaguliers mentions an experiment which he made upon a leaden pipe, whoſe inward diameter was $1\frac{1}{8}$ inch, and found that at 1400 yards diſtance from the ſpring of water that ſupplied it, it did not give a tenth part of the water that it would have given at thirty yards from the ſpring, though both places were at the ſame depth below the ſurface.

All care ſhould be taken in the conſtruction of a conduit-pipe, to avoid obſtructions occaſioned by lumps of ſolder hanging in the inſide of the pipes, or by roughneſs at the joints, if the pipes are put together by ſcrew-joints. All the cocks and plugs in the pipe ſhould have water-ways fully equal to the ſection of the pipe.

Thoſe who execute water-works are moſt tempted to fail in this point by making the cocks too ſmall, becauſe large cocks are very expenſive.

The engineer ſhould be ſcrupulouſly attentive to this, for a ſingle contraction of this kind may occaſion the extra expence of many hundred pounds in making a large pipe to be thrown away, becauſe if the pipe will yield no more water than can paſs through the ſmall cock, it would have been as well to have laid a ſmall pipe all the length.

It is of the moſt material conſequence that there be no contraction in any part of a conduit, and it is alſo prudent to avoid all unneceſſary enlargements; for when a pipe is full of water moving along it, the velocity in every ſection muſt be inverſely proportional to the area of the ſection: hence the velocity is diminiſhed wherever the pipe is enlarged; and it muſt again be increaſed where the pipe contracts.

This cannot be done without expending force in the acceleration; and conſuming part of the impelling power, whether it be that of a column of water, or the force of a machine.

No advantage can be gained by the ſlow motion which takes place at every enlargement in a pipe; but every contraction, by requiring a reſtoration of the former velocity, employs a part of the impelling force; this force muſt be equal to the weight of a column of water whoſe baſe is the contracted paſſage, and whoſe height is ſufficient to produce that velocity with which the water muſt paſs through the contraction.

This point has often been overlooked by engineers of the firſt eminence; and has, in many inſtances, impaired the performance of their beſt works.

Another point, which muſt be attended to in the conducting of water through pipes is, that the motion of the water ſhould not be by pulſations, but continuous. When the water is to be driven along a pipe by the ſtrokes of a reciprocating engine, it ſhould firſt be forced into an air-veſſel, that the elaſticity of the confined air may preſerve an uniform motion along the whole length of pipe. If the water is ſuffered to reſt at every ſucceſſive ſtroke of the piſton, the whole maſs muſt again be put in motion through all the length of the pipe. This requires a uſeleſs expenditure of power, over and above the force which may be neceſſary for raiſing or conveying the water to its deſtination. By employing an air-veſſel and double or treble acting pumps we remove this imperfection, becauſe it keeps up the motion in the intervals between the ſtrokes of the piſton. The compreſſion of the air by the active ſtroke of the piſton muſt be ſuch as to continue the impulſe during the momentary inactivity of the pump.

Pipes are ſubject to obſtructions from the depoſition of ſand or mud in the lower parts of the pipes, and from the collection of air in the upper parts of their bendings. The velocity of the water ſhould always be very moderate, and then ſuch depoſitions of heavy matters are unavoidable; care ſhould therefore be taken to have the water freed from all impurities, before it enters the pipe by proper filtration; and to diſcharge the ſediment which is unavoidable, there ought to be cleanſing plugs at the lower parts of the bendings, or rather a very little way beyond them. When theſe are opened, the water will iſſue with greater velocity, and carry the depoſitions with it.

It is much more difficult to get rid of the air which chokes the pipes, by lodging in their upper parts. This air is ſometimes taken in along with the water at the reſervoir, when the entry of the pipe is too near the ſurface; but it is eaſy to avoid this ſource of the air, by making the water enter the pipe beneath the ſurface. For if the entry of the pipe is two feet under the ſurface of the water at the ſpring, no air can ever get in, and a float may be placed over the entry, with a lid hanging from it to ſhut the pipe before the water runs too low.

Air is diſengaged from ſpring-water by the motion of the water in paſſing along the pipe. When pipes are ſupplied by an engine, air is very often drawn in by the pumps. It is alſo diſengaged from its ſtate of chemical union, when the pumps have a ſuction-pipe of ten or twelve feet, which is very common. In whatever way it is introduced, it collects in all the upper part of bendings, and accumulates till it will choke the paſſage, ſo that ſcarcely any water will be delivered.

To illuſtrate this, ſuppoſe that the water of a ſpring, or collection of ſprings, is to be conveyed through a pipe to the place of delivery, at a mile or half a mile diſtant from the ſpring; and that the ground, over which the pipe is carried, has many undulations, and aſcents and deſcents, where it paſſes over ſmall intermediate hills and valleys. We will ſuppoſe the place of declivity to be but a little lower than the water at the ſpring, for example 9 or 10 feet. If the ſurface of the water in the ſpring comes down to the entrance-mouth of the pipe, or only near it, much air will run down with the water into the pipe; and wherever the ground riſes in the courſe of the pipe, this air will lodge itſelf in the upper parts of the bends of the pipe, and thereby diminiſh the water-way ſo as to force the water to paſs through a paſſage of one-fifth or one-ſixth, ſometimes one-tenth of the proper bore of the pipe when full.

Sometimes, though no air ſhould get into the mouth at the ſpring, there will be theſe lodgments of air from the firſt running of the water; for when the water firſt enters into the pipe, if after coming down from the ſpring it has

 to

to riſe again, to paſs the ſummit of a ſmall hill, it will run over the eminence without carrying all the air before it, as it had done in other parts of the pipe, before it arrived at ſuch eminence. Hence ſome air is left in the higheſt part of the bend, but the water which paſſes by the air runs forward and fills the pipe again in the deſcending part, and ſo goes on in a full bore, till it comes to the next eminence, where it again runs over the higheſt part of the riſing pipe, leaving a ſpace of air at top, which diminiſhes the water-way. Then filling the pipe full again, it proceeds till its next riſing, and there the water-way is again contracted by the air.

To clear the pipe of this air, if the pipe is of lead, the common way, as practiſed by plumbers, is thus: at every riſing ground the pipe is laid bare at the higheſt place, and a nail is driven into the upper ſide of the pipe, ſo as to make a hole through the metal. Whilſt the nail is ſticking in, the lead is hammered all round the nail, with the pen of the hammer, ſo as to make a little button or ſpout. When the nail is withdrawn, the air will blow out violently, till at laſt the water will ſucceed the air; and with a ſtroke or two with the face of the hammer the hole can be quite ſtopped up.

This is done at every eminence of the pipe, until all the air is diſcharged, and the full quantity of water will be delivered at the oppoſite end of the pipe. If the mouth of the pipe at the ſpring never receives any air, by the deſcent of the ſurface of the water, the pipe may give its full quantity for years.

The way to know when the whole water is delivered is to meaſure it, when the pipe has been fully cleared of air, as above-mentioned; and when by meaſure, the quantity of water appears to be deficient, the pipe muſt again be cleared of air or other obſtructions.

If the ſpring is much higher than the place of delivery, the places where the air will accumulate in the pipe will not be juſt at the higheſt part of the pipe, but a little beyond it; becauſe the water running with more velocity and force, drives the lodged air ſtill forward down the pipe, and it muſt lodge in the part where the pipe begins to deſcend again, its own tendency to aſcend to the top being counteracted by the motion of the water. In this caſe, the nail-hole muſt be made beyond the greateſt elevation, or elſe the run of the pipe muſt be ſtopped for ſome time, ſo that the water may ceaſe to be in motion, the air will then go back gradually to the higheſt part of the pipe, where it may be let out.

Suppoſe that the water, inſtead of coming from an elevated ſpring, be forced up its whole way from a place much lower by an engine, and up the conduit, then the places where the air will lodge will be beyond the eminences of the pipes, but nearer to the upper end. In theſe caſes, it will not be ſufficient to prick the pipe with a nail, becauſe air will be continually forced in with the water, and will refill thoſe places in the pipe from which the air had been emptied. The obſtructions thus happening often occaſion the burſting of the pipe, or it gives too ſmall a quantity of water, and does damage to the engine.

In ſuch a caſe, the following contrivance muſt be uſed: a ſmall leaden pipe, about thirty feet in length, which is called a rider or air-pipe, is laid at the higheſt part of the main-pipe, and extends along the top thereof. It communicates with the main at the top of the eminence, and alſo at two other places, at fifteen feet on each ſide of the eminence. This air-pipe has a little branch and cock. Now if the cock is opened when the engine is working, the air will be puſhed forward till it is diſcharged by the air-pipe and cock. If the air goes beyond the eminence, the pipe of communication will certainly diſcharge it. When water comes out at the cock it muſt be ſhut, and the main-pipe will then be full of water, but after ſome time, the cock being left ſhut, air will gather again in the eminence of the main-pipe and lodge; but, if the air-cock is again opened, the air will be diſcharged.

When water is forced up by an engine into an elevated ciſtern, from which it is to run down a main-pipe to the reſervoir where it is wanted, this air-cock will alſo be very neceſſary, becauſe the water in the ciſtern ſometimes covers the entrance-mouth of the deſcending pipe, and ſometimes not. In that caſe, air goes down with the water.

In leaden or iron pipes of conduit, the diſcharge of air is abſolutely neceſſary if there are any riſes in the pipe. In wooden pipes the air often paſſes through the wood and eſcapes; but if the pipes are tight and thoroughly ſoaked, the air-pipes and cocks are very uſeful. When water runs from a raiſed ciſtern through a diſtance of a mile or two, ſome perſon ſhould turn the air-cocks two or three times a day.

This trouble may in ſome caſes be avoided, by carrying the air-pipe perpendicularly upwards, to an equal or greater height than the entrance mouth of the main-pipe. In this caſe, the water will riſe up in the air-pipe to near the ſame level as the water at the entrance, but cannot run over. Neverthelefs, if any air paſſes along the main-pipe, when it arrives at the air-pipe, it will riſe up therein in bubbles through the water contained in the perpendicular air-pipe and eſcape. By taking advantage of ſome tall building, or large tree to ſupport the perpendicular air-pipe, this expedient may in general be applied.

Deſaguliers contrived a valve which ſhould open to let out the air, and ſhut again when the water came. It was an inverted braſs valve ſhutting upwards, and falling down by its own weight, with cork fixed to the under ſide of it, to make it riſe and ſhut when the water came. This ſucceeded in firſt clearing the pipe of air, but it did not anſwer to keep it clear; becauſe, when the valve had been ſhut ſome time, if air ſhould extricate itſelf from the water, it would be denſe air, whoſe force would be equal to that of the water, and would keep the valve ſhut as well as the water did before, although the air at firſt could not ſhut the valve. The only remedy for this difficulty is to make the valve very ſmall, and make a hollow copper veſſel for a float. This will riſe with conſiderable force to ſhut the valve, when the water acts upon it; and it will be ſufficiently heavy, when the water forſakes it, to pull open the valve.

The ſame author afterwards made a better contrivance. It is a ſmall ſquare box of caſt-iron, made tight on all ſides, except where the air-pipe communicates with the bottom of it, and alſo where a ſpout is fixed on the top to let out the air. This ſpout is provided with a cock, ſituated withinſide of the box, and to the plug of the cock a ſmall arm or lever is fixed, having a hollow ball of copper at the extremity of the arm or lever. This ball floats on the ſurface of the water in the box, and when it riſes opens the cock, or ſhuts it when it falls. When the air in the pipe accumulates, it paſſes along the air-pipe and enters into this box, and as the quantity increaſes, the ſurface of the water in the box ſubſides, until the float at the end of the lever, opens the cock and allows the air to eſcape, and this it will always do before any air can accumulate in the pipe.

It is beſt to place the air-box near to the main-pipe, but it muſt have communication by an air-pipe with the main-pipe, at two or three different places, in order that it may certainly receive all the air which gathers in the great pipe.

On the Diſcharge of Water by lateral Branch-Pipes from a Main-

Main-Pipe.—It is a common cafe in water-works, that water is required to be drawn off through a fmall pipe, from the fide of a main-pipe, in which the water is not at reft, but in motion, with a much greater velocity than the flow occafioned by the water which is drawn off through the fmall pipe. It is often required to know what quantity fuch fmall pipe will yield. When water is paffing along a pipe, its preffure on the fides of the pipe is diminifhed in confequence of its velocity; and if a pipe is derived from it, the quantity drawn off muft alfo be lefs than if the water in the great pipe was motionlefs. It is therefore of great importance to determine what is the diminution of preffure which arifes from the motion along the main-pipe.

It is plain, that if the water fuffered no refiftance in the main-pipe, its velocity would be that which is due to the height through which it had defcended, and it would pafs along without exerting any preffure. Alfo, if the pipe were fhut at the end, the preffure within the pipe would be equal to the whole depth of water. Between thefe limits we fhall find what we feek. If the head of water remains the fame as when the pipe was ftopped, and the end of the tube be contracted, but not ftopped entirely, the velocity in the pipe will be fmall; and the natural velocity due to the defcent being checked, the particles will re-act on what obftructs their motion. This action will be uniformly propagated through the fluid in every direction, and will exert preffure on the fides of the pipe. Now obftructions of any kind, arifing from friction or any other caufe, will produce a diminution of velocity in the pipe. The refiftance, therefore, which we afcribe to friction, produces the fame lateral preffure which a contraction of the orifice would do, provided that it would diminifh the velocity in the pipe, in an equal degree.

We will firft confider the cafe of an horizontal pipe, in which the whole impelling force is applied at one end of the pipe, either by a pump or by a column in a perpendicular pipe at that end. This force muft be tranfmitted or carried by the water through the whole length of the pipe, wherein part of it will be abforbed in overcoming the obftruction and friction, and the remaining force will produce the velocity with which the water iffues at the open end of the pipe. It is evident that every part of the horizontal length of fuch a pipe muft bear a different degree of preffure, when the water is in motion; thus, at the end where it is difcharged, there is no preffure exerted on the pipe to burft it open, becaufe the water can efcape freely; but at every other part a force muft be exerted, which is fufficient to overcome all the refiftance which the water will meet with, in running from fuch part to the open end, where it is difcharged.

In fhort, whatever part of the column of water in the refervoir, or of the preffure which impels it along the pipe, is not employed in producing velocity, muft be employed in acting againft fome obftruction; and by the re-action of this obftruction, an equal preffure is tranfmitted to all parts of the pipe. The chief queftions will be, in what part of the pipe are thefe obftructions fituated, and at what part is the force applied which is to overcome them; becaufe that part of the pipe which is between the two, muft bear the ftrain of tranfmitting the force from the place where it is applied, to the place where it is to operate.

In the cafe where the impelling force is all applied at one end of the pipe, and the only refiftance is the friction of the water in running through the horizontal pipe, the preffure to burft the pipe, will begin at nothing at the open end of the pipe, and regularly increafe from that to the other end. Its quantity for 100 feet in length may be afcertained for any given bore of the pipe, and velocity of the water, from Mr. Smeaton's table of friction already given, and may be adapted to all other lengths by a fimple rule of proportion.

If in addition to the refiftance by friction, which takes place equally in all parts of the length of the pipe, there are any particular caufes of obftruction at the extreme end or at any other part, the force neceffary to overcome fuch refiftance muft be added to that required to overcome the friction, as found by the table; and all this tends to burft open the pipe, or that part which is between the impelling force and the obftruction, which may arife either from a perpendicular column or lift, up which the water is to be forced, or from a contraction.

Example 1.—A fteam-engine with a forcing-pump is employed to force water through a pipe, which proceeds horizontally for 1800 feet, and then rifes up 60 feet perpendicular, to a ciftern at the top of a tower; the diameter of the pipe is five inches, and the motion of the engine is fuch, that the water moves with a velocity of 140 feet *per* minute through the pipe. It is neceffary to fupply a ciftern in a houfe from the middle of the main-pipe, by a fmall branch-pipe of one inch bore and 100 feet long; this ciftern is 55 feet above the great horizontal-pipe, or five feet beneath the elevated ciftern; required the velocity with which the water will flow through the fmall branch-pipe, when the engine is not at work, and when it is at work.

When the water in the great pipe is motionlefs, there is the preffure of a column of five feet to force the water through the branch-pipe. Mr. Smeaton's table fhews, that for one inch bore and 100 feet long, a preffure of five feet, or fixty inches, will produce a velocity of 180 feet *per* minute; but when this pipe is running, the water in the great pipe muft move alfo. The area of the pipe of five inches, is twenty-five times as great as the pipe of one inch; therefore, the motion of the water in the great pipe, will be only one twenty-fifth of 180 feet, or 7.2 feet *per* minute. Find the neareft velocity to this in the table, or ten feet *per* minute, and under five inches bore, we find .07 inches the height neceffary to produce that motion, if the pipe was 100 feet long; but as it is 960 feet, the height required will be $.07 \times 9.6 = .672$ of an inch. This fhould be deducted from the five feet preffure which urges the water through the fmall pipe; but fo fmall a quantity is not worth notice: hence we may ftate the velocity when the engine is not at work at 180 feet *per* minute, and the difcharge from a bore of one inch, will be .98 of a cubic foot *per* minute.

When the engine is at work, the fame preffure will be exerted with the addition of all the preffure neceffary to overcome the friction of the water, in running along the great pipe with a velocity of 140 feet *per* minute. Look for this velocity in the table, and for five inches bore it fhews, that a column of 7.6 inches muft be allowed for every 100 feet of the pipe. The length of the pipe meafured from the place where the branch-pipe proceeds to the ciftern at the top of the tower, is 900 feet horizontal, and 60 perpendicular, *viz.* 960; therefore, multiply 7.6 by 9.6, and we have 73 inches for the height, which muft be added to the five feet, and makes 133 inches for the whole column or force, which urges the water to flow through the branch-pipe, when the engine is at work: laftly, by referring to the table in the column of one inch bore, we find that 135 inches will produce a velocity of 270 feet *per* minute, and the difcharge will be 1.47 cubic feet *per* minute.

The fame inveftigation fhews us, that the main-pipe at the place where the branch-pipe proceeds from it, muft bear the preffure of a column equal to 66 feet one inch when the engine

engine is at work, although it bears only 60 feet when it is at reft. But if we confider the whole length of 1860 feet, the friction will be equal to a column of eleven feet ten inches, fo that the preffure, when the engine is at work, will be near 72 feet, at that end of the pipe which joins to the pump.

Example 2.—We will now confider the reverfe of this cafe, that is, take away the pump and fteam-engine, and let the water be propelled through the great pipe, by the water defcending from the ciftern, with a fall of 60 feet. What will be the preffure which caufes the water to flow through the fmall branch-pipe?

To find this, we muft calculate with what velocity the water will flow through the whole length of the great pipe, by the theorem and example we have already given for water in pipes. Having found this, calculating on the whole length of the pipe, we muft make another calculation, reckoning only as much length of the pipe as is contained between the ciftern of fupply, and the place where the branch-pipe joins the main-pipe.

Then take the difference between thefe two velocities, and it fhews what refiftance or friction the water muft overcome in running along the remainder of the pipe, *viz.* from the place where the branch-pipe joins to the open end of the pipe, where the water is difcharged. Now if a fimple orifice was to be made at that part of the great pipe where the branch-pipe joins, the water would flow out with a velocity equal to the difference of the two velocities, making the proper deduction for the friction of the water in paffing through the orifice.

But if we wifh to know the velocity with which the water will flow through the branch-pipe, we muft find the depth of column neceffary to produce the velocity equal to the difference of the velocities of which we have before fpoken, calculating according to theory, without regard to friction; and then with the depth fo found, we can feek in the table of friction in pipes, for the refult or flow of water through the fmall branch-pipe.

The cafe of a regularly inclined pipe is confiderably different, becaufe the impelling force is not all applied at one end of the pipe; but every portion of the pipe having a defcent, has alfo a portion of the impelling power applied to it. When this pipe is of a certain length, the water arrives as its maximum velocity without accelerating as it proceeds further down the flope; becaufe the accelerating power of the water is in equilibrio with the obftruction, that is, the power of defcent acquired in a foot or an inch of the flope, is juft equal to the refiftance in the fame diftance; confequently, the water exerts no preffure on the pipe to burft it open, any part of the water would continue to flide down the flope with its uniform velocity, even if it was detached from that water which followed or which preceded, and it derives no impelling power from any column of water. The effect would be juft the fame, if the pipe was fplit down the middle and converted into two open troughs.

It is clear, that in this cafe, no water can be obtained from any lateral branch-pipes, unlefs they defcend from the pipe.

Let us confider the fame pipe when the inclination is not a regular flope, but when fome parts flope more rapidly than others. In this cafe, the impelling force is not applied regularly upon every part of the length of the pipe, as in the former inftance; the confequence is, that in thofe parts which have a more rapid flope than the inclination of a line drawn from one end of the pipe to the other, the water will have a tendency to accelerate beyond the regular velocity which is due to the regular flope, and with which it muft ultimately flow out of the pipe; and on the other hand, in places where the flope is lefs rapid than this line, the tendency of the water will be to flow more flowly than the regular velocity. Now the pipe being clofe and of an equal bore, the water muft flow with the fame velocity in every part of the length; and although fome portions of the contained water tend to run forwards fafter than the regular velocity, yet other portions tend to hang back; by means of the pipe, the force is tranfmitted from one place to another, and thefe forces become all combined together to produce an uniform velocity.

We fhall find, on farther confideration of thefe actions, that fome parts may be fubjected to a preffure or ftrain to force or burft it open, and other parts may at the fame time be ftrained in an oppofite direction, *viz.* to crufh the metal of the pipe inwards.

Thus at every point where the pipe fuddenly changes its flope or rate of inclination, from an eafy flope to a very rapid defcent, then the water will have a tendency to run down fuch floping part of the pipe, and pafs away fafter than other water can come down the eafy flope; the confequence is, that a fuction or afpiration takes place within the pipe, and if a fmall branch-pipe were applied in fuch a fituation, water may actually be drawn up from a confiderable depth. This has been fhewn by M. Venturi, who calls it the lateral communication of motion between fluids.

This is a certain proof that the bore of the pipe is too fmall at fuch places. An attentive confideration of thefe circumftances, will fhew the propriety of making a long pipe with different bores at different places, where the flope is different; for, by judicioufly increafing the bore of the pipe where the flope is lefs, the action may be made uniform throughout. But this cannot be done in cafes where the changes of flope are exceffive; for inftance, when the pipe defcends rapidly into a deep valley, and muft rife again with a rapid flope in an oppofite direction. This is the cafe with the pipes which fupply Edinburgh, and in many fituations is unavoidable.

The refiftance arifing from friction is greater or lefs according to the velocity of the motion; but whatever is the inclination of a pipe, provided it is long enough, the velocity with which the water runs through it will fo adjuft itfelf, that the fum of all the refiftance in the whole length of the pipe, will exactly balance the fum of all the forces, which the water exerts by its defcent. But if the pipe is too fhort, the forces of defcent down the pipe may overbalance all the refiftances. In this cafe, the water will tend to accelerate, and the water which has defcended near to the bottom of the pipe, will draw after it that water which has juft entered the upper part of the flope, inftead of the water in the upper part, forcing forwards that water which is beneath it.

Dr. Robifon obferves that there are fome curious circumftances in the mechanifm of thefe motions, which makes a certain length of pipe neceffary, for bringing it into the equilibrium of motive force, and refiftance, which he calls *train.* A certain portion of the interior furface of the pipe muft act in concert in obftructing the motion. We do not completely underftand this circumftance, but we can form a pretty diftinct notion of its mode of acting. The film of water contiguous to the pipe is withheld by the obftruction of friction, but glides along; the film immediately within this is withheld by the outer film, but glides through it, and thus all the concentric films glide within thofe around them, fimilar to the tubes of a telefcope, when we draw it out by taking hold of the end of the innermoft. Thus the ſecond film paſſes beyond the firſt or innermoſt, and becomes the outermoſt, and rubs along the tube. The third does the ſame in its turn, and thus the central filaments will at laſt come to the outſide, and ſuſtain their greateſt poſſible obſtruction. When this is accompliſhed, the pipe is in train.

This requires a certain length of pipe which we cannot determine by theory; but it is evident that pipes of greater diameter muſt require a greater length, and this is probably in proportion to the number of filaments, or as the ſquare of their diameter.

Du Buat found this ſuppoſition agree with his experiments. A pipe of one inch in diameter ſuſtained no change of velocity by gradually ſhortening it, until it was reduced to ſix feet, and then it diſcharged a little more water. But a pipe of two inches in diameter gave a ſenſible augmentation of velocity, when ſhortened to twenty-five feet; he therefore ſays, that the ſquares of the diameter in inches, multiplied by 72, will expreſs the length in inches neceſſary for putting the water in any pipe in *train*.

When pipes are of any conſiderable length, the waters of a larger pipe will run with a greater velocity than thoſe of a ſmaller pipe having the ſame ſlope. A pipe of two inches diameter will give much more water than four pipes of one inch diameter; it will give as much as five and a half of ſuch pipes, or more, becauſe the ſquares of the diſcharges are very nearly as the fifth powers of the diameters.

On the requiſite Strength for Water-Pipes.—We have ſhewn that, in certain caſes, the water running through a pipe will exert little or no ſtrain to burſt the pipes. This may be the caſe in great portions of the length, or even in the whole length; nevertheleſs we may obſerve, that at all parts ſo ſituated, an open canal would anſwer all purpoſes as well as a cloſe pipe. It is not neceſſary to employ a cloſe pipe in any caſe, except where it is ſubjected to a ſtrain. We may alſo obſerve, that it is prudent in all caſes to make the pipe ſufficiently ſtrong to reſiſt the full preſſure of the impelling column, when the motion of the water is ſtopped; becauſe this may happen accidentally, and then the pipe will burſt.

In order to adjuſt the ſtrength of a pipe to the ſtrain, we may conceive it as conſiſting of two half cylinders joined by ſeams, parallel to the axis or length of the pipe; the ſtrength of ſuch ſeams to reſiſt the ſeparation of the two half cylinders will be equal to the ordinary ſtrength of the materials of which the pipe is made. The inſide preſſure tends to burſt the pipe by tearing open theſe ſeams, and the force which acts upon any given length of the pipe (as an inch or a foot), is the weight of a column of water whoſe baſe is the diameter of the pipe, by the given length (as an inch or a foot), and whoſe height reaches up to the ſurface of the water in the reſervoir. This follows from the common principles of hydroſtatics, and may be calculated by the rules for columns of water already given.

Suppoſe the pipe to be of lead, one foot in diameter, what will be the force to burſt open one inch in length, at the depth of 100 feet under the ſurface of the reſervoir? Water weighs $62\frac{1}{2}$ pounds *per* cubic foot, the baſe of the column is 1 foot by 1 inch, or $\frac{1}{12}$th of a ſquare foot, and the tendency to burſt open an inch long of the pipe is $100 \times$

$$62\tfrac{1}{2} \times \tfrac{1}{12} = \frac{6250}{12} = 521 \text{ pounds nearly.}$$

Therefore, an inch long of each ſeam is ſtrained by $260\frac{1}{2}$ pounds. A rod of caſt lead, one inch ſquare, is pulled aſunder by 860 pounds. (See STRENGTH *of Materials.*) Therefore, if the thickneſs of the ſeam is $= \frac{260}{860}$ inches, or one-third of an inch, it will juſt withſtand this ſtrain. But we make it much thicker than this, eſpecially if the pipe leads from an engine which ſends the water along it by ſtarts.

M. Montgolfier ſtates, that a pipe one inch in diameter, and one line in thickneſs, will bear a column of 50 feet, French meaſure, from which if we deſire to know the proper thickneſs for any other diameter, with the ſame preſſure, we ſhall find it by ſimple proportion. Thus, if the diameter be 4 inches, the thickneſs muſt be four lines; or if the preſſure is augmented we proceed in the ſame manner, by direct proportion, ſo that for 100 feet it muſt be two lines thick for one inch diameter, and 8 lines thick for 4 inches diameter.

To make full uſe of this mode of reckoning, he gives the following table of the preſſure which pipes of different ſubſtances will ſuſtain.

	Feet high.
Copper pipe, 1 inch bore, and 1 line thick, will ſupport a column of water - - -	400
Braſs pipe of good quality, and the former dimenſions	300
Lead pipe, made of ſheet lead - - -	50
Caſt-iron pipe, 2 inches bore, and 4 lines thick, will ſuſtain at leaſt - - - - -	500
Elm wood $1\frac{1}{2}$ inch diameter, and 2 inches thick,	30 or 40

That is, they may ſafely be made of that ſize, but will bear ſometimes 110 feet preſſure.

Lead Pipes.—The plumbers uſe caſt pipes of lead, and alſo make pipes of tough ſheet lead turned up, and burned or melted together in the longitudinal joints; the different lengths of lead pipe are ſometimes burned together with lead at the joints, when they are laid in the field, inſtead of ſoldering, becauſe this is much cheaper. Leaden pipes may be turned up of any ſize, but are not uſually caſt of more than four inches bore. Unleſs the caſt pipes are very ſound, they are not ſo good as turned-up pipes; hence it is not adviſable to uſe caſt pipes of more than $2\frac{1}{2}$ inches bore. There muſt be great care taken in making the turned-up pipes, that they may be perfectly cylindrical.

Small lead pipes are made by caſting and drawing them through a plate, like wire. See our article PIPES.

The proper thickneſs for lead pipes, according to Deſaguliers, is as follows: a pipe, 7 inches diameter, ſituated from 140 to 80 feet below the reſervoir, muſt be $\frac{3}{4}$ of an inch thick; that part which is from 80 to 60 feet beneath the reſervoir, muſt be half an inch and an eighth thick; from 60 to 30 feet $\frac{1}{2}$ an inch; and the remainder from 30 feet up to the reſervoir $\frac{3}{8}$ of an inch.

For pipes of four inches diameter, half an inch will do from a depth of 200 feet to 100 feet; from 100 to 40 feet depth $\frac{3}{8}$ of an inch thick; and from 40 feet deep up to the reſervoir $\frac{1}{4}$ of an inch in thickneſs.

Deſaguliers deſcribes a method of proving the ſtrength of pipes experimentally, by a ſmall forcing-pump, to inject water into a piece of the pipe at one end, whilſt a valve is applied to the other, which valve is loaded with ſuch a weight as will equal the weight of the intended column of water; therefore, if the pipe bears this preſſure, it will bear the column of water.

Lead pipes are very improper for water-works, where the water is forced by an engine; for at every ſtroke or puſh from the engine, the water raiſes the ſtop-valve of the pump, and

and when the valve ſhuts again, the water falls with it, and gives a ſudden blow againſt all the ſides of the pipe. By the lateral preſſure, this force acts in a direction perpendicular to the ſides of the pipe, with the weight of a pillar of water whoſe baſe is the ſection of the pipe, at the place of the ſtroke, and the height is equal to the whole height of the water above that place; and it ſtrikes with the ſame velocity that the valve falls. Now if the firſt ſtroke of this water makes the lead ſwell outwards but the 100th part of an inch, the lead having no elaſticity, will remain in that poſition, and not ſhrink back; then ſuppoſe the next ſtroke ſwells the lead outwards the 100th part of an inch more, the diameter of the pipe will become ſo much larger and remain ſo. The next ſtroke will ſtill make it wider, and ſo on for many ſtrokes, till at laſt the lead becomes ſo thin that it muſt break. This is inevitable if the force is great enough to begin the enlargement, for after every ſtroke the force of the water ſtriking will be greater than the preceding, in conſequence of the enlargement, and will ſoon burſt the pipe. An iron pipe is beſt to be uſed, for even if it were in itſelf as weak as the lead, it would not be liable to be enlarged, although each ſtroke ſhould make it yield, but by the elaſticity of the metal it would return again to its own dimenſion after every ſtroke. The ſame will happen in pipes of copper or wood, becauſe thoſe ſubſtances are elaſtic.

Wood pipes are made of elm or oak, bored through the middle with a ſucceſſion of augres, increaſing in ſize until the deſired bore is attained. Belidor ſays a man can bore 39 feet of elm pipe, two inches diameter, in a day, but only $6\frac{1}{2}$ feet of oak pipe. The manner of laying and joining pipes is fully explained in our article PIPE.

Care muſt always be taken that wood pipes are bored in the heart of the wood, and that the heart is of ſufficient thickneſs about the bore of the pipe. Elm pipes of nine inches bore, that are from 80 to 140 feet beneath the furface of the water in the reſervoir, muſt have the heart of elm three inches thick after it is bored: therefore, a tree muſt be choſen of no leſs than 18 inches diameter in the ſmalleſt part. For a depth from 60 to 80 feet, the heart muſt be $2\frac{1}{2}$ inches thick, which a tree of 17 inches in diameter will afford; for a depth of from 30 to 60 feet, the heart muſt be two inches thick, and the tree 16 inches in diameter; and for any height under 30 feet, the heart need be but $1\frac{1}{2}$ inch thick, for which a tree of 14 inches will ſuffice.

From theſe proportions it may be determined what thickneſs the heart of elm ſhould be for pipes of leſs bore at the ſame depths, taking it thinner in proportion to the diameter.

Belidor recommends, in laying wooden pipes, to uſe a compoſition of mutton fat beaten in a mortar with powder of brick-duſt, ſo as to make a ſort of wax. When there are cracks in the wood, ſmall wedges wrapped with tow, and covered with this compoſition, are to be driven in to ſtop them.

Earthen Pipes.—M. Belidor ſtates, that the beſt kinds in France are made at Savigny, near Beanvais; they are in lengths of two feet, which enter three inches into one another, and are made of all diameters, from two to ſix inches; when the pottery is ſeven lines thick, they will bear a column of twenty-five feet of water. The joints are made of a compoſition of pitch, aſhes, and brick-duſt with mutton fat: this is applied hot; but for larger pipes, a cement of lime is uſed.

One of the lengths of the pipes for the ſupply of Edinburgh is made of pottery.

Iron Pipes.—The methods of joining and laying iron pipes will be found in our article PIPE; but we ſhall give a

TABLE of the Weight of Iron Pipes caſt at Carron Iron-Works in 1769, being their Standard for dried Sand Caſtings, allowing every 36 Cubic Inches of Caſt Iron to be equal to 10 lbs.

Diameter of the Inſide, or Bore.	Full Diameter of the Flanch.		Length of the Pipe.	Thickneſs of the Pipe.	Weight of the Pipe.		
Inches.	Ft.	In.	Feet.		Cwts.	qrs.	lbs.
2	0	8	6	$\frac{3}{8}$	0	2	10
$2\frac{1}{2}$	0	$8\frac{1}{2}$	6	[illegible]	0	3	4

13	1	11	9	$\frac{7}{8}$	11	0	26
14	2	0	9	$\frac{7}{8}$	11	2	7

It was afterwards found that, in a long courſe of practice, it was better to make iron pipes rather thicker; becauſe in moulding there is ſome uncertainty if the metal is equally thick all round.

WATER, *Jets of*, fountains were formerly the ornaments of all garden and pleaſure-grounds; but are now ſo far out of faſhion, that we only find them in the gardens of the greateſt palaces.

The moſt celebrated are thoſe of Verſailles and St. Cloud in France, Fraſcati, near Rome, and Peterhoff in Ruſſia. The ſubject of the latter is the conteſt of Jupiter with the Titans; it contains a column of nine inches diameter, which ſpouts ſixty feet high.

The fountains of Verſailles, which are very numerous and magnificent, are fully deſcribed by Belidor.

They conſiſt of four grand pieces, which contain excellent bronze ſtatues, repreſenting ſome ſubject of the mythology, beſides a great number of jets for the ornament of ſmaller pieces of ſculpture. The baſon of Latona conſiſts of many jets, which throw up water obliquely 30 feet high, into three large baſons, from which it pours down in caſcades. The water-piece of Neptune and Amphitrite conſiſts principally of perpendicular jets, which are very numerous. The baſon of Apollo contains the god in his chariot, drawn by four horſes; the great jets of this piece riſe 57 feet, and the ſmaller jets 47 feet. The baths of Apollo contain moſt excellent ſculpture, and large ſheets of water in caſcade. There are alſo the pyramids of water, mountains of water, alleys of water, theatre of water, &c.

We have no room left for treating this ſubject, which is of ſome intricacy, and ſhall conclude with Mr Mariot's table, which ſhews the altitude of a reſervoir neceſſary to produce a jet of a certain height; and alſo the quantity neceſſary to ſupply jets of a certain bore, meaſured in Paris feet and Paris pints, 42.36 of which are equal to a cubic foot Engliſh.

Altitude of the Jet.	Altitude of the Reſervoir.	Quantity of Water diſcharged in a Minute from an Adjutage ſix Lines in Diameter.	Diameter of the Conduit-Pipe, ſuited to the two preceding Columns.

See our article Jet d'Eau, Vol. XVIII.

Water, in *Gardening*, a well known uſeful article in gardening, as applicable to numerous ſorts of young plants and trees, ſeed-beds, &c., eſpecially in the droughty ſpring and ſummer ſeaſons, both ſuch as grow in the full ground and in pots in the open air, as well as thoſe in green-houſes, ſtoves, hot-beds, &c. : and alſo in ornamental deſigns, in pleaſure-grounds, parks, &c., either when formed into regular pieces, circular, oval, or in oblong or ſerpentine canals, &c.; likewiſe when varied in a ſomewhat natural expanſe, in curves and bendings.

In forming deſigns of this ſort, the nature of the ſupply ſhould be firſt conſidered, whether it be by ſprings in or near the place, by currents or ſtreams paſſing through, or ſo nearly adjacent as to admit of being conducted to the place ; or by being conducted by ſome neighbouring river, brook, or lake, &c. by means of pipes or ſmall cuts, or by being collected iſſuing from higher grounds, and conducted by proper channels. And another circumſtance, equally neceſſary, is to conſider the means by which it may be retained afterwards. In a looſe earthy, ſandy, or gravelly bottom, it will ſoon ſink away, eſpecially in dry weather, unleſs there is a conſtant current or flow of water running in ; but in a naturally ſtrong clayey bottom, of proper thickneſs, both at the ſides and below, it may be retained in ſome tolerable degree. In moſt caſes, ſome art, however, will be neceſſary in this buſineſs. See Basons, &c.

Where it is eaſily attainable in any of the above modes, it ſhould not be omitted, on a ſmaller or larger ſcale, eſpecially in grounds of any conſiderable extent ; but where intended principally as reſervoirs for watering gardens, they may be of much more moderate dimenſions than when deſigned for ornament, and may be formed either in a circular manner, an oblong canal, pond, or cut, &c.; the ſtiffneſs of theſe forms being always broken by varying curves of the margins or borders, conſtantly forming them where the ſupply of water can be moſt conveniently procured.

Ornamental plats, or pieces of water in pleaſure-grounds, are very deſirable, as being great additions to the beauty, variety, and embelliſhment of them, when properly diſpoſed and contraſted with ſome nearly adjoining detached clumps of plantation, and bounded with a proper expanſe of graſs-ground, ſpreading from the verge conſiderably outwards. In general, when any ſpaces of water, on a larger or ſmaller ſcale, are intended, they ſhould be diſpoſed, as conſpicuouſly as poſſible, in ſome principal diviſion ; either ſometimes at or near the termination of a ſpacious open lawn, or occaſionally in ſome other ſimilar open ſpace ; and ſometimes diſpoſed more or leſs internally, in ſome central or other grand opening ; in all of which an expanſe of water has a fine effect. The particular forms may be adapted to the nature of the ſituation, and the extent to that of the ſupply of water that can be had.

In parks and pleaſure-grounds, the moſt proper ſituations for plats, or other forms of water, are ſome rather low convenient places for containing and ſupplying it, which are ſo diſpoſed as to diſplay an agreeable rural view of the water from the reſidences and principal lawns and walks belonging to them, either near at hand, or at ſome conſiderable diſtance from them ; and where there are occaſionally other accidental ſights and views of it, from other parts of the ground, unexpectedly taking place in an abrupt or ſudden manner. In theſe ſituations the forms and appearances of it may likewiſe be greatly varied and diverſified, according to their particular nature and other concurring circumſtances, ſo as to take off any ſort of formal regularity which they may have naturally. They may alſo have oval, oblong, winding, curving, or bending ſerpentine directions given to them, as may be the moſt natural and ſuitable ; and they may be of ſmall or very conſiderable extents, in proportion to the nature of the ſituations, and the ſizes of the grounds, as well as the ſupplies of water which can be commanded. They are ſometimes in large grounds, formed in the manner of natural bending rivers or ſtreamlets, which ſweep round riſing ſwells of land, planted with trees in the form of clumps, or other modes, ſo as to produce a natural and agreeable effect.

Mr. London, in his ingenious work "On forming, improving, and managing Country Reſidences," thinks that water, in whatever point of view it may be taken, whether as neceſſary to the produce of a country, the delight of the traveller, or the intereſt of romantic rural ſcenery, is one of the moſt lovely ornamental materials of nature. Its effects in all theſe ways are highly uſeful, intereſting, and beautiful ; without it all ſoils are barren and unproductive, roads are dull and unintereſting to the taſteful traveller, and rural ſcenes are often tame and diſguſting. For as it occurs in ſpringy banks, purling rills, or winding brooks, it equally engages and delights ; while in the more diſtant view, in larger expanſes, as thoſe of great rivers, glaſſy lakes, or the extent of the ocean, it exalts and fills the mind with aſtoniſhment. And in ſecluded country ſcenery it is not leſs ſucceſsful in affording variety and pleaſure, either by the beauty of its varied appearance, the roar of its fall among rocks and cliffs, the foam and din of it in the ſmall caſcade, or the melancholy of it in the ſtagnant pool, ſhaded by over-hanging boughs.

But though much has been ingeniouſly and uſefully written on this intereſting material of ornamental rural improvement, and the neceſſity and means of a better taſte inculcated in the management of it, little alteration has yet been effected in the modes of practice, as few examples of artificial water rendered pictureſque have been ſet before the public. The former old, naked, tame, ſhaving, formal methods, ſtill continue to prevail too much in the diſtribution and manner of conducting it. There are ftill not a few who are infected with

——————— that ftrange difeafe
Which gives deformity the power to pleafe :

Collections of ornamental water may, it is faid, properly be confidered as of two kinds ; as thofe defigned to be feen in a general view, and in connection with the adjoining fcenery ; and thofe to be feen only when near. The former forts chiefly confift of lakes, rivers, ponds, bafons, and others of fimilar kinds ; the latter of fprings, rills, rivulets, cafcades, and others of the fame nature. There are fcarcely any fituations in which waters of the fpring, rivulet, and others of the fame nature, may not be placed. In nature, rills are ufually found deep funk in dells, as in inftances where they run down the fides of hills, or pafs through foils of the fandy kind. Where they pafs through a fertile valley, or level meadow, they have commonly a very regular courfe ; and when they are met with in hollow places, their courfe is for the moft part ftraight, or approaching to it. The fituations of rivers, lakes, and ponds, are almoft invariably in the loweft parts of the furface of the land. It is, indeed, impoffible that they could be otherwife. Water, whenever it occurs, is conftantly a ftriking feature in grounds, and in this way has always its peculiar fituation : when that fituation is changed, every feature is perverted ; truth, nature, and harmony, are fet at defiance, and the moft glaring difcord fubftituted in their place, ftriking inftances of which prefent themfelves in many different ornamented fituations.

The general fhape of pieces of water muft depend upon the nature of the character which is to be created or given them. Whatever may be the magnitude or dimenfions of lakes or ponds, they fhould be of irregular fhapes, more or lefs wooded, and never entirely naked, being conftantly diftinguifhed by prominences and maffes ; and as often as occafion may ferve, further varied by iflands managed in a fimilarity of manner. And the forms and directions of rivers fhould be given by their fizes, and the nature and kind of country through which they are to pafs. Large rivers, in fertile plains, are, for the moft part, much lefs varied in their courfes than thofe of the fmaller kind ; and both are a great deal lefs fo than thofe which have their directions through hilly uneven furfaces, or through land of a rocky nature. Large rivers can never be imitated where there does not exift a very confiderable ftream ; as without this, the neceffary degree of motion can never be given ; but the directions or courfes of natural rivers may, it is fuppofed, be frequently altered, varied, improved, or divided, with the moft advantageous effects in the way of ornament ; in all which cafes the remarks here given will be applicable. Much might be effected in this way at many of the fine ancient feats of this country, and a high degree of grandeur and magnificence of effect be produced.

In regard to the margins or borders of waters, and the accompaniments of them, it is fuggefted that there are two arguments or reafons, which clearly fhew that the former, in every piece of water, whatever may be its character, fhould be broken and diverfified. The firft of which is, that thereby intricacy, variety, and harmony in form, colour, and difpofition, are produced, in the place of monotony or difcord ; the fecond is, that this mode prevails in nature. Intricacy, variety, and harmony, are produced in the outline, by making the fmall parts irregular, confiderably fo in fome places, and lefs fo in others, according to the kind of water ; in the ground by producing breaks clofe to and alfo at fome diftance from the water ; by fhewing the naked or various-coloured earth and gravel interfperfed among abruptneffes, fmooth flopes, levels, and by every form and difpofition of furface : it is further heightened by the introduction of ftones of different fhapes, and placed in varied or intricate *difpofition ;* and alfo by roots, decaying trunks, or branches of trees. It is further fuggefted, that another fruitful fource of thefe beauties is plants, graffes, low growths, fhrubs, and trees. Plants and graffes may, it is fuppofed, be employed both for cloathing fuch parts of the furface as are fmooth, for varying others, and affifting difpofition. Shrubs and trees may be ufed for the laft purpofe upon a more enlarged fcale. Plants, graffes, and low growths, give intricacy and fhade to fmall breaks, and the interftices among ftones, rocks, &c. Shrubs and trees give intricacy to large receffes, either of fimple margin, or containing thefe leffer enrichments, which, fhaded by trees, will be heightened in effect. All this, it is fuppofed, we fee accomplifhed in nature in fuch a beautiful manner, as far furpaffes every fort of defcription ; it may, it is believed, be admired by perfons of feeling alone, without much judgment or knowledge of the principles by which it pleafes or produces the effect noticed ; but this kind of knowledge and judgment is highly ufeful in directing what to copy from nature, and how to apply it to artificial pieces of water. Without it, perfons, it is contended, may argue either for copying the deformities or fingularities of nature, or for mifapplying them when copied, as has been done by feveral. There is a difference of character in the margin and accompaniments of a lake, river, and brook, though each is varied or harmonious. Each differs alfo according to the nature or ftyle of the country, or foil of the land through which they may have to pafs, as is evident from a great number of different inftances fcattered over the country, in which there are particular differences in the banks, adjacent grounds, and accompaniments, that give an interefting variation of character to each individually.

There are fome other ornamental appendages which are occafionally placed near to or upon water, fuch as erections of the bridge, and other kinds. There is no greater ornament to a piece of water of the nature of a river than a bridge, and few objects fo generally pleafing, becaufe fo univerfally ufeful. This notion has been taken advantage of, it is fuggefted, by improvers, but for the moft part in a very injudicious manner. Their bridges are too commonly formal, and unconnected with the fcenery, either by their unfuitable magnitude, or by the loftinefs of their arches, ftraddling acrofs a fhallow ftagnated river, as is the cafe in many well-known fituations. They want, it is contended, that beautiful fimplicity, connection, and picturefque effect, which may be feen in many highway bridges acrofs ftreams or rivers, and which is produced there by *neceffity* and time. Thus the arches, it is faid, are made low when the banks on each fide are tame and level, becaufe otherwife carts and carriages would have greater difficulty in afcending them. The architecture is fimple, becaufe, in general, the builders were not allowed to incur the expence of ornaments. The plants, ivy-bufhes, and trees which group with them, have fprung up in the courfe of time, but they may be fpeedily imitated by art. The broken parapets, piers, or arches, fupplied by open railing, or a few pales, are the effects of time, or accident, and in fome cafes are worth imitating in the fcenery of a refidence. Thefe circumftances might eafily be copied in ornamental fcenery, and if judicioufly fupplied, it is faid, will invariably fucceed in producing a good effect. Foot-bridges of planks, or rude boles and trunks of trees, fuit well, it is fuppofed, with many fcenes of the rural kind. They have frequently been attempted, it is afferted, but feldom with complete fuccefs, owing to the tafteleffnefs of thofe who contrived them.

The

The other ſorts of erections which have been uſually employed for the purpoſe of *ornamenting* water, it is contended, have rarely either picturesque effect, or any uſe; ſuch, for inſtance, as thoſe of aquatic temples, ſtatues, river-gods, and other ſimilar abſurdities, or what may be called falſe decorations. Boat-houſes, however, of ſimple conſtructions, and for the moſt part all uſeful ſorts of erections, may occaſionally be introduced with propriety and good effect. The Perſian-wheel, the forcing-wheel, the corn-mill, and ſome others of ſimilar kinds, are had recourſe to with excellent effects in different places. "The water-wheel and corn-mill at Warwick-caſtle, it is ſaid, is perhaps the grandeſt appendage to that noble building; whether in reſpect to the train of ideas which it awakens in the mind reſpecting its former compared with its preſent uſe, &c., or its effect in connection with the caſcade, for which it forms an excellent apology. And though caſcades of this kind be formal of themſelves, yet the idea of their utility, it is ſuppoſed, compenſates, in a conſiderable degree, for the want of picturesque grandeur; and ſtill the *roar* meets the ear through woods, or diſtance, with the ſame force as in thoſe which are natural."

Mr. London further ſuppoſes, that the picturesque improvement of the pieces of water which already exiſt will be attended to by all thoſe who at preſent have artificial waters, in imitation of rivers, lakes, ponds, or brooks, and who are in the habit of making improvements of this kind upon their grounds. Such proprietors may, he thinks, be aſſured that no part can ſtand in greater need of alterations than ſuch waters; and ſhould they go on with others, except planting, to the neglect of this, they will not certainly merit the approbation of men of taſte, as taſte always prefers excellence to quantity. "If, it is ſaid, any proprietor ſhould heſitate to alter a piece of water which he has long been accuſtomed to ſee without being ſenſible perhaps of any great deformity, in conſequence of habit, if he looks from his windows to a ſerpentine river, winding among ſmooth naked turf, with only here and there a few clumps placed at ſome diſtance from its margin; if the water preſents one uniform glare of light, clear blue, or dull green, and ſeldom varied by any ſhadows or reflections but thoſe of clumps and ſky, let him, before he decides in favour of the tame river, imagine that in place of this a broad irregular lake, forming bays and receſſes, retiring among thick woods, and with its margin in ſome places abrupt, broken, and varied by ſtones, plants, and creepers; in one place ſmooth, ſloping, and covered with graſs; and in another clothed with ſhrubs, trees, and low growths; then let him imagine that he ſees theſe trees, woods, and the different coloured earths and ſtones of the banks, reflected upon the ſtill ſurface of the water, which, in ſome places, was covered with dark ſhadows from the wood, and in others was bright and clear as the heavens: let him conſider how intereſting this would appear, even at a diſtance, and how long he might be employed in tracing with the eye the various receſſes, dark places, and reflections, while ſtill much remained indiſtinct or unſeen, and therefore either employed the imagination in completing it according to its own ideas, or awakened curioſity to walk down and examine it minutely, by tracing, as far as could be done without the interruption of thickets and briars, the various windings and intricate margin of the whole. Let him only contraſt this with the effect of the piece of water already there, which he can *ſee* and *know* as completely by a ſingle glance as if he viewed it an hour; and could examine the two extremities, which are all that could be diſcovered by walking down to it, as completely in a few minutes as if he were to encompaſs it a whole day. If the contraſt does not ſtrike him, he certainly, it is contended, as far as regards his own taſte, is juſtified in preſerving his water as it is; but if otherwiſe, he ought to commence improvement immediately, not only in gratification of his own ſentiments, but alſo in juſtice to every attempt to promote and introduce good taſte in a country where he is a proprietor, and among a people upon whom he is dependent for his rank and affluence. Different ſtyles of improvement may, it is obſerved, be ornamental, and admired while they are in faſhion; but it is only ſuch as this, which are picturesque, or natural, that can ſtand the teſt of time."

The firſt thing to be conſidered in the alteration of artificial pieces of water, is the character which ought to be adopted; and the next, the execution of that character in the beſt manner poſſible, and with the leaſt expence of labour and money. The former has been already fully noticed, and the latter will be particularly conſidered below. In many caſes, however, the alterations required are ſo very ſimple, as to ſtand in need of little art, either in the deſigns or the practical parts, as has happened in altering the waters of different fine country-ſeats.

In ſhort, the management of natural pieces of water, where they come within the province of picturesque improvement, moſtly conſiſts in rendering them more characteriſtic, and by the occaſional introduction of *particular effects*. The leading principles in effecting the firſt of theſe improvements have been made ſufficiently obvious already; and the latter are derived from what takes place in nature; as in the caſes of waterfalls, caſcades, ſprings, and drooping banks or rocks, on the margins of large brooks or rivers, all of which may, it is ſuppoſed, be imitated in particular inſtances. Alſo, in rills and ſmaller ſtreams there are dank-pools, ponds, and little lakes, which often occur in their courſes, that are highly worthy of imitation for their intrinſic beauty, their contraſt with the narrow rills, and their uſe in landſcape. Beſides, it is ſuggeſted that a great advantage of ſuch pools, or little lakes, is, that they may be made to appear natural where no other variety of ſtill water could poſſibly be attempted. And that, in nature, they are found on the ſides of declivities, where they are, for the moſt part, covered by wood, and ſeen only on a near view. In level places or ſituations, or ſuch ſurfaces as are not ſtrikingly inclined, they are or may be opened in ſome parts, for the purpoſe of being ſeen from diſtant places in the grounds, as is admirably done in ſome caſes.

Another ſort of occaſional appearance or effect is *iſlands*, and they are particularly deſerving of imitation, eſpecially in lakes and ponds; nay, even in large rivers or brooks they have often a good effect. In large rivers they are moſtly long and narrow; and in brooks frequently ſo large as to be wholly out of proportion to the ſtream, containing much extent of ſurface; but ſometimes th ey ar extremely ſmall, and only contain a ſingle buſh, a few buſhes, trees, or ſtones and plants; each of which caſes may be ſeen in almoſt every brook, and they deſerve imitation. Iſlands in ponds, it is ſuppoſed, ſhould rather be numerous and near together, than large and diſtant, and be ſituated rather approaching the ſides than the middle parts: the apparent magnitude of a piece of water may, it is ſuggeſted, be greatly heightened from the main point of view, by placing moſt of the largeſt iſlands next the eye, as well as by the mode of planting them. In regard to planting iſlands in general they ſhould be wooded, but not wholly, and never in ſuch a way as to exclude the appearance of ſurface, broken ground, rocks, roots, and ſtones, which are more natural to iſlands than to ſhores, becauſe it muſt always be ſuppoſed that it has been ſome of theſe materials which have either occaſioned the accumulation of the iſland, or prevented it from being waſhed away afterwards.

Waterfalls and caſcades are alſo occaſionally introduced in extenſive pleaſure-grounds, where there is the advantage of a rivulet, by which they may be formed either in one large fall, or in two or three ſmaller ones in ſucceſſion, having large rough ſtones placed below to break the water, and increaſe the ſound of the torrent in its fall and paſſage over them, in ſome degree ſimilar to that peculiar to natural caſcades. And fountains, ſpouting water from images, &c. are ſometimes introduced in the centre of ſmall or moderate baſons, or other reſervoirs of water in gardens or grounds, where a ſupplying head of water is conveniently ſituated ſufficiently high to raiſe and throw the water from the jet or ſpout, in a continued full ſtream, to a conſiderable height, which falling in the baſon, keeps the water of it in motion, prevents ſtagnation, and is thereby rendered more proper for keeping and breeding fiſh of the gold and ſilver kinds, &c. and the ſpouting and falling of the water have a refreſhing effect in the heat of ſummer. In parterres, ſhrubbery grounds, and particular kinds of gardens, water is introduced either in the forms of ſtill ponds, drooping fountains, or jets d'eau; but as theſe are all artificial, no perfect mode can be afforded for imitation. They, however, moſt of them proceed in ſome meaſure on the principle of contraſt, which, in every modification of matter, is capable of producing either incongruity, variety, or harmony; conſequently, of effecting ſcenes which ſhall diſguſt, pleaſe, or highly intereſt the beholder. Jets d'eau are not at preſent in ſuch diſrepute as they were formerly in this country; but they are, for the moſt part, leſs underſtood, and their proper uſe leſs comprehended.

Mr. London, in the above work, remarks, that the epithets waterfalls and caſcades denote different characters in ornamental improvements. Where the water falls over a ridge of rock in one or more *ſheets*, they are properly denominated waterfalls; and where its fall is broken and interrupted by the irregularity of the ridge, and by other fragments of rocks and ſtones, they are properly caſcades. Both kinds, it is ſuggeſted, may be imitated in improved ſcenery, though hitherto this has ſeldom been well accompliſhed, on account either of the reſtricted practical knowledge of perſons of taſte, or the limited or vitiated taſte, or deficiency of judgment, in thoſe who have had the neceſſary practical experience in matters of this kind.

However, waterfalls may either, it is ſuppoſed, be imitated directly, by being copied from nature, or indirectly, by the introduction of weirs for the uſe of water-mills, as already hinted. In imitating nature, the *ſtrength* or *durability* of the whole muſt be equally taken into conſideration with that of the beauty. The firſt depends upon the general form of the whole materials, and the ſecond principally on the foundation; but in a partial way alſo, on the quality of the materials, and the execution. In every caſe which is upon a large ſcale, the foundation ought to be the natural rock, if poſſible; but on a more moderate or ſmall ſcale, it may be a ſecure cauſeway, fixed by oak piles and croſs-planks, the work being performed with great care, and in an exact manner; uſing ſuch mortar, where neceſſary, as is capable of reſiſting water.

It is noticed, that there is one variety of waterfall which may be occaſionally ſeen in nature, and which is highly worthy of imitation, though it is not known to have ever yet been attempted to be introduced. It is that where a ſmall rivulet or rill, at its junction with a river or brook, falls over a rock in one ſmall ſheet. It is ſtated that, "at Matlock Bath, the noiſe of a ſmall waterfall of this kind forms one of the fineſt circumſtances of the ſcenery about that place; — borne upon the breeze, its grateful harmony meets the ear in almoſt every part of the adjacent ſcenery, in murmurs as varied as their paſſages through woods and open glades, along the ſurface of the Dove, under the echoing cliffs of the Tor, or aſcending the heights of Abram. This remarkable effect, it is contended, produced by ſuch a ſmall quantity of water, ought to be the greateſt encouragement to ſuch as poſſeſs brooks or rivulets, as few caſes can occur where it may not be imitated; not indeed with ſuch remarkable ſucceſs, becauſe the ſurrounding ſcenery may not be ſo varied, but ſtill with ſuch an effect as would amply compenſate for the expence, which in every caſe could be but trifling." Others are ſuggeſted, and the beſt manner of forming them clearly explained by drawn figures.

The nature of waterfalls for the purpoſe of driving machinery are, it is obſerved, generally pretty well underſtood; and that as no diſguiſe in the maſonry is requiſite, but art is commonly to appear; the principles of ſtrength and durability noticed above are what chiefly demand attention. But it is remarked that it is to be regretted that ſo few who have rivers take advantage of it, and that ſo many make caſcades equally formal and unnatural, without any real uſe, and with little beauty, either of character in themſelves, or fitneſs and connection with the ſcenery about them.

As to caſcades, what has been ſaid in reſpect to waterfalls will in general apply. In thoſe which are upon a ſmall ſcale, and where there is a plentiful ſupply of water at all ſeaſons of the year, the ſame forms may be built with ſimilar care in reſpect to foundation, ſolidity, and mortar, they being then diſguiſed by rocks of different ſizes in a natural manner, in different ways, according to the different circumſtances of the places. The ſame general principles in relation to form will be applicable to all kinds of *heads*, fiſh-ponds, &c.; only in theſe caſes the materials are commonly clay or gravel; which laſt ſhould always be well *puddled* with clay or ſtiff loam on the ſide next the water. In deſigning waterfalls and caſcades, one principal conſideration is, it is ſaid, to adapt them properly to the ſcenery. In ſome caſes, they are quite inadmiſſible, as in all rivers or brooks without ſtones or rocks in their beds or margins; and in others where they are few, or where the ground on each ſide is level, they can never be made of any great magnitude. An attention to nature is, however, ſufficient to guide us in this, as well as in every thing elſe which relates to the ſubject; a ſubject which, it is ſaid, is ſo highly intereſting and comprehenſive, that it would require a very great ſpace to give a complete elucidation of it in every reſpect. See Water-*Falls*.

It may be noticed, that in the buſineſs of forming ground for water, the earth muſt be excavated to a proper depth, gradually ſloping from the verge to the middle, from three to four or five feet deep; ſometimes, however, in low ſituations, the place is naturally hollowed in ſome degree, ſo as not to require a general excavation, or only in particular parts, and ſome general regulations to the whole, which in extenſive deſigns is a conſiderable advantage. Where the ſides and bottom are of a ſandy, gravelly, or ſtony nature, or abound in looſe ſoil, and there is not a conſtant ſupplying ſtream, they muſt be well ſecured by the application of a thick coat of well-wrought clay. And where this claying is neceſſary in the preparatory excavation, a proper allowance ſhould be made

made for the additional coat of clay, to the extent of twelve or fifteen inches in thicknefs, and of feveral inches of gravel over it, to preferve the clay from being wafted by the motion of the water, and keep it clear, which would otherwife be muddy. But previous to the claying, the loofe and uneven parts in the bottom and fides of the cavity fhould be well rammed, to make the whole firm, even, and fmooth; then beginning in the middle fpace with the clay, and proceeding gradually outward, being careful that no ftones, fticks, or other matter, get mixed with it, to occafion fiffures, or cracks, by which the water may efcape, laying it evenly, a fmall thicknefs at a time, and fpreading it regularly, treading it well with the naked feet; and if dry weather, cafting water on it occafionally, ramming it well from time to time with wooden rammers; then gradually applying more clay, in the fame manner, to the proper thicknefs, being careful that every part is fo well puddled and rammed, as not to leave the fmalleft vacancy. Thus continuing the claying in a regular manner each way, from the bottom to the top of the circumference, fmoothing the furface evenly, and in dry weather covering it, as the work proceeds, with matts or ftraw litter, or with the ftratum of pebbly gravel. When the whole is finifhed, the water fhould be let in.

When this has been done, the top or verge muft be regulated and levelled, forming it evenly from the edge of the water, in a gradual regular expanfion to fome extent outward, without any ftiff flope clofe to the water, diftinct from the furrounding fuperficies; laying the ground with grafs turf, efpecially along the margin, continuing it as far down as the general level of the water. Where the extent is confiderable it may be fown with grafs-feeds.

In conftructing the excavations for a body of water in fuch fituations as are deficient of materials in fome of their parts, as too low in fome of their boundaries, as either at the ends or fides finking below the general furface of the ground, or the height at which the water is intended to ftand; thefe parts muft be ftrongly banked up to the neceffary height in a fubftantial manner, having a fufficient body of proper materials applied, efpecially where the part is to form a head at the end of a canal, or other fimilar piece of water; the whole being inwardly faced with a ftrong body of well puddled clay.

It is well known by every one, the above writer fays, that the expence attending the formation of artificial water by the modes which have hitherto been chiefly practifed is enormous, and in fome inftances fcarcely fupportable; but by adopting improved methods, fuch as thofe which have been fuggefted, it will in almoft every cafe be greatly reduced, and become much cheaper, often to a very remarkable degree. This will be rendered quite evident by confidering the different neceffary operations in their formation, as they relate to each method of proceeding; fuch, for inftance, as the excavation of the bed for the water, the formation of the head, the fpreading of the earth taken out, and the management of the furrounding furface. In regard to the firft, the principal reafon why it becomes fo expenfive is, that a river is commonly imitated inftead of a lake, which, on account of the natural flope of all grounds, requires not merely larger heads, but a far greater number of them. By in a great meafure imitating lakes, one head is, for the moft part, all that is required; and this alfo, many times, of a far fmaller dimenfion than thofe in the cafes of rivers. This alone often makes a very material difference in the coft.

In what relates to the fpreading of the excavated earth, and the regulation of the furrounding furface, as in the methods hitherto purfued in landfcape gardening, whatever may be the natural character or tendency of the furrounding furface, it is to be reduced, by levelling, to a fmooth, even lawn, or pafture, floping in a gradual manner from the margin of the water. This of courfe caufes a prodigious expenditure of money; and what is ftill more difagreeable, it is too frequently quite uncertain, and only capable of being calculated after the finifhing of the whole work. The quantity of cubical yards to be removed in the work of excavating can be eftimated very nearly to a certainty; but the bufinefs of levelling is intricate, troublefome, and often of great extent; hence the great excefs of expence which is frequently incurred beyond the eftimate in this refpect in pieces of made water. If any one plan ever had the advantage over another, it is contended that certainly picturefque or natural pieces of water have the full and complete fuperiority over thofe of other kinds in what regards expence. In them, it is maintained, the natural character of the ground is preferved or improved, and confequently no expence of levelling is incurred; the fuperfluous earth produced in the procefs of excavating being formed into irregular inequalities, or diftributed along the banks in fuch a manner as to augment or increafe their character and picturefquenefs, as is evident in numerous inftances. Under other circumftances, vaft expence may often be run into, without much, if any, beauty being produced; when it could have been effected to a great extent by the modes which are here advifed without laying out much money. Farther information on this very interefting fubject may be gained by confulting Mr. London's excellent work.

Water, *Rain*, *Collecting of*, *for Farm Ufe*, in *Rural Economy*, the providing it in proper fituations for the purpofe. This practice was formerly adopted in different parts of the country: as in moft towns, and in the yards, ponds for the ufe of cattle, are ftill to be met with, which have an artificial appearance. In extenfive pafture heavy or about the houfes of many old farm-lands, pools or land diftricts, pits have evidently been formed by art for the purpofe of catching fuch rain-water as may be brought to them by the ridge-furrows, ditches, or other fuch means, as well as that of land-fprings. The art too has been long practifed on the fouthern chalk-hill parts of the kingdom, and ftill contlnues, in a great meafure, to prevail; and on thofe, in fome northern diftricts, it has been more lately eftablifhed, and fpreads itfelf on the neighbouring heights with vaft benefit. It is certainly neceffary and ufeful in all dry high fituations. It may probably, in fome cafes, alfo be collected into fuch pits, from the roofs of the buildings, for fuch purpofes, with much advantage; though it has been much too common to draw it up, at great labour and expence, from deep wells formed in the bowels of the earth.

Lately much more attention has been beftowed on this matter than was formerly the cafe, in moft places, and in fome with the greateft fuccefs and benefit. It fhould never be neglected where the want of it is confiderable, as live-ftock never do well under fuch circumftances. See Pond, *Made* Streams, and Watering *Live-Stock*.

Water, *Sea*, *Management of Land gained from*, in *Agriculture*, the bringing ground of this fort into cultivation. It has been obferved, that the principal difficulty that can occur in any fituation will be to keep off the water of the rivulets or rivers that may come from the furrounding lands, and to carry away and deliver to the fea the furface-water collected from the land gained: the next important con fideration is that of clearing this land of furface incumbrances. It will often happen, it is faid, that the ground to to be defended is interfected by a river. This is, it is thought, the moft expenfive and difficult cafe that can occur; but it is here only neceffary to carry the defence along each fide of it to the fea; and there, where it interfects the other line of defence, to place a flood-gate, which may prevent the tide from entering, except when it may be neceffary to admit veffels or other things, and which fhall allow the water of the river to pafs into the fea. Small rivulets and fprings may either be turned along the margin of the land gained, and be let out at one end of the defence where it joins the land, or be led the moft convenient way to one or more of the valves or flood-gates, which it is neceffary to make in all defences for excluding the water within. The water collected on the furface of the land gained, may generally be let off by the above flood-gates or valves; but where the defence is extended into the water, this cannot be the cafe, as the level of the fea will moftly be above that of the land. In this cafe, wind-mills for driving pumps muft be placed at proper diftances, according as the particular cafe may be. Perhaps, in general, one fmall wind-mill driving four pumps, may be fufficient for freeing a thoufand acres of ground of water. The expence of fuch a pump-mill would not, it is faid, be above twenty or thirty pounds. By making a fmall defence-bank, from two to four feet high, fome diftance within the larger one, all the water collected between that and the original fhore would be accumulated; and it might be led in a raifed canal in the fame level to a flood-gate in the outer defence. This would, it is thought, leave very little water to be drawn up by the pump; and in this way, though twenty thoufand acres were gained, one wind-mill only would be neceffary. Often, and indeed in moft cafes, in place of a wind-mill, the brooks, rivulets, or fprings collected within, might eafily, it is faid, be made to turn a water-wheel, which would be more permanent and uniform than that turned by the wind. A bafon might alfo be conftructed, fo that the ebb and flow of the tide would turn a draining-wheel; and a great many other methods might, it is fuppofed, be fuccefsfully adopted. Thus, in land gained from the fea, there cannot, it is thought, be any difficulty in preferving it from water, from whatever quarter it may come. When the land to be gained is more or lefs covered with ftones, thefe fhould be put in flat-bottomed boats at low water; and when the tide floats them, they fhould be rowed to the propofed line of bank defence, and be then dropped. This mode of conveyance will generally be found the moft economical for all the folid materials which are at a diftance. Where the ground is fandy or poor on the furface, and argillaceous earth or rich loam below, it may be trench-ploughed to fuch a depth, as to turn up the good and bury the bad foil. If the foil be fhallow, and even rocky, it may ftill, it is faid, be rendered valuable. The moft rocky parts may be covered five or fix inches deep with mouldy matters, and the whole be fown with either meadow grafs-feeds, to be floated with frefh water, or kept as meadow; or with other proper and fuitable grafs-feeds, and kept as falt-marfh. When mud of a good quality and confiderable depth is gained, it may, in fome cafes, it is thought, be defirable to fummer-fallow it for one or more feafons, after it has been fecured from the fea. At other times it may be better to fow it with rape-feed for the firft feafon, and to fummer-fallow it the next, as a preparation for a corn-crop, &c.

It is obferved that no fort of land can be gained from the fea but what is of great value for the purpofe of cultivation, and efpecially as it can for the moft part be flooded by frefh water as well as by that of the fea at all times. By flooding, the moft barren fand or rock, with only an inch or two of foil upon it, will bear excellent pafture. Indeed, much of the fand in thefe fituations that is often reckoned barren and ufelefs, is mixed with broken fhells, and on being examined will be found to contain three or four parts in ten of calcareous matter. Moft of the large rocks, too, within the falt-water mark are, it is faid, in a ftate of rapid decompofition, and fo fragile on the furface, as to be eafily penetrated by the roots of grafs-plants; more particularly after they have been expofed for fome length of time to the action of the atmofphere. The large detached ftones often found within the water-mark are not here meant, as thefe are fuppofed to be either buried in the ground, or boated off as above; but thofe continued rocks which frequently conftitute the bafis of the fea-fhore for great diftances, the furface of which is fo completely oxydated, and occafionally decompofed and reduced fo as to be called *rotten*, that they are capable of affording either an excellent manure for certain foils, or are fit and proper for fupporting the vegetation of faline plants in their actual condition.

The quantity of land of this fort that is eafily capable of being obtained and thus cultivated is very confiderable indeed, perhaps not lefs than fome millions of acres in the whole ifland. See WASTE *Land*, and WATERING *Land*. Alfo SALT-*Marfh*.

WATER, *Gum*. See MUCILAGE.

WATER, *Hungary*. See HUNGARY *Water*.

WATER, *Laurel*. See LAUREL.

WATER, *Lime*, is common water, in which quicklime has been flaked. See LIME-*Water*.

WATERS, *Ophthalmic*, or *Eye*, are fuch as are good in diforders of the eyes. See COLLYRIUM, EYE, and OPHTHALMIA.

WATER, *Tar*. See TAR-*Water*.

WATER, in *Anatomy*, &c. is applied to divers liquors, or humours, in the human body.

Such is the *aqua phlegmatica*, phlegmatic water; which is a ferous fluid contained in the pericardium.

WATER, in *Geography* and *Hydrography*, is a common, or general name, applied to all liquid tranfparent bodies, flowing on the earth.

In this fenfe, water and earth are faid to conftitute our terraqueous globe.

Some authors have rafhly and injurioufly taxed the diftribution of water and earth in our globe as unartful, and not well proportioned; fuppofing that the water takes up too much room.

The quantity of water on this fide our globe, Dr. Cheyne fufpects to be daily decreafing; fome part thereof "being continually turned into animal, vegetable, metalline, or mineral fubftances; which are not eafily diffolved again into their component parts." Philofoph. Princip. of Relig.

Many modern philofophers are of the fame opinion.

An inundation, or overflowing of the waters, makes a *Deluge*; which fee.

WATER, among *Jewellers*, is properly the colour or luftre of diamonds and pearls; thus called, by reafon thefe were anciently fuppofed to be formed, or concreted of water. The term is fometimes alfo ufed, though lefs properly, for the colour or hue of other precious ftones.

WATER is alfo ufed in divers ceremonies, both civil and religious. Such are the *baptifmal water*, *holy water*, &c.

WATER, *Holy*, is a water prepared every Sunday in the Romifh church, with divers prayers, exorcifms, &c. ufed by the people to crofs themfelves with at their entrance, and going out of church; and pretended to have the virtue of wafhing away venial fins, driving away devils, preferving

from

from thunder, diffolving charms, fecuring from, or curing difeafes, &c.

The ufe of holy water appears to be of a pretty ancient ftanding in the church: witnefs St. Jerom, in his life of St. Hilarion, and Gretfer, de Benedict. cap. x. &c.—M. Godeau attributes its original to Alexander, a martyr under the emperor Adrian.

Many of the reformed take the ufe of holy water to have been borrowed from the luftral water of the ancient Romans: though it might as well be taken from the fprinkling in ufe among the Jews. See Numbers, xix. 17.

Urban Godfrey Siber, a German, has a differtation, printed at Leipfic, to fhew, by proofs brought from church hiftory, that one may give holy water to drink to brutes.

Bitter Waters of Jealoufy.—In the Levitical law, we find mention made of a water, which ferved to prove whether or no a woman were an adultrefs. The formula was this: the prieft, offering her the holy water, denounced, "If thou haft gone afide to another, inftead of thy hufband, and if thou be defiled, &c. the Lord make thee a curfe and an oath among thy people, by making thy thigh to rot, and thy belly to fwell; and this water fhall go into thy bowels, to make thy belly to fwell, and thy thigh to rot." And the woman fhall fay, *Amen*. "Thefe curfes the prieft fhall write in a book, and blot them out with the bitter water. When he hath made her drink the bitter water, it fhall come to pafs, that, if fhe be defiled, the water fhall enter into her, and become bitter, and her belly fhall fwell," &c. If fhe be not defiled, fhe fhall be free, and conceive feed." Numbers, chap. v.

WATER, *Interdiction of Fire and*. See INTERDICTION.

WATER *of Flax and Hemp*, &c. that which is ufed for fteeping or raiting them in, in the view of procuring the pure vegetable fibrous matters that they contain. The writer of the "Elements of Agricultural Chemiftry" has obferved, that this water poffeffes confiderable fertilizing powers. It appears, it is faid, to contain a fubftance analogous to albumen, as well as much vegetable extractive matter. It putrefies very readily. And that as a certain degree of fermentation is abfolutely neceffary for obtaining the matters of the flax and hemp in a proper ftate; the water to which they have been expofed fhould on that account be ufed as a manure as foon as the vegetable fibre is removed from it.

WATER, *Black*, a difeafe in neat cattle and fheep, which is not unfrequently of a ferious nature. It has not, however, been yet properly or fully inveftigated.

In neat cattle it is faid to arife from fudden changes in the ftate of the weather from heat to great cold, the taking of cold on being turned into low wet paftures in the early fpring feafon, and the want of proper water in long dry times. Some fuppofe too that it may be caufed by frefh paftures of particular forts, and that certain vegetables picked up by the cattle may produce it. It confifts of a difcharge of a dark black bloody nature from the kidneys, and fometimes probably from other parts of the body. It is moft probably produced by inflammation terminating fuddenly in a ftate of great debility and relaxation of the parts, fo as to admit the dark grumous blood thrown out to pafs away in this manner.

In flight cafes of this nature the cattle do not feem to be a great deal affected by the difeafe, but where the bloody fluid paffed away is confiderable, and lafts for fome length of time, the animals become reduced to a very low ftate or condition, and great weaknefs is the confequence, which if not fpeedily removed by fome proper remedy, the cattle foon fink under the preffure of the complaint.

In the cure, except the difeafe be taken at its commencement, bleeding will feldom be ufeful or neceffary, but the bowels fhould be well cleared out by powerful evacuating remedies of the falt kind, and kept properly open by their repetition, fo that the cattle do not become in the leaft conftipated, which would be hurtful and dangerous. When the difcharge continues, balls compofed of alum, ruft of iron, and armenian bole, made up with Venice turpentine, may often be of fervice, when given in fufficient quantities; but a more powerful and effectual remedy will be found in a ftrong decoction or infufion of bark, with vitriolic acid, and the tincture of opium, given in the proportion of a pint of the firft, two drachms of the fecond, and three drachms of the laft. This may be repeated once or twice in the courfe of the day where neceffary, the bowels being always well kept open.

By fome of thefe means the difeafe may moftly be removed without any great difficulty.

Some think that much benefit often arifes from the ufe of nitre in full dofes in this diforder, as well as from the change of pafture, in fome inftances, as from low to fuch as are rather high in their fituation.

In *fheep* the difeafe is characterized by much the fame appearances, taking place fuddenly, moft commonly among thofe of the hog kind, and fuch as are apparently ftrong, while feeding in rank paftures of the clover or other luxuriant grafs kinds. In thefe cafes, there is fometimes much dark bloody watery fluid met with in the ftomachs of the fheep after death. The difeafe in thefe animals is moftly very rapid in its progrefs, therefore the fheep in fuch paftures fhould be conftantly well looked to, in order to difcover if any of them be indifpofed.

In the prevention of the black water in thefe animals, fome have found great benefit by the ufe of about half a tea-fpoonful of fulphuric or vitriolic acid in mixture with a fmall fpoonful of the compound tincture of cinnamon, when given in a cup of cold water to each fheep in the morning, and cotting or houfing them in the night feafon.

In other cafes, when the difeafe appeared to be prefent, much advantage has been faid to be produced by giving a ftrong infufion of oak-bark with aromatics, well acidulated with the fulphuric acid, and to which has been added a little of the tincture of opium. The bowels are to be kept in an open ftate at the fame time.

The immediate removal of the fheep into clofer fed and drier paftures, will always be attended with great benefit in this difeafe, and the fupplying them with dry food might perhaps in fome cafes be of utility.

WATER, *White*, a name often given to a dangerous difeafe in fheep.

WATER *in the Head*, a denomination frequently applied to a difeafe in the head of fheep. See GID and STURDY.

WATER *Braxy*, among *Animals*, a difeafe in fheep, which has been difputed by fome; but which the writer of the "Shepherd's Guide" is confident exifts, having feen and diffected feveral cafes of it after death; and is affured, too, that it does confiderable damage on fome particular farms, in fome fituations; but that whether it be a fpecies of the common braxy or not, will, it is thought, admit of a doubt, though it is always viewed and confidered by the fhepherd as fuch. It is ftated in addition alfo, that in two external appearances it has a refemblance to it. The firft of which is, that the animal, when living, feems affected much in the fame way, lying frequently down, and loitering behind the reft of the flock, appearing likewife fomewhat fwelled in the body. And that the next is, that, like all others affected with the braxy of any kind, it will not bleed

to

to any extent on opening a vein. The cutting of a vein in the tail, fpould, or below the eye, will make other fheep bleed plentifully ; but from thefe fcarcely a drop will iffue ; and even on cutting the principal vein in the throat, only a very fmall quantity, it is faid, proceeds to flow out.

However, in the interior appearances it differs very widely and materially. On opening the fheep, the whole entrails are, it is obferved, fwimming in bloody water, none of which is within the bowels, but only within the rim of the belly. The gall-bladder is very fmall, appearing as having been moftly fpilled previoufly to the death of the animal, and the urinal bladder is contracted and fhrunk up to a fize fcarcely noticeable. The fmall fibres connecting it with the other parts are inflamed, and on bringing it near the nofe fmells fomewhat like the other braxy. The bladder feems entirely without urine, but on blowing it up it is always quite found, and never burfts ; the guts and flefh are a little difcoloured, and have a fmell peculiar to that diforder. The fmaller department of the ftomach or *reid* has fome purple fpots on it ; and, on being felt with the finger, thefe are thicker in the texture than the other parts of it. They feem, too, to have bled a portion inwardly ; this fome fuppofe iffues from the liver.

In an effay inferted in the appendix to the Rev. Mr. Findlater's Account of the Agriculture of the County of Peebles in Scotland, it is faid to be a difeafe that is analogous to the fuppreffion of urine, which is caufed by the want of fufficient activity and exertion. And that it confifts in the bladder being over-diftended with urine, which raifes violent inflammation in that organ, and produces an incapacity to difcharge the urine that is accumulated. The confequence of which is, that the urine regurgitates over the body ; the whole carcafe is tainted by fetid gafes ; the bladder becomes gangrenous, burfts, and the animal dies. That young and vigorous fheep are moft liable to this fort of braxy. And that the immediate caufe of the difeafe is feeding too freely on rich fucculent diuretic food, and refting too long in the morning on the layers, taking place frequently when the fhepherds are more negligent than ufual in removing them.

It is fuppofed that the difeafe may be prevented by avoiding too free an ufe of fucculent diuretic food, and by moving the animals from the layers on which they are early in the morning, making them walk about for fome time in the view of encouraging them to pafs their urine and purl.

In attempting the cure, in cafe the bladder be greatly diftended and affected, which may be known by there being a great fulnefs in the lower part of the belly, the urine may be endeavoured to be drawn off by the introduction of fuitable implements of the catheter kind, or by cautioufly letting it off by incifion or puncture, where that cannot be done. In either of thefe ways, when effected, great relief will be afforded.

And in the view of allaying or preventing inflammation, the ufe of proper purging and evacuating injections fhould be had recourfe to, fuch as Glauber, or other falts of the fame kind ; or even warm milk and water be thrown up.

The firft writer, however, thinks that no remedy for the difeafe has yet been pointed out that can be fully depended upon. See Braxy, and Striking *Ill*, *Blood*, or *Sicknefs*.

Water *Farcy*, a difeafe in horfes of the œdematous or partial dropfical kind, which is often very troublefome in its removal. It has no relation or refemblance, however, to that of the real farcy, being wholly different in its nature, caufes, and effects, though fometimes ignorantly fuppofed to be of the fame kind. It occurs in horfes of all kinds and defcriptions, and at moft periods of their exiftence. It is a foft watery fwelling below the fkin, and is caufed by whatever has a tendency to weaken and deftroy the natural vigour and ftrength of the body, whether in a local or general manner, but more efpecially in the former, fuch as low bad keep, want of fufficient cleaning and dreffing, taking the animals into cold water in a warm ftate, too great expofure to cold rains, and many others. It often, too, happens after fevere colds of the epidemical kind. The fwellings take place in different parts, but particularly in the legs, having a pitted or dimpled appearance when preffed by the finger. In fome cafes, the difeafe has a more general dropfical afpect, the water not being confined to any one part, but fhews itfelf in feveral, over the whole body, by fuch fwellings. Thefe cafes, for the moft part, proceed from foul feeding, or the effects of eating too greadily of rich luxuriant after-grafs. In the former cafe, the limbs and the whole body are fometimes feen enormoufly fwelled, and become very hard, the belly and fheath parts being very greatly diftended.

In the cure of the difeafe, in all the cafes, the great objects are the removal and difcharge of the water, and the prevention of its future formation by every poffible means. The former are to be attempted by the giving of ftrong diuretic purgative remedies, and the latter by the ufe of medicines of the ftrengthening kind, fo as to brace up and reftore the tone of the relaxed folids of the whole body.

In the firft of the above intentions, the combining of calomel and fquills with jalap and aloes, in the proportions of about one drachm each of the two firft, to two drachms each of the two laft, for a large horfe, may be very ufeful, when made into a ball, and given every night, or every other night for four or five times, and repeated as there may be occafion ; throwing in, in the intervals, bark and other tonics, in full quantities, to reftore and keep up the ftrength of the animals.

Rather ftrong infufions of the fox-glove with aromatics may likewife be tried, and oak-bark in powder, with the fame, be given in large dofes at the fame time they are made ufe of.

The horfes fhould frequently, too, have good mafhes in which nitre has been put.

Gibfon, however, advifes the horfes to be purged once or twice in ten days, and to have intermediately a pint night and morning of the ftrong decoction or infufion of black hellebore, prepared by boiling or infufing it in water, and then adding to four parts of it two of white wine, that has ftood upon the fame for fome length of time in a warm ftate ; or a ball compofed of nitre, fquills, and camphor, in the quantities of two drachms of the firft, three drachms of the fecond, and one drachm of the third, made up with honey, and given once a day, either alone, or wafhed down with a hornful or two of the above infufion.

The horfes fhould be kept warm, and have plenty of dry food while they are under thefe courfes of medicine. See Farcin.

Water *Sicknefs*, a difeafe among fheep of the dropfical kind. It is a diforder, or fort of affection, arifing in the weak ftates of their conftitutions, which is incident to all the varieties of foil and climate, it is faid, in its different forms and degrees of violence, from Shetland in the north of Scotland, to the moft fouthern parts of this country, wherever fheep-hufbandry is carried on. It is obferved to occur, in general, among aged fheep, that are fubjected to its attacks in confequence of weaknefs, either of the more general or more local kind. It moft commonly feizes the animals towards the

the end of the harveft-feafon and winter, and on farms which are moftly deftitute of fhelter. It is, in fact, faid to be the genuine offspring of cold and moifture, and perhaps of every thing that debilitates the vigour of the animals.

The appearances that diftinguifh it to be prefent are fwellings in the legs towards night, which difappear in the morning, when the lower jaw often becomes a good deal fwelled. The eyes are dull, the urine, when noticed, is high coloured, the tongue is dry, and as the difeafe advances, the belly often becomes tenfe, and water is felt undulating in it, efpecially on being ftruck on one fide with one hand, while the other is kept fteady on the other fide. The fheep lofe their heart and vivacity, their appetites fail them, they become thin and lean, and at laft fall away and die.

In regard to the prevention of the difeafe, a dry well-fheltered fheep-walk is faid to be good in that intention; and the neighbourhoods of fea-fhores are ufeful in the fame view, as have been found by experience. But if the diftemper fhould fhew itfelf in a fevere manner, in very wet feafons, in winter or fpring, night-fhelter is found of particular benefit in ftopping the increafing ftate of the malady. The animals, too, fhould have good, green, fweet, dry hay chopped and given them, at the fame time with a little oats or bran in fome cafes.

In the cure of thofe which are difeafed, a fhed or room in a houfe, and a full allowance of the fame forts of dry food, are particularly neceffary and ufeful. Some have tried tapping in the advanced ftage of the diforder, but with only a temporary relief. Two drachms of cream of tartar given twice a day, in a little warm thin oatmeal-gruel, have been known to have a remarkably good effect. In the more early ftages of the complaint, fmall quantities of calomel with fquills would probably remove the difeafe, efpecially if accompanied with a few hornfuls of a ftrong decoction of oak-bark two or three times a week. By thefe means, difeafed fheep, when taken early, would perhaps be readily reftored.

In the above-named part of Scotland, the difeafe is faid to be called by the title of fhell-ficknefs, as well as that which is here given it.

WATER-*Calamint*, in *Botany*, the name ufed by fome for a fpecies of mint. See MENTHA.

WATER-*Crowfoot*, in *Agriculture*, the name of a plant of the weed kind, on which cows are faid by fome to be very fond of feeding. And in the fifth volume of the Tranfactions of the Linnæan Society, Dr. Pulteney has obferved that it is not only relifhed by fwine, but that they thrive remarkably upon it, requiring little or other food until put up to fatten. The produce of it cannot, however, be great, fo that the ufe of it muft be limited.

WATER *Crefs*, in *Gardening*, the common name of a fmall creeping plant of the herb kind growing in watery fituations, fuch as the fides of rivulets, rills, brooks, or other fmall trickling ftreams; and which is much employed as a fallad herb, and for eating with bread and butter, or in other modes in its natural ftate, as being highly cooling and agreeably bitter. See CRESS.

WATER-*Barrow*, *Swing*, in *Rural Economy*, an improved contrivance of this fort. See QUENDON *Water-Barrow*.

WATER-*Bearer*, in *Aftronomy*. See AQUARIUS.

WATER-*Bellows*, in *Mechanics*, a machine ufed to blow air into a furnace, by the action of a column of water falling through a vertical tube. The orifice where the water enters the tube is fo contrived, that the water fhall be mixed with air when it enters the pipe; and this air will be carried along with the ftream through the tube, and is collected into a proper receiver, from which it is conveyed to the furnace in a continued blaft. Thefe machines are much ufed on the continent, but have never been introduced in England, becaufe they will not produce by any means fo great a current of air as may be raifed by the fame fall of water, when employed to work bellows, or other machines, by means of a water-wheel.

M. Reaumur has given a minute defcription of the water-bellows employed for the iron furnaces, in the provinces of Dauphiné and Pays de Foix, in France, where fuch machines are called *trompes*. The water is conducted to the furnace by a trough or paffage, having an inclination of one inch in a toife; the body of the trompe is a vertical tube, about 27 French feet in height, and 16 inches diameter on the outfide: it is made of two pieces of fir hollowed out, and bound together by hoops of iron.

The form of the interior of the tube contributes materially to its effect. The mouth or upper orifice, where the conduit-trough pours the water into it, is 13 inches diameter: from this it diminifhes, in the manner of a conical funnel, till at a depth of three feet from the mouth, it is only four inches diameter, which part is called the throat. Here the opening of the tube enlarges all at once to a fize of nine inches, which it continues for all the reft of the height. Immediately beneath the throat, (that is, the upper part of the

the tube where it becomes nine inches diameter,) ten vent holes are bored through the fides of the tube; they are cylindrical, and two inches diameter; their direction is inclined, fo that they point downwards at about an angle of 45 degrees; they are arranged at equal diftances round the tube in two rows, the upper row having fix holes, and the lower row four: it is through thefe holes that the air enters. The tube is fupported in a vertical pofition by a framing, and the lower end is introduced into a ftrong ton or cafk, fix feet deep, and almoft as much in diameter, though it is rather fmaller at top than at bottom. The tube defcends through the head of the cafk 18 inches, fo that it terminates within $4\frac{1}{2}$ feet of the bottom of the cafk; and a kind of table made of a flat round ftone, or a plate of caft-iron, is placed horizontally in the centre of the cafk, at 18 inches beneath the orifice of the tube, being fupported by a crofs of wood, placed upon four legs, from the bottom of the cafk. The cafk is well clofed on all fides, particularly round the tube, where it paffes through the head; but there is an air-pipe conducted away from the top of the cafk, to convey the air to the furnace; and from the bottom of the cafk there is an opening, by which the water can pafs away. The opening is regulated by a wooden fhuttle, which pens up the water to fuch a height within the cafk, that the opening through which the water iffues will be always beneath the furface of the water, fo as to prevent the efcape of the air by the fame paffage.

The action of this machine is not fo eafy to explain as its ftructure, and it has at various times occupied much of the attention of philofophers. Father Kircher was the firft who defcribed the machine in his Mundus Subterraneus; but he did not fatisfactorily explain the reafon of its action. In the Memoires des Scavant étrangers, Barthes, the father, has given a theory which is very defective; and Dietrich was of opinion that the air was produced by the decompofition of the water.

M. Reaumur explains it thus:—The funnel of the tube is always full of water, which iffues rapidly through the throat; but finding immediately a larger place, the ftream difperfes and fcatters into drops, becaufe it is no longer enclofed within a cylindrical furface: it does not, therefore, take any conftant figure, but the ftream is compofed of different fmall ftreams, or rather fucceffions of drops, which are continually changing their pofition with refpect to each other. Now the intervals between thefe feparate ftreams or drops are occupied by the air which is within the cavity of the tube: fuppofe that between two ftreams feparated by air a third comes to defcend, it will pufh the air before it with all its force, and carry the air down to the cafk; and this will be replaced by frefh air, entering at the vent-holes. The irregular arrangement which the ftreams or drops take, either at their iffuing from the throat or in continuing their fall, is fuch that few drops do not carry fome air down before them into the cafk: the water falling upon the table within the cafk dafhes on all fides, and releafes the air which rifes in the cafk, and iffues through the air-pipe to the furnace, whilft the water falls to the bottom of the cafk, and efcapes gently through the fluice.

A fingle trunk of the dimenfions juft defcribed is found fufficient to blow a forge or finery; but for a fmelting furnace, three are joined together, having a common trough of fupply, and the air-pipes from the three cafks are joined together. M. Reaumur fuppofed that a greater height of the fall would produce more air, becaufe it is longer expofed to thofe changes of pofition in the different ftreams of water; but he fuppofed that no adequate advantage would be gained by an increafe of the diameter of the tube, becaufe it would be more likely, in falling in a large body, to defcend in a clofer column.

The machines of the Pays de Foix are fomewhat differently conftructed: in thefe the water is conveyed into a refervoir, from the bottom of which a fquare trunk or tube defcends to the refervoir or air-cheft, which is made very long; and the air-pipe proceeds from an elevated part of it, to prevent the danger of fpray or fmall drops being carried into the furnace. Inftead of a throat and the vent-holes, the tube is made to divide into two branches, at the point where it paffes through the bottom of the upper refervoir: thefe branches rife above the furface of the water in the refervoir, fo that it cannot enter into them, but the water is admitted at an opening between thefe two branches, fo that in effect the tube is divided into three, the centre being an opening for the water to defcend, whilft the two outfide branches admit the air to mix with the water and go down.

The editor of the Art des Forges fuppofes that the vent-holes are ufelefs, but that the violent agitation of the water in paffing the throat, and dafhing upon the table within the cafk, is fufficient to change the water into air. This is the fame hypothefis as that of Dietrich.

Thefe various explanations rendered the fubject ftill more obfcure; and in 1791, the Academy of Touloufe invited philofophers to determine the caufe and the nature of the ftream of air which is produced in thefe machines. M. Venturi, profeffor of philofophy at Modena, gave the real anfwer in an excellent paper on the principle of lateral communication of motion in fluids.

To explain the principle, this philofopher fuppofes a number of equal balls to roll along in a horizontal trough, in contact with each other, with an uniform motion at the rate of four balls in a fecond: fuppofe, on arriving at the end of the trough, they fall fuddenly to a depth of 16 feet. Now, from the laws of gravity, each ball will perform this defcent in a fecond of time; and as four balls fucceed each other in each fecond, it follows that there will always be four balls in the air at the fame time. The relative pofitions of thefe will be as follows: the uppermoft ball will be one foot from the point where they begin to fall, the fecond four feet, the third nine feet, and the fourth fixteen feet. This arifes from the acceleration which always takes place in defcending bodies. A confideration of this circumftance will give a proper idea of the difunion and fucceffive feparation of the particles which the accelerating force of gravity produces in fluids, or in bodies which fall in a ftream.

The rain-water flows out of gutters by a continual current; but during its fall, it feparates into portions in the vertical direction, and ftrikes the pavement with diftinct blows. The water likewife divides, and is fcattered in the horizontal direction. The ftream which iffues out of the gutter may be one inch in diameter, and ftrike the pavement over the fpace of one foot. The air which exifts between the vertical and horizontal feparations of the water which falls is impelled, and carried downwards. Other air fucceeds laterally; and in this manner a current of air or wind is produced round the place ftruck by the water. M. Venturi went to the foot of the cafcades which fall from the Glacière of La Roche Mêlon on the naked rock at La Novalêfe, towards mount Cenis, and found the force of the wind to be fuch as could fcarcely be withftood. If the cafcade falls into a bafon of water, the air is carried to the bottom, whence it rifes with violence, and difperfes the water all round in the form of a mift.

He formed one of thefe artificial blowing engines of a fmall fize; the vertical pipe was two inches in diameter, and four

four feet in height: it was a plain cylindrical tube, without any throat or funnel. But he found, when the water accurately filled the ſection of the orifice, and all the lateral openings of the pipe were cloſed, the pipe no longer emitted any wind.

According to this writer, the circumſtances which favour the moſt abundant production of wind are as follows:—The ſeparation of the deſcending balls is more rapid in the upper than in the lower part of the fall. In order, therefore, to obtain the greateſt effect from the acceleration of gravity, it is neceſſary that the water ſhould begin to fall at the orifice of the vertical tube with the leaſt poſſible velocity, and that the depth of the water in the horizontal trough ſhould be no more than is neceſſary to fill the ſection of the vertical tube. The vertical velocity of this ſection is ſuppoſed to be produced by a height or head of water in the trough, of a depth equal to the diameter of the tube.

We do not know by direct experiment the diſtance to which the lateral communication of motion between water and air can extend itſelf, but we may with confidence aſſume that it can take place in a vertical tube, whoſe ſection is double that of the original ſection with which the water flows from the trough into the pipe. Let us then ſuppoſe the ſection of the pipe to be double the ſection of the water in the trough, and in order that the ſtream of water may extend and divide itſelf through the whole double ſection of the pipe, ſome bars, or a grate, are placed in the orifice of the vertical tube, to diſtribute and ſcatter the water through the whole internal part thereof.

Since the air is required to move in the blowing-pipe with a certain velocity, it muſt be compreſſed in the receiver. This compreſſion will be proportioned to the ſum of the accelerations which ſhall have been deſtroyed in the inferior and cloſe part of the vertical pipe, that is, the part beneath the vent-holes. Taking this cloſed part of the pipe $1\frac{1}{2}$ foot, we ſhall have a preſſure ſufficient to give the requiſite velocity in the air-pipe. The ſides of this portion of the pipe, as well as thoſe of the receiver, muſt be exactly cloſed in every part, to prevent the eſcape of the air.

The lateral openings in the upper part of the pipe may be ſo diſpoſed and multiplied, particularly towards the top, that the air may have free acceſs within the tube.

In ſome machines of this kind, the conſtructors ſeem to have been of opinion, that a great height was required in the water-fall; but Dr. Lewis, who made a great number of experiments upon the ſubject, ſhews that an increaſe in height can never make up for a deficiency in the quantity of water; four or five feet, he thinks, is a ſufficient height for the water to fall: and where there is a greater height, it may be rendered uſeful by joining two or more machines together in ſuch manner, that when the water has once committed its air in the condenſing caſk or veſſel, it ſhall flow out into a new reſervoir, and from thence deſcend through another funnel and cylinder, and fall from it into a condenſing veſſel, where the air is extricated and carried off through the air-pipe.

Another kind of water-bellows was invented by the ingenious Martin Triewald, of Sweden, and is deſcribed in the Philoſophical Tranſactions. The machine conſiſts of two caſks or tuns open at bottom, and ſo loaded, that they will ſink into water in the ſame manner as diving-bells. Theſe being ſo ſuſpended that they can be alternately lowered down into water and drawn up again, will by proper valves and pipes afford a continual blaſt of air.

Fig. 15. *Plate Water-works*, repreſents theſe water-bellows in profile. A A are two caſks, made nearly the ſame ſhape as diving-bells, being in the form of a truncated cone, or wider below than at top, where they are furniſhed with cloſe heads B B, but at the lower ends A A are quite open. In the heads B B are valves V, which open inwardly, and are made like the palates of other bellows, with their hinges and the valves themſelves covered with hatters'-felt. They are cauſed to ſhut by eaſy ſteel ſprings till the air from above opens them, which happens only when the bellows receive their motion upwards. The valves are ſhut by means of the preſſure of the air within, when they ſink down into the water.

On the ſame heads two pliable leather tubes R R are fixed, one at the top at each water-bellows, which tubes are made and prepared in the ſame manner as thoſe uſed in water-engines for extinguiſhing of fire. Theſe leathern tubes or pipes reach from the bellows to the tubes T T, which carry the wind into the furnace, or any other place, according to pleaſure.

Theſe two bellows are ſuſpended from the lever by iron chains K K, which are faſtened to two ſweeps S S, by which means they hang perpendicular from the balance-beam, and at the ſame diſtance from the centre of its motion C on the oppoſite ſides. On the top of this balance-beam are fixed two ſloping gutters F F, into which the ſtream of water runs from the gutter G, and gives motion to the whole work, performing the ſame ſervice as an overſhot or any other water-wheel; but they coſt much leſs, and give as even and regular motion as a pendulum, for as ſoon as ſo much water runs into either of the inclined planes of the gutters F F, that the weight of the water exceeds the friction near the centre of motion C, and the weight of that bellows which is ſunk down into the water, the gutter immediately deſcends with an increaſing velocity till the balance meets with the reſiſtance of the wooden ſprings H H; during this time it has raiſed the oppoſite water-bellows, or that bellows which is fixed under the oppoſite gutter, the gutter which has been filled being come down to the ſpring H, delivers all the water it has received, and at the ſame time the water begins to run into the oppoſite gutter, which receives its load of water almoſt as ſoon as the former is emptied, ſo that one of the gutters begins its effect as ſoon as the other has finiſhed, and this continues alternately as long as the ſtream of water is ſupplied. Theſe ſloping gutters upon the balance-lever, therefore, perform all the effect which a water-wheel does in working the ordinary bellows, and by means of the ſame power of deſcending water, but acting reciprocally on oppoſite ends of the balance-beam.

Theſe water-bellows blow the fire on the ſame principle, which produce the effect of the ordinary bellows, *viz.* that the air which enters the bellows, and which they contain when the top is raiſed, is again compreſſed or forced into a narrower ſpace when the bellows cloſe; and ſince air like all other fluids moves to that place where it meets with the leaſt reſiſtance, it muſt conſequently go through the opening which is left for it, with a velocity proportioned to the force by which the air is compreſſed, and muſt blow ſtronger or weaker in proportion to the velocity with which the top and bottom of the bellows are made to approach each other; the blaſt alſo will laſt a time proportioned to the quantity of air that was drawn into the bellows through the valve or pallet.

The ſame operation takes place in the water-bellows, for the air which they contain muſt neceſſarily be compreſſed by the water, which riſes alternately into the bellows A A, and obliges the air to go through the leathern tubes R R, as being the place where the air meets with the leaſt reſiſtance.

In this machine, the chief part of the weight to be

moved

moved is balanced in equilibrio, for the bellows A A may be confidered as two nearly equal heavy weights in a pair of fcales, which in a great part balance each other. The difference is occafioned by that bellows which finks down into the water, being fo much lighter, as it lofes its weight by the quantity of water it difplaces, from the bulk of air contained beneath the furface of the water. This difference is compenfated by the weight of the water which falls down along the floping gutter, which acquiring the power of a falling body, increafes in the fame proportion as the bellows to be raifed by it increafes in weight; for the bellows which finks down into the water does not at once lofe its weight in the water, but gradually as it defcends deeper; and in the fame manner, the afcending bellows does not at once become heavier than the other, but the weight gradually increafes from the time it is firft raifed till it is quite raifed.

Mr. Hornblower fome years ago propofed an hydraulic bellows of the fame kind as M. Triewald's, except that, to avoid the flexible tubes of leather R R, he employed a lead pipe to go down to the bottom of the ciftern of water in which the bellows defcended, and turn up again beneath the bellows, fo that the orifice of the pipe was above the furface of the water; it therefore communicated at all times from the interior of the bellows to the furnace. Mr. H., in Nicholfon's Journal, mentions a very ftriking difference between thefe water-bellows, in which the moving cheft was eighteen inches fquare and moved perpendicularly nine inches, and a common pair of fmith's leather-bellows of thirty inches long.

The leather-bellows threw confiderably more air to the fire, and its nozzle, compared with the water-bellows, was as 73 to 60 in diameter, but it did not produce fo great an effect in bringing on the heat; and the noife of the water-bellows was fo great as to almoft drown that of the common one. The only difference in other refpects is, that in the hydraulic bellows, the pipe went under ground for about eight feet, and the connecting pipe of the other came down about the fame diftance from the fhop above.

WATER-*Bomb*, a name given by our chemift Godfrey to a machine he invented on the plan of Greyl's difcovery, for the extinguifhing of accidental fires in houfes. He confidered firft, that the unchangeable fize of Greyl's engine was a very great objection, and on this plan contrived a medicated liquor, which was fuch an enemy to fire, that a very fmall quantity would extinguifh as much as a much larger of common water; and this liquor had the farther advantage, that it might be kept ever fo long without corrupting, and by that means the veffels containing it would remain always fit for ufe; whereas in Greyl's method they muft have been rotted by the corrupting and fermenting of the water, after a few years. The author of this invention tried it twice in public with us, and both times with all the fuccefs that could be wifhed; but the ftructure of the veffel was fo much the fame with that of Greyl's, that Godfrey cannot be allowed any farther merit as an inventor, than that of contriving the medicated liquor inftead of common water. The machine is a wooden veffel, made very firm and ftrong, that the liquor, when once put in, cannot leak out any where; in the centre of this is an oblong cylindric veffel, which is filled with gunpowder; a tube is brought from this to the head of the barrel; and this being filled with combuftible matter, and the inner cafe with powder, and both made of plate-iron, that no water may get in, the veffel is then filled with the medicated, or antiphlogiftic liquor. The top of the tube is then covered, and the thing fet by for ufe.

When there is occafion for it, it is only neceffary to uncover the tube, and fetting fire to the matter in it, it is conveyed to the veffel containing the powder, and the whole machine being thrown into the place where the fire is, is torn to pieces by the explofion, and the extinguifhing liquor fcattered every way about, on which the fire is quenched in an inftant.

The contriver of thefe things propofed the making of three kinds of them, the one containing five gallons of the liquor: this was the largeft fize, and contrived for the largeft rooms, and moft urgent neceffities. The fecond kind contained three gallons; and the fmalleft, which was meant for a clofet, or other little room, contained only two gallons. Thofe of the fmaller kind alfo had fometimes a peculiar difference in their ftructure, the powder-veffel being placed not in the centre, but at the bottom: the intent of this was to fit them for chimneys, when on fire, as by this means the liquor, not being wanted to be fcattered on all fides, was carried moftly upwards. Thefe were fixed on the end of a long pole, and by this means thruft to a proper height up the chimney; and the tube that communicated the fire was placed downwards.

The manner of ufing the machines for rooms on fire, is this: the perfon who has the care of them is to throw them as nearly as may be into the middle of the room, and then to retire to a little diftance: as foon as he hears the explofion, he may fafely enter the room, and with a cloth, or any thing of that kind, put out any remaining fparks of fire that there may be in particular places. If the room be fo large, that one of the machines cannot difperfe the liquor to every part of it, two are to be ufed, one being laid at each end: and if feveral rooms are on fire at once, as many of the machines are to be ufed, one being thrown into each room. If a whole houfe is on fire, the lower rooms are firft to be taken care of, and after thefe the upper, as they afcend.

Our Godfrey had fcarce better fuccefs than his predeceffor Greyl; for while he was making his public experiments, one Povey, collecting fome of the fragments of his broken veffels, found out the ingredient ufed in the medicated liquor, and made and fold the things in the fame place where he had proved his right to them. It is probable that the medicated liquor was no other than common water, with a large quantity of fal ammoniac, that falt having this virtue of extinguifhing fire in a very remarkable degree. But it is to be greatly wondered at, that while all the world were convinced by experiments of the ufe of the machine, the author made but little advantage of it, and it is now difufed. Act. Erudit. Ann. 1724, p. 183.

The fociety of arts and manufactures, &c. made trials of balls prepared in Mr. Godfrey's method, by his grandfon, in a proper edifice erected for this purpofe; and they found, that, after the fire had prevailed for a confiderable time, and the flame forced its way through the chimney and windows, it difappeared, and was entirely extinguifhed by the explofion of two of thefe balls. See FIRE, *Extinguifhing of.*

WATER-*Borne*, in the *Sea-Language*, denotes the ftate of a fhip, with regard to the water furrounding her bottom, when there is barely a fufficient depth of it to float her off from the ground; particularly when fhe had for fome time refted thereon.

WATER-*Camblets*. See CAMBLET.

WATER, *Cataract of*. See CATARACT.

WATER-*Clock*. See CLEPSYDRA.

WATER-*Colours*, in *Painting*, are fuch colours as are only diluted

diluted and mixed up with gum-water: thus called, in contradiftinction to *oil-colours*. See WASHING.

The ufe of water-colours, makes what we call LIMNING; as that of oil-colours does PAINTING, properly fo called.

Painters in water-colours have been often afflicted with the difeafe called colica pictonum, occafioned by the poifonous quality of feveral of the pigments which they ufe; and which, by putting the point of their pencils between their lips, whilft they are ftudying their fubject, they infenfibly fwallow. Dr. Fothergill fays, that, when the vomitings are abated, copious difcharges by ftool are procured, and the functions of the bowels in a degree reftored to their ufual ftate by the method purfued in the cure of the colica pictonum; nothing contributes fo effectually to reftore the ufe of the limbs, when impaired by thefe caufes, as the liberal and conftant ufe of the tinctura guaiacina volatilis; which may be given in fuch quantity, as to keep the body gently open; mixed with a little common fugar or honey, and then diluted with any weaker mucilaginous liquor, as thin gruel, or barley-water, or marfhmallows-tea. Med. Obf. vol. v. p. 394.

WATER-*Cifterns*, for *Rural Purpofes*, fuch as are formed for different domeftic ufes. In high, dry, upland fituations, cifterns of this kind are of great utility and importance in many parts of the country. In the account of the agriculture of the North Riding of Yorkfhire, it is ftated that in the high eaftern parts of it, water-cifterns or refervoirs are made by the inhabitants within the ground, which are highly ufeful: thefe, it is faid, are fed by the rain-water which falls upon the roofs of the buildings, and is conducted from thence by fpouts. That in thefe cifterns a very ample fupply of foft water is always ready at hand; and that by their being under ground, and kept clofe, the water is fweet and fuitable for every domeftic or other ufe.

A water-ciftern of this fort is ftated to be formed in this manner. A cube of the required fize being dug in the ground, and the fides made even and perpendicular, the bottom is covered with fo much clay, as that, when well beaten, will be four inches thick; a foundation of ftone is then laid round the fides; upon the clay, a brick floor is laid in terras, the furface of which fhould not be lower than the top of the foundation; the fides are then built a fingle brick thick, and the bricks laid in terras, a foot fpace being left betwixt the wall and the earth, which is gradually filled with clay in a foft ftate; and this well beaten as it ftiffens; the whole is arched over, leaving a hatchway for a man to go in and clear it out, and an opening or paffage into a drain, for the furplus water to run or be taken off, when the ciftern is full.

The water is raifed for ufe by means of a pump. In thefe cafes, as keeping all external air out of the ciftern contributes, it is faid, much to the fweetnefs of the water; the pipe by which the ciftern is fed fhould be continued to within a few inches of the bottom, and the furplus water be conveyed off by a pipe rifing from near the bottom to the extreme height the water is defigned always to be at, when that takes place, and there communicate with the drain: by thefe precautions, it is faid, there will be no more of the furface of the water expofed to the external air, than what is within thofe pipes and that of the pump.

This method of forming water-cifterns may be found ufeful, cheap, and convenient, in many places, where fuch water is neceffary to be preferved pure and fweet.

Cifterns of this fort have fometimes the title of water-cellars, and are of great convenience and ufe for farm-yards. See WATER, *River*, *Collecting of*, and WATERING *Live-Stock*.

WATER-*Courfes*, in *Agriculture*, are fuch larges ditches or paffages for taking off the water as are formed, and remain conftantly for the purpofe in different places, and properly belong to the public.

They fhould be kept conftantly well opened and cleared out, not having too much fall given them, fo as to deftroy the evennefs of their bottoms. See SEWER.

WATER, *Cut*. See CUT-*Water*.

WATER, *Dead*, in *Sea-Language*. See DEAD-*Water* and SHIP-*Building*.

WATER-*Engine*, in *Mechanics*, denotes either an engine to raife water, or any engine that moves by the force of water.

WATER-*Falls*, in *Ornamental Gardening*, are thofe falls of water which are formed and introduced in pleafure or other grounds for the purpofe of producing ornamental and picturefque effects, or which naturally exift in fuch fituations. They are of different kinds and forms, being fometimes of the nature of cafcades, and at other times contrived for the intention of driving fome particular fort of interefting machinery, fo as to afford an agreeable and ftriking picture in the rural fcenery of the particular place where they are bad recourfe to. They are ufually conftructed, where they do not exift naturally, either by means of large rocky ftones thrown rudely together into a fort of ridge form of head, over which the water paffes, formed in the way of weirs, or built in mafonry in a careful and exact manner, according as the different nature of the circumftances and fituations may require. See WATER.

Mr. London, in his ufeful work on "Country Refidences," has well defcribed and delineated feveral different modes of forming water-falls. They fhould, he thinks, be natural, ftrong, and lafting, from the general form of the whole of the materials, the fecurity and folidity of their foundations, and the quality of the work and materials ufed in building them.

WATER, *Foul*, in *Sea-Language*. See FOUL.

WATER-*Fowl*. See FOWL.

WATER-*Furrow*, in *Agriculture*, a deep open furrow drawn by the common or a large double mould-boarded plough made for the purpofe, in a proper direction of the field in arable lands, or thofe in the ftate of tillage, for the ufe of conveying and taking off the fuperabundant hurtful water, and preventing the ftagnation of it from injuring the crops. This is efpecially neceffary and proper in the winter feafon, and often in others. It is therefore effential that, as foon as poffible after fowing moft forts of grain, but particularly wheat, when there is any difpofition in the foil or land to the retention of moifture in too large a proportion, there fhould be as many water-furrows opened in this way as may be fufficient for carrying off and completely removing the excefs of water, and thereby preferving the ground in a properly dry and found condition for the healthy growth of the crops. It is obferved by the writer of a late Calendar of Hufbandry, that the making of proper water-furrows is a circumftance of much importance in the culture of wheat, but that it is oftentimes ftrangely neglected. It is a work, however, that fhould be well and effectually performed on all lands, except thofe that are perfectly dry all the winter through. The water-furrows fhould be formed by the plough, as foon as the field bas been finifhed ploughing, fowing, and harrowing, and then a fpit of earth fhould be dug from out of the bottoms of them, and laid on one fide oppofite the rife of the land or ridge, and the loofe mould in the bottom parts be well fhovelled and cleaned out, fo as to make a perfectly free paffage for drawing off the wetnefs; the openings of all the common ridge-furrows being

being likewife well cleanfed at the fame time, fo that the water may have an eafy fall out of every one of them into the large water-furrows. The number of thefe large furrows muft conftantly depend on the variations of the furface, and fome other circumftances of the lands: the only general rule is to make them fo many in number, as that no water may be fuffered to ftand on any part of the land in the wetteft weather. In the bottoms or low parts of fields, or in other places of them where there is a double flope of the land, it is neceffary to form and cut double water-furrows at the diftance of about a yard or four feet from each other, in order to take the water from each defcent fingly.

The fame writer, too, farther advifes, that in all lands fown with clover or other graffes among the corn, thefe forts of furrows fhould be dug a fpit deep, and the mould raifed in that way be carefully thrown out. Many farmers, it is faid, are not attentive enough to this point. They only fcour the furrows in fuch cafes. They fhould, however, it is thought, confider how long the grafs crops are on the ground, which may be two or three winters; confequently it muft be very material to fuch crops to lie dry all that length of time, which fcouring alone will not effect, at leaft not in a fufficiently perfect manner. Particular attention fhould alfo be paid to the fpreading of the earth that is dug out of the furrows in thefe cafes, as if the men be not cautioned, they will lay it too thick and injure the crops; it fhould be chopped and rendered fmall, and then fpread with great care, in order that the feeds may rife freely through it.

In the cafe of arable land, thefe furrows fhould be often examined during the winter feafon, to fee that they are perfectly open and free; the clods, lumps, and other fuch matters that may have fallen into them, being cleared out by means of the fpade.

This is a practice which is either much overlooked, or very imperfectly executed, in a great many diftricts of the kingdom. The fides of the furrows in thefe cafes fhould always be made to ftand firm, and to have a good flope each way, which prevents their falling in and mouldering down fo much. The name of water-furrow drain is fometimes given to this fort of furrow. See WATER-*Furrowing*.

WATER-*Furrow Fall Plough*. See the next article.

WATER-*Furrowing*, a term ufed to fignify the operation of opening water-furrows. It is a fort of work moftly executed by the affiftance of a large plough for the purpofe and the fpade, but fometimes by the plough alone. And in fome parts of the county of Effex, particularly in the neighbourhood of Colchefter, they have a method of doing it by means of a machine that is termed a fall-plough: in the lines where this fort of furrowing is to be performed acrofs the ftitches or ridges, this fort of tool is ufed there once in fix, feven, or eight years, for the purpofe of lowering, or, as they call it, *falling* the furface. They firft gather four or fix furrows by the plough; then follows this implement acrofs thefe furrows, in their loofe frefh ploughed ftate, taking up the parts of the mould, and dropping them on the crowns or fides of the ftitches or ridges, and when finifhed, the water-furrows are ploughed and fcoured in the common manner: the invention is faid to have merit, as the water certainly takes a freer courfe than in the ufual method. In a dry feafon, a large extent of ground can be done in a fhort time, at little expence, in this way.

Some think this work done in the neateft and moft effectual manner by means of a fhovel; and that an old worn fhovel is the beft for the purpofe. See WATER-*Furrow*.

WATER-*Gage*, the name of a fimple contrivance for meafuring and afcertaining the depth or quantity of any water in its application to any purpofe, or otherwife. See GAGE.

WATER-*Gang*, a term applied to a channel or paffage cut through any fpot to drain and free a place of water by carrying off a ftream from it.

WATER-*Gavel*, in our *Old Writers*, a rent paid for fifhing in, or other benefits received from, fome river.

WATER-*Gilding*. See GILDING.

WATER-*Lanman*, a fmall glafs inftrument, which is a tube of about three-quarters of an inch in diameter, with a ball about $1\frac{1}{2}$ inch at one end, the other end being hermetically clofed; the ball contains water, and the empty fpace is rendered nearly a vacuum by boiling the fluid previoufly to fealing it. In this inftrument the heat of the hand applied to the wetted tube, is fufficient to produce bubbles of vapour, which enter the ball, but fpeedily collapfe. The feries of thefe condenfations is as quick as 15 or 16 in a fecond. But in the fteam-engine the condenfation is prodigioufly more rapid. When a fmall double fteam-engine, on the conftruction of Boulton and Watt, having all the parts and gear of the large engines, but its cylinder being only $2\frac{1}{2}$ inches diameter, and the length of ftroke $6\frac{3}{4}$ inches, was fet to work; it gave 600 ftrokes *per* minute, or about twice as many as the beats of a common watch. By an eafy calculation it may be fhewn, that the fteam condenfed was then much more than 300 cubic inches *per* fecond; and if the condenfation, inftead of being effected in maffes of about a pint at a time, could have been performed by fucceffive collapfes of each cubic inch in an open fpace, the pulfes would have produced the tone of the loweft E flat in the treble cliff. But the number of cubic inches condenfed in a large fteam-engine, *e. g.* a three-feet cylinder with an eight-feet ftroke, will be eight or nine times as much at the ufual rate of working. See Nicholfon's Journal, vol. iv. 8vo.

WATER-*Level*, the level which is formed by the furface of ftill water, managed in fome way or other in a convenient manner for its application in different cafes; and which is perhaps the trueft of any for moft ufes. The term is alfo applied to and fignifies the level ufed in watering land, and performing different other operations in the bufinefs of agriculture. See LEVEL, SPIRIT-*Level*, and WATERING *Land*.

WATER-*Levels* are alfo lengths of canal in fome places, that are not connected by locks with other navigations; but at the ends of which the goods are unloaded into team-waggons. See CANAL.

WATER-*Line and Reel*, the ftrong large line and reel of the garden kind, which is ufed in forming fome part of the works in watering of land.

WATER-*Lines*, (fee SHIP-*Building*), are the lines of floatation fuppofed to be defcribed by the furface of the water on the bottom of a fhip. Of thefe the moft particular are thofe denominated the *light water-line* and the *load water-line*; the former, namely, the light water-line, being that line which fhews the depreffion of the fhip's body in the water when light or unladen, or when firft launched, called the *launching draught of water*; and the latter, which exhibits the fame when laden with all her guns and ballaft, or cargo.

WATER-*Logged*, in *Sea Language*, denotes the ftate of a fhip when, by receiving a great quantity of water into her hold, by leaking, &c. fhe has become heavy and inactive upon the fea, fo as to yield without refiftance to the effort of every wave rufhing over her deck. In this dangerous fituation of a fhip, the crew have no refource, except to free her

her by the pumps, or to abandon her by the boats as foon as poffible.

WATER, *To Make.* See MAKE.

WATER-*Machine.* See MACHINE.

WATER-*Mead* or *Meadow*, in *Agriculture*, a term applied to that fort of meadow or other inclofed low ground, which is capable of being improved and kept in a conftant ftate of fertility and productivenefs, by means of water from fome adjoining river, brook, or ftream, being thrown and conducted over it in the winter or other proper feafon. This manner and beneficial practice of forming meadows has prevailed locally for fuch a very great length of time in different parts of the country, efpecially in Wiltfhire, Gloucefterfhire, and Devonfhire, that it is extraordinary that it has not been generally adopted and introduced into other diftricts, where it is equally capable of being had recourfe to without great difficulty, and where it may be equally advantageous and proper. This neglect has been afcribed by a late intelligent writer to a deficiency of information among farmers in general, in regard to the nature and management of the bufinefs, and particularly in what relates to the nature of levels, and the means of adjufting them in different cafes. Thefe circumftances, it is fuppofed, have confined it to the weftern diftricts and parts of the kingdom. Other caufes may, however, have operated in this way, as the facilities afforded by the fituations of the lands in general, the numerous rivulets and ftreams always ready at hand for the purpofe, and many others of the fame nature.

It is neceffary that water-meadows fhould have fuch a form, either by nature or art, as that this fluid may be capable of flowing over their furfaces in a rapid manner, in order to produce and promote the early and quick growth of the grafs in a healthy ftate. It is effentially neceffary, too, to their perfect fuccefs and completenefs, that there be at all feafons a full command of the water, as well as of the means of diftributing it to every part of them, and of difcharging it in a complete manner, whenever it may become requifite. See WATERING *Land.*

As to the advantages to be derived from meadows of this kind, they are very confiderable, not only in the vaftly increafed quantities of hay which they afford, but alfo in the point of early fpring food for ewes and lambs, as well as in many other refpects and particulars.

It may be obferved, that from the grafs of water-meadows being fo very forward in the months of March and April, it is in general fed down or paftured in the fpring with fheep; and to thofe farmers who keep them for breeding or fattening, becomes almoft invaluable, from the great fcarcity of green food at fuch a period; but that after being flooded in the latter end of the laft of thefe months, they are moftly fhut up for hay in the fummer.

And the after-grafs is eaten off in autumn by neat cattle, it being confidered as very pernicious and dangerous for fheep to pafture on water-meadows at that feafon. A remarkable inftance of its fatal effects is ftated by the writer of the Corrected Account of the Agriculture of the County of Suffex. Eighty ewes from Weyhill fair were turned into fome field adjoining a watered meadow: a fcore of them broke into the meadow for a night, and were taken out in the morning, and kept till lambing; when they produced twenty-two lambs, all of which lived, but every one of the ewes died rotten before May-day. The remaining fixty made themfelves fat, nor could a rotten fheep be difcovered amongft them. It is an extraordinary fact, it is faid, though not eafily accounted for, that the grafs of watered meadows fhould be fo nourifhing to fheep in the fpring, and yet have fo deftructive an effect on them in the autumn. The fact feems, however, to be well and indifputably eftablifhed. It may probably depend upon the grafs being in a more foft and loofe watery ftate of production in the autumn than what it is in the vigorous growth of the fpring. See TATH and WATER-*Tath.*

By the author of the "Treatife on Watering Meadows," it is advifed that no fheep, except thofe that are juft fat, fhould ever be fuffered, even for an *hour*, in watered meadows, as they will infallibly rot them at any other feafon than the fpring, but efpecially if made from low, boggy, or fwampy ground; but that it is not fo, when made from dry heathy land. Others, however, think it dangerous on all, and therefore always to be avoided.

It cannot be doubted but that on farms of this nature, where it is convenient to have three or four meadows that can be watered, they will be found particularly advantageous; as, while neat ftock are eating the firft, it is faid, the fecond will be growing, the third becoming dry, and the fourth under water: by which an extenfive fyftem of feeding and producing of dry fodder may be carried on.

It is noticed by Mr. Smith, in a late effay on thefe kinds of meadows, that even a fmall piece of this fort of meadow, which will produce an early crop of fpring feed at the very time of the greateft preffure of fcarcity, and when the turnips ought to be off the ground, muft be much more valuable to a poor arable farm than can eafily be imagined by any one who has not witneffed the great utility derived from them, in many parts of Wiltfhire. What, but for the water-meadows, could enable the Wiltfhire farmers, it is afked, to bring to market a much greater number of fheep, and that at an earlier feafon than can be produced from any other county in the kingdom? The water-meadows have unqueftionably a great fhare in doing this.

They afford there, it is faid, an early fupply of grafs for the forward or early breed of lambs, on which they begin to feed them about the middle of March, having previoufly withdrawn the water from them, and laid them perfectly dry. It is obferved, that on a good crop of grafs of this kind, it has been faid, that five hundred couples may be fed on an acre for one day. The practice is to hurdle out, daily, fuch a portion of the ground as is neceffary, leaving a few open fpaces in the hurdles, through which the lambs may feed forward on the frefh grafs. The hours they are fuffered to feed on this grafs, in fuch cafes, are from about ten o'clock in the morning until five in the afternoon, when they are generally folded on the contiguous barley fallows, or lands in preparation for that crop. This is a practice or fort of management, too, which is fuppofed to have a great advantage, in confequence of its manuring a part of the farm without the dunghill. The manure, however, in fuch cafes, is drawn from, and at the lofs of fuch meadows.

The writer of the Corrected Report of the Agriculture of the County of Middlefex mentions a remarkable inftance of the beneficial and fertilizing effects of water in thefe meadows, as occurring in the early part of the autumn of 1796, when fuch grafs lands as had not had the advantages of water, as in thefe cafes, were nearly burnt up. A clofe of about twenty acres, which had been watered in this way, had, it is faid, a moft luxuriant after-grafs of from fix inches to a foot in depth; and a neighbouring inclofure of near forty acres afforded fupport for three months to forty-feven horfes and bullocks, all which throve very well. And another cafe of the fame nature is recorded, in which forty acres employed in this way were found equal to the fupport of five hundred Wiltfhire ewes, from the middle of the month of March to the firft of May, or about fix weeks;

and

and that the improvement of the ſtock in that time was one ſhilling a week, or three pounds fifteen ſhillings the acre. In ſome parts of the ſame county, five pounds worth of hay might alſo, it is ſaid, be taken off the firſt week in May. Theſe facts and ſtatements ſtrongly prove and diſplay the utility of theſe meadows, wherever they can be properly provided.

In ſpeaking of the management of water-meadows, the author of the eſſay already noticed remarks, that in thoſe great diſtricts of water-meads, which in Wiltſhire are watered by the common conſent of many different proprietors and occupiers of land, the operation of floating muſt begin and end at certain fixed periods, which it is neceſſary for every one to know, and regularly adhere to, not only in order to the production of a crop of graſs, but for the procreation of thoſe animals that eat the graſs: conſequently, as every farmer knows at what time he ſhall have graſs for his ſheep, he ſo manages his breeding flock, that his lambs may be ſtrong enough at the uſual time of feeding to go with the ewes to take their food in the meadows, and return to the fold for lodging.

It is noticed, that the time to commence the feeding on the meadows upon thoſe large ſtreams in this county is generally about the twenty-fifth of March: therefore, if the winter be very mild and favourable for the growth of graſs, it ſometimes gets to ſuch a height as many farmers, unaccuſtomed to the herbage, might think to be much too coarſe and luxuriant for ſheep, and even too high to be fed off with cattle. So great was the luxuriance of the graſs in the water-meads of Wiltſhire, it is ſaid, ſome years ſince, occaſioned by the mild growing weather immediately after the commencement of floating, that ſome farmers laid their meadows dry, and fed them off in November, and the following month; and then, by floating again, obtained a crop of feed in the ſpring before the uſual period. Many who did not adopt this method lamented that their graſs was too high, even in the month of February; and it was then not uncommon to ſee it in the water-meads nine inches high, but laid on the ground, and white at the bottom, before the lambs were ſtrong enough to go into the meadows. Some apprehended, it is ſaid, that the long four graſs would be waſted; yet it was aſtoniſhing with what avidity the ſheep devoured it, and even preferred the parts that were the longeſt, and rendered white at bottom, in conſequence of the extreme thickneſs: this they would, it is obſerved, gnaw down to the very roots. It was remarked by Mr. Davis, it is ſaid, that the graſs then on one Rickwood's mead was ſuch a crop as, at the uſual time of cutting it, would have been eſtimated at 18 cwt. *per* acre. Many declared that they never ſaw the crop of the water-meads ſo very abundant and early; but on viſiting the ſame meadow, at the particular requeſt of the above-named friend of the writer, on the tenth of March, when it had been in feeding more than three weeks, and aſking the floater if they ever began to feed it ſooner, he replied that he had had the management of the meadows more than thirty years, and never knew it ſo early but once, when they began feeding it on the eleventh of the firſt month in the year. The writer walked over the greateſt part of this extraordinary piece of ground with ſome conſiderable difficulty, it is obſerved, from the thickneſs and height of the graſs; and he could diſcover but one place, to the great credit of the floater, which was worſe than another, and that not two rods ſquare. The man ſoon ſaw it noticed, it is ſaid, and before the writer could mention the circumſtance, told him he knew what he was looking at, and had contrived to do away even ſuch a trifling defect: ſo this may be truly ſaid to be, the writer thinks, a ſpotleſs meadow. This ſhews the nice attention and great care beſtowed in forming water-meadows in this diſtrict; and in ſome other counties the care beſtowed upon the water-meadows is probably not much, if any leſs. This would ſeem to be particularly the caſe in the county of Glouceſter, where very great attention is given to the floating of them, to the manner of feeding them down by live-ſtock, and the ſhutting them up for the production of hay, as well as in every other part of their management.

They are there, too, equally valuable and important in the quantity and utility of the produce which they afford, as well as the qualities of it, yielding much profit to individuals, and advantage to the whole diſtrict.

The utility and benefit of water-meadows are indeed now beginning to be every where well underſtood, wherever they are capable of being formed in a convenient and ſuitable manner.

Water-meadows are in general calculated to afford an early ſpring feed for ſheep, or other ſorts of live-ſtock, which may be continued in feeding by them until towards the beginning of the month of May, when, if deſigned for the producing of hay, that muſt then ceaſe; as, if perſiſted in even for a ſingle week in that month, the hay would, as ſuppoſed by ſome, be wholly ruined in quality, being rendered ſoft, woolly, and unſubſtantial, as in the caſe of aftermath crops: but being then ſhut up, and floated for ſome days, a crop of hay is next produced, which is in readineſs for the ſcythe in about ſix weeks; and this crop being removed, and the meadows again floated as before, a third or aftermath crop is afforded, for being paſtured by neat cattle and horſes, but never, or in few caſes, by ſheep, or for being uſed as cut green food in houſe-feeding, which, in ſome caſes, is probably the moſt beneficial application of it; as where one or two more ſuch crops are cauſed and taken in the ſame way, at the ſame ſeaſon.

The great ſuperiority of the produce from water-meadows is thus rendered very evident, and the uſes of it not of leſs value or importance.

Water-meadows ſhould conſtantly be well eaten down before they are floated, but eſpecially in the autumn.

It is of great advantage, in many different reſpects, to have ſeparate water-meadows, which can be alternately in the courſe of feeding off, floating, and being laid dry, as has been already ſeen; as, by this means, their benefits can never be loſt for any length of time. And it is particularly beneficial in providing an uninterrupted ſucceſſion of aftermath paſturage, or of that ſort of graſs for being cut and uſed green in the ſtalls.

Any thing which is done to the ſurfaces of water-meadows, in the way of rolling or giving them preſſure, ſhould always be done while they are in a quite dry ſtate, about the beginning of the month of March, and never when they are much in a moiſt condition.

The hay produce of meadows of this ſort is moſtly proper for all kinds of neat cattle and ſheep, but not ſo ſuitable for horſes, eſpecially thoſe of the working or team kind.

WATER-*Meaſure*. Salt, ſea-coal, &c. while aboard veſſels in the pool, or river, are meaſured with the corn buſhel heaped up; or elſe five ſtriked pecks are allowed to the buſhel. This is called water-meaſure; and this exceeds Wincheſter-meaſure by about three gallons in the buſhel.

WATER-*Microſcope*. See MICROSCOPE.

WATER-*Mill*, in *Rural Economy*, that ſort of mill which is turned by the power or force of water applied in ſome way or other. As mills of this kind often form and oppoſe great obſtructions to different improvements of the farmer,

 and

and especially in the practice of watering land, they should consequently be diminished in number as much as possible in such cases, and those of the tide and wind kinds be substituted in their places, as might be done with great facility in many instances. See MILL.

WATER, *Mother*, in *Chemistry*. See CRYSTAL.

WATER *Ordeal*, or *Trial*, was of two kinds; by hot, and by cold water. See ORDEAL.

WATER-*Organ*. See ORGAN.

WATER, *Petrifying*. See PETRIFYING.

WATER-*Poise*. See HYDROMETER, and ARÆOMETER.

Dr. Hooke has contrived a water-poise, which may be of good service in examining the purity, &c. of water. It consists of a round glass ball, like a bolt-head, about three inches in diameter, with a narrow stem or neck, one twenty-fourth of an inch in diameter; which being poised with red lead, so as to make it but little heavier than pure sweet water, and thus fitted to one end of a fine balance, with a counterpoise at the other; upon the least addition of even $\frac{1}{1000}$th part of salt to a quantity of water, half an inch of the neck will emerge above the water, more than it did before. Phil. Transf. N° 197.

WATER-*Proof Cloth and Leather*. It would be very desirable to render the principal articles of clothing impenetrable to water, provided it could be done without injuring the pliability of the cloth.

The most common resource is to line the garment with oiled silk, such as is used for hat-covers and umbrellas; that is, silk which has been dressed with a varnish of drying linseed oil, so as to prevent the admission of water. This effectually guards the wearer of such a garment from becoming wet; but it is not perfect, for the outside cloth can imbibe moisture, which will evaporate by the wind, and cause great part of that coldness which renders wet clothes so prejudicial.

What would be desirable is, that we should give to cloth the same property which we find in the fur of several animals; the otter, beaver, and water-rat. This is a repellence of water, which when thrown upon the animal rolls off in pearl drops, without wetting the fur in the least; but we observe this only in the living animal, and when in a state of health, for these animals are known to be sick when they are found to be wetted after having dived in the water. This perfection has not yet been attained, but we shall proceed to state what has been attempted, with a view of water-proof varnishing for cloth.

Mr. Albert Angel, in 1781, had a patent for preparing an elastic varnish for this and various other purposes. His receipt is, linseed oil, or nut oil, one gallon; bee's-wax (yellow or bleached), one pound; glue or size, six pounds; verdigris, a quarter of a pound; litharge, a quarter of a pound; spring or rain water, two quarts; to be put into an iron kettle, and melted down till it forms the composition.

Caoutchouc, or elastic gum, called Indian rubber, is a substance which has engaged the attention of philosophers, ever since it has been known. Its singular elasticity, its flexibility and impenetrability to water, have caused it to be considered as very valuable for this purpose.

It is not possible to effect the liquefaction of caoutchouc, by means of heat; it will melt as well as other resins, but when cooled, it remains liquid and adhesive. Alcohol or spirit of wine, the usual solvents of resinous substances, do not act upon it, nor is it dissolved in water, as gums are; it was then tried to dissolve it in drying oils, and it was found that by the aid of heat, the caoutchouc may be dissolved, and form an excellent varnish, supple, impervious to air or water, and resisting a long time the action of acids. With such varnish Messrs. Charles and Roberts covered their air-balloons.

Several essential oils, as those of turpentine and lavender, act upon the caoutchouc, even when cold, and these are of no great price. The disagreeable smell of the oil of turpentine becomes, perhaps in process of time, less disagreeable than that of the lavender.

The oil of turpentine always leaves a kind of stickiness.

The following process is described in a patent granted to Mr. Henry Johnson of London in 1797, for rendering cloth and other articles water-proof.

The article to be operated upon, must first be cleansed from all grease or dirt by washing it with an alkaline solution, and then stretched in a frame. The water-proof compound, as it is termed, is formed by dissolving caoutchouc or Indian rubber in spirit of turpentine, (the smell of which is taken off by adding oil of wormwood, and spirit of wine in equal quantities;) this forms a sort of varnish, which is capable of being spread, or washed over the surface of the leather or cloth, always applying it on the wrong side of the article, or that side which is not to be seen. The varnish is laid on by means of a large piece of Indian rubber, instead of a brush or sponge. To conceal the varnish and make a good internal surface to the cloth or leather, it must be sifted over with some substance, such as silk, wool, or coney, cut very fine, in the same manner as flock paper is made; and being left to dry, in a few days the flock, by its adhesion to the varnish, forms a very good lining, at the same time that it conceals the varnish. These articles were called by the patentee hydrolaines, and were loudly recommended by advertisements, but never came much into use.

M. Pelletier's Method of making Varnish of Caoutchouc, or elastic Gum, by dissolving it in sulphuric Ether.—Boil the elastic gum for the space of an hour in common water, by this it becomes soft enough, to be cut into small threads; being thus divided, put it again into boiling water, and keep the vessel on the fire for about another hour; this second boiling penetrates the elastic gum very sensibly, and deprives it of that hardness which it possesses in the first state.

When the gum is thus divided and softened, put it immediately into a matrass, or any other closed vessel, containing rectified sulphuric ether. In the course of a few hours the ether penetrates the elastic gum (which swells very considerably), and at the end of a few days the solution is complete, without the assistance of heat, provided a sufficient quantity of ether is made use of.

According to this process, the solutions are of a white colour and transparent; the heterogeneous and sooty particles, which the elastic gum generally contains, fall to the bottom of the vessel in which the solution is made, and have a sooty appearance, so that by merely decanting the solution it may be obtained very clear.

Mr. Parrish and Mr. Ackermann have likewise had patents for the same object; the latter succeeded much better than the elastic varnishes.

Water-proof Leather.—In the memoirs of the Academy of Sciences at Turin, 1789, is a paper by the chevalier de St. Real, on the manner of rendering leather impermeable to water, without diminishing its strength or its suppleness, and without sensibly augmenting its price. M. St. Real shews that skins may be tanned in such a way as to give this desirable quality to the leather, and in other respects with benefit to the tanner, by reducing all the processes of the art to the following.

For strong ox or cow leather, which is used for making the outer soles of shoes and boots.

1st, Soak the green hides, separate from each other, in running

running water, a ſufficient time to extract all the ſoluble animal matter or lymph; it will be eaſy to determine when that is done, by putting a piece of the hide into water, and heating the water gradually; if no ſcum is formed upon the ſurface, it is a proof that no lymph remains.

2dly, Place the hides (after they have been waſhed and cleaned) in a cauldron, ſimilar in conſtruction to thoſe in which common ſalt is made; fill the cauldron with water, which is to be heated to 167 degrees of Fahrenheit, and no more: after the hides have been one hour expoſed to this degree of heat, take them out.

3dly, Stretch them upon the horſe, and proceed to take off the hair in the uſual manner.

4thly, Put them again into the cauldron (which ſhould be ſo contrived that it may receive as much water from a cock on one ſide as is let out from a cock on the other ſide), and ſo keep up in this cauldron a conſtant current of water, of the heat of 60 degrees.

5thly, Let the hides remain in this cauldron till the water no longer contains any animal jelly; which may be eaſily known by evaporating a ſmall quantity of it.

6thly, Take the hides out of the water and place them upon the horſe, that the cellular and muſcular membrane may be taken off.

7thly, Waſh the hides again in running water, then put them again into the cauldron, or one ſimilar to it, which is to be filled with filtered tan-liquor. This liquor is to have the ſame degree of heat that the water had in the former operation; the ſkins to remain in it till they are completely tanned, taking care to put freſh tan-liquor in the place of that which ſhall appear to have loſt its energy by the combination of its aſtringent principle with the hides; this may be readily known by dropping in a few drops of a ſolution of green vitriol.

The author ſtates, that leather made according to this ſyſtem would be more free than any other from the animal jelly, which is not combined with the tan, and conſequently would be leſs ſuſceptible of moiſture. The fibrous part of the ſkin being more ſtrongly acted upon by the tan-liquor when heated, would become more firm and more difficult to be penetrated by water; it would be increaſed in ſtrength and compactneſs, without loſing any part of its ſuppleneſs.

That excellent Swediſh leather ſo ſuperior to all other, of which boots, breeches, and great-coats are made, is capable of reſiſting the moſt violent rains. This leather is prepared in Jutland with hot water.

In the common way the tanner contents himſelf, before he delivers the leather to the ſhoe-maker, with beating thoſe parts which are ſoft, or which have a very irregular ſurface, upon a ſmooth log of wood with a mallet. The more careful tanners beat all their hides; and this practice is general in England.

Beſides the ſtrong ſole-leather already mentioned, leather of a different kind is uſed in a great variety of arts and manufactures. It is made of ſkins of cows and oxen, but more generally of calves'-ſkins; it ſerves to make the ſoles of pumps, or women's ſhoes; for belts, harneſſes, covering trunks, &c. or the inner ſoles of men's ſhoes, and the upper-leathers; in ſhort, any kind of work in which the thickeſt and ſtrongeſt leather is not required. All this ſort of leather is curried, becauſe leather as it comes out of the pits is by no means fit for the various uſes for which it is intended: it is rough, of an unequal thickneſs, and unmanageable. The object of the currier's art is to ſupple it, and to give it an uniform compactneſs and denſity; this object he fulfils by the following operations:

1ſt, He treads the ſkins, that is, after having ſoaked them till they are ſoftened, he kneads them with his feet, to make the water penetrate every part equally.

2dly, He works them with the pummel; this is done by applying to the ſkins a ſquare tool made of hard wood, about a foot long and five inches broad; it is furrowed longitudinally, and convex at the bottom and flat at top; it is fixed to the workman's hand by a leather ſtrap ſo that it cannot ſlip. This tool by being worked forcibly along both ſides of the ſkin, firſt upon the ſide of the epidermis, and then on that of the fleſh, forms the grain of the leather, and gives it ſuppleneſs.

3dly, He then works the ſkin with an iron inſtrument with a blunt edge; with this he ſcrapes very ſtrongly thoſe parts which are too thick, thoſe in which there is left any fleſh, or any tan, and thoſe in which there are hollows; ſtriving as it were to preſs the ſuperfluities of the thick parts into thoſe which are too thin, and thus to give to every part of the ſkin an equal thickneſs and an uniform denſity.

4thly, He pares the ſkin with a paring-knife; this paring-knife is circular: the workman cuts away thoſe thick and projecting parts which the operation juſt deſcribed was not able to remove; ſo that this laſt operation may be conſidered as completing the object of the preceding one.

After the four operations above-mentioned, the leather is ſupple and ſmooth, and of an equal thickneſs and denſity in all its parts: it is now in a ſtate capable of being employed by the workmen who make uſe of it. But the very operations which give it theſe valuable properties appear to injure its compactneſs. The leather by being beat, ſtretched, and ſcraped, muſt neceſſarily become more ſpongy, and conſequently more permeable to water. To remedy this inconvenience, the currier impregnates it with fat or oil.

To dreſs leather with fat, it muſt firſt be made perfectly dry. The pores of the leather are then dilated, by paſſing it over a clear ſtrong fire, and it is rubbed over with a kind of woollen mop dipped in melted fat, pretty hot. The fat thus applied to each ſide of the leather penetrates into its ſubſtance, lodges within its pores, and adhering there fills them up ſo as to preclude the entrance of any moiſture; ſhould the leather be wet when the fat is applied, it will remain upon the ſurface, and not penetrate into the ſubſtance.

The manner of dreſſing leather with oil is the reverſe of this, and is founded upon the property which water poſſeſſes of ſwelling thoſe ſupple and elaſtic capillary tubes into which it inſinuates itſelf; alſo that of its not being miſcible with oil, and upon that of its evaporating much more ſpeedily than oil.

The currier therefore ſoaks thoſe ſkins in water which he means to dreſs with oil, and while they are yet wet, he ſpreads over them with a wool mop any kind of fiſh oil. As the water evaporates, the oil takes its place; and conſequently the more the ſkins were ſwelled with water, the more thoroughly they become impregnated with oil.

M. St. Real found the cow-leather dreſſed with fat imbibes more water than the calf-ſkin dreſſed with oil; but he attributes this difference to the manner in which the currier applies the fat. He rubs the leather with a kind of mop, dipped into melted fat moderately warm, it ſeems impoſſible that, by this manner of applying it, the fat can penetrate into the interior parts of the leather; the air contained in its pores oppoſes an invincible obſtacle to the penetration of it. On the contrary, there is no air in the pores of the wet leather upon which the oil is applied, and the permanent fluidity

fluidity of the oil itſelf alſo facilitates its paſſage into the leather.

To make the leather imbibe the fat, he propoſes three or four days immerſion in running water, to drive out the air; then to ſoak the leather in melted fat, of the temperature of 167 degrees of Fahrenheit, till all the water in the leather is evaporated by the heat; the fat would then penetrate into the interior pores of the leather, and render it impermeable to water.

If leather is compreſſed, it evidently diminiſhes the thickneſs, and increaſes its compactneſs; and if it is beaten with an iron hammer upon a very ſmooth anvil, it produces a permanent contraction of its pores. Leather is in that reſpect very much like iron, and all other metals which harden by beating; and, conſequently, our author ſuggeſts that it would be of great advantage to compreſs the leather before it is uſed, by paſſing it between a pair of rollers, ſuch as are uſed to flatten metal: this would ſtiffen the leather.

It appears from experiment that the ſtrong ſole-leather, by being properly impregnated with fat, and compreſſed in the rollers, abſorbs only one-thirteenth part of water, imbibed by the ſame leather which has not undergone thoſe operations. The quantity of water which the firſt abſorbs, and which amounts to about one-thirtieth part of its weight, is ſo ſmall, that it does not render it capable of wetting any ſubſtance it may come in contact with, nor does the leather appear wet when taken out of the water; it may therefore be conſidered as almoſt impermeable to it.

The cow-leather, when impregnated with fat, and compreſſed, abſorbs about one-ninth part of the water abſorbed by leather of the ſame nature which has not undergone thoſe operations. The quantity of water abſorbed by the firſt amounts only to the thirty-fourth part of its own weight.

The calf-ſkin, when impregnated with fat and compreſſed, abſorbs only one-third part the quantity of water that the ſame quantity of leather abſorbs when it has not undergone thoſe operations; and that quantity is not ſo much as one-fortieth part of the weight of the leather.

In this manner, without making any alteration in the uſual method of tanning, except with reſpect to the thin ſole-leather, it is poſſible to render leather very nearly impermeable to water, by the known operations of currying, provided to them are added compreſſion by rollers, and ſoaking in fat, as before deſcribed. The additional greaſing and preſſing will not ſenſibly increaſe the price of the leather, for it retains only about the ſixteenth part of its weight of fat.

The leather which had paſſed through the rollers was not diminiſhed in its ſtrength; for it ſupported, without breaking, weights as heavy as were ſupported by leather of the ſame kind which had not undergone that operation.

In 1794 Mr. Bellamy of London obtained a patent for a method of rendering leather water-proof, which he thus deſcribes.

Take nut oil, one gallon; poppy-oil, one gallon; and linſeed-oil, two gallons; or they may be in other proportions: put them into an iron veſſel, and ſet it over a gentle fire. To every gallon of the mixed oils, put half a pound of umber, or white copperas, ſugar of lead, colcothar, or any other proper drier, but obſerving to uſe a larger proportion than the above, when the oil is to be prepared for new leather, or a leſſer proportion when it is to be prepared for old.

Let the oils remain on the fire, and give it as great a degree of heat as it can bear without burning, or cauſing it to riſe, for ſix or ſeven hours; and if it will not dry ſufficiently continue the ſame degree of heat till it does: then take it off the fire, and when it is a little cooled, it is ready to be applied to make water proof leather.

This is done by a bruſh being dipped into the prepared matter, and rubbed or bruſhed into the leather.

When the article is well filled with the prepared oils, lay it on an even board, and ſcrape off what is ſuperfluous with a thin iron tool; then put it to dry in a warm room, and when ſufficiently dry it will be fit for uſe.

For ſole-leather of thick ſubſtance, let it be gently warmed, and with a bruſh or pad, made of wool or hair, rub or bruſh the prepared matter on the leather, till it is thoroughly ſaturated; then let it dry in a warm place, and it is ready for uſe.

The proportion of the mixtures of oils, muſt be varied according to the nature of the oil, and alſo according to the nature of the leather, for the ſame kind of oil will not always have the ſame qualities.

Oils expreſſed at different times will frequently have a greater or leſs propenſity to finiſh; and muſt, on that account, have more or leſs of the poppy or nut oils. If the drying oil finiſhes reluctantly, there muſt be added a leſſer quantity, or none at all, of the nut or poppy oils, and a ſmall quantity of an eſſential oil added, till it will finiſh with eaſe and beauty. The ſame kind of leather will alſo require a different mode of treatment; for if the leather be new it will abound more with the natural greaſe of the animal which produced it, and it will require the oil to be ſo managed as to abſorb or neutralize the greaſy quality, that it may finiſh without loading the leather, and making it unpleaſant to the wearer. When this is the caſe, one-fourth part of eſſential oil of turpentine muſt be mixed with the above oils when prepared; and *vice verſâ* if the leather is old.

Another of Mr. Bellamy's receipts is as follows: to one gallon of the above prepared oils add one pound of gum reſin, half a pound of pitch, a quarter of a pound of tar, and a quarter of a pound of turpentine. Let them be well incorporated with the oils, by firſt heating the whole maſs gently, and then increaſe the fire till the whole is thoroughly mixed; or he propoſes to add to the oils, gums ſandarac, maſtic, anime, copal, amber, together or ſeparate, or aſphaltum, or one-ſixth part of bee's-wax. In ſhort, any bituminous, reſinous, or adheſive matter, which will reſiſt acids, alkalies, and water, and will unite with drying oils, provided when mixed in proper proportions they do not render the leather hard, or make it crack, or otherwiſe diſagreeable.

In the Annales de Chemie, Mr. Hildebrand of St. Peterſburgh propoſes the three following methods of rendering ſole-leather impermeable by water.

The firſt preparation is made by boiling $1\frac{1}{2}$ lb. of minium with 20 lbs. of oil of linſeed, or hemp-ſeed; continue the boiling till the metallic oxyd be entirely diſſolved, and the mixture aſſumes a carbonaceous dark brown colour: apply this compoſition to the inſide of the hides till they can abſorb no more of it; then dry them, in ſummer by the heat of the ſun, in winter before a fire. When the compoſition becomes too thick, it may be liquified by the addition of oil of turpentine.

The ſecond preparation is ſimply either of the ſame oils, in part diſhydrogenated by fire; it will ſerve equally well for upper leathers.

The third preparation is a mixture of two ounces of black pitch with a pound of tar, melted together by a gentle heat;

the leather is then anointed with the mixture, and dried. Soles thus prepared ought to be used with the smooth side inwards.

Another receipt for an elastic water-proof varnish is, gum asphaltum, two pounds; amber, half a pound; gum benzoin, six ounces; linseed-oil, two pounds; spirits of turpentine, eight pounds; and lamp-black, half a pound; united together in an earthen vessel over a gentle fire.

The leather is to be nailed on a board, and the varnish applied upon it; it is then to be passed into an oven several times, the varnishing being each time repeated, till the leather is completely covered.

Mr. William Baynham took a patent in 1816 for a water-proof varnish, which very much resembles those of his predecessors. It is prepared as follows: six gallons of linseed oil, one pound and a half of rosin, and four pounds and a half of red litharge, or any other substance usually known under the denomination of dryers, are to be boiled together till they acquire sufficient consistence to adhere to the fingers, and draw out into strings when cooled upon a piece of glass or otherwise. It is then to be removed from the fire, and when sufficiently cooled, thinned to about the consistence of sweet oil, by adding spirits of turpentine to it, which generally requires about six gallons. It is left to settle for a day or two, and then carefully poured off from the grounds; and about one pound and a half of ivory or lamp-black, and one pound and a half of Prussian blue ground in linseed oil, added to and intimately mixed with it. It is then ready for use.

To apply this varnish, stir it up, and lay it on with a brush until it lies on the surface of the leather with an even gloss; then hang up the article which has been operated upon until the next day: repeat the application as before, taking care to leave the surface as thin and even as possible. This must be repeated each successive day, until it has the desired appearance.

WATER, *Raiting*, in *Rural Economy*. See RAIT.

WATER-*Rocket*. See ROCKET.

WATER-*Sail*, in a *Ship*, denotes a small sail, spread occasionally under the lower studding-sail, or driver-boom, in a fair wind, and smooth sea.

WATER-*Scape*, of the Saxon *waterschap*, denotes an aqueduct, drain, or passage for water.

WATER-*Shield*. See HYDRASPIS.

WATER-*Shoot*, a young sprig, which springs out of the root or stock of a tree.

WATER-*Shot*, in *Sea Language*. See MOORING.

WATER-*Spout*. See *Water*-SPOUT.

WATER-*Table*, in *Architecture*, is a sort of ledge, left in stone or brick walls, about eighteen or twenty inches from the ground; from which place the thickness of the wall begins to abate. See WALL.

WATER-*Thermometer*, a thermometer made with water by Mr. Dalton, for the purpose of ascertaining the precise degree of cold at which water ceases to be farther condensed; and likewise how much it expands in cooling below that degree to the temperature of freezing, or 32°. With this view he took a thermometer tube, such as would have given a scale of ten inches with mercury from 32° to 212°, and filled it with pure water. He then graduated it by an accurate mercurial thermometer, putting them together in a bason filled with water of various degrees of heat, and stirring it occasionally: as it is well known that water does not expand in proportion to its heat, it does not therefore afford a thermometric scale of equal parts, like quicksilver.

From repeated trials agreeing in the result, he found that the water-thermometer is at the lowest point of the scale it is capable of, that is, water is of the greatest density at $42\frac{1}{2}$° of the mercurial thermometer. From 41° to 44° inclusively, the variation is so small as to be just perceptible on the scale; but above or below those degrees, the expansion has an increasing ratio, and at 32° it amounts to $\frac{1}{8}$th of an inch, or about $\frac{1}{180}$th part of the whole expansion, from $42\frac{1}{2}$° to 212°, or boiling heat. During the investigation of this subject, his attention was arrested by the circumstance, that the expansion of water was the same for any number of degrees from the point of greatest condensation, no matter whether above or below it: thus he found that 32°, which are $10\frac{1}{2}$° below the point of greatest density, agreed exactly with 53°, which are $10\frac{1}{2}$° above the said point; and so did all the intermediate degrees on both sides. Consequently, when the water-thermometer stood at 53°, it was impossible to say, without a knowledge of other circumstances, whether its temperature was really 53° or 32°. Our ingenious author, recollecting some experiments of Dr. Blagden in the Philosophical Transactions, from which it appears that water was cooled down to 21° or 22° without freezing, was curious to see how far this law of expansion would continue below the freezing point, previously to the congelation of the water, and therefore ventured to put his water-thermometer into a mixture of snow and salt, about 25° below the freezing point, expecting the bulb to be burst when the sudden congelation took place. After taking it out of a mixture of snow and water, where it stood at 32°, (that is, 53° *per* scale,) he immersed it into the cold mixture, when it rose, at first slowly, but increasing in velocity, it passed 60°, 70°, and was going up towards 80°, when he took it out to see if there was any ice in the bulb; but it remained perfectly transparent: he immersed it again, and raised it 75° *per* scale, when in an instant it darted up to 128°, and that moment taking it out, the bulb appeared white and opaque, the water within being frozen: fortunately it was not burst; and the liquid which was raised thus to the top of the scale was not thrown out, though the tube was unsealed. Upon applying the hand, the ice was melted, and the liquid resumed its station. This experiment was repeated and varied, at the expence of several thermometer bulbs, and it appeared that water may be cooled down in such circumstances, not only to 21°, but 5° or 6°, without freezing; and that the law of expansion above-mentioned obtains in every part of the scale from $42\frac{1}{2}$° to 10°, or below, so that the density of water at 10° is equal to the density at 75°.

WATER-*Tight*, in *Sea-Language*, the state of a ship when not leaky.

WATER-*Tracing Crescent*, in *Rural Economy*, the tool formed in the manner of the gardener's edging-iron, but made much larger, and in the crescent form, very thin and well-steeled, and sharp in the edge, having a stem about three feet in length, with a cross handle for bearing upon in working with it, in cutting out the sides of the different conductors of the water in watering land. See WATERING *Land*.

WATER-*Ways*, in *Ship-Building*, the side-strake of a deck wrought next the timbers, and much thicker than the deck, but reduced to the thickness of the deck in front: it makes a channel for the water to run through the scuppers, and prevent leaking at the side.

WATER-*Wheel*, an engine for raising water in great quantity out of a deep well. See PERSIAN-*Wheel*, and WATER, *Raising of*, supra.

WATER-*Workers*, in *Agriculture*, a term applied to the makers and formers of meadow-drains and trenches, or wet ditches,

ditches, as in the practices of watering and draining of land, or otherwise.

Water-*Worm, Reproduction of*, in *Natural History*. See Reproduction, and *Water*-Worm. See also Vermes.

Water *Key*, in *Geography*, a small island in the bay of Honduras, near the coast of Mexico. N. lat. 17° 30′. W. long. 88° 40′.

Water *Key*, a small island in the Spanish Main, near the Mosquito shore. N. lat. 12° 15′. W. long. 82° 55′.

Water *Key, South*, a small island in the bay of Honduras. N. lat. 16° 35′. W. long. 88° 45′.

Water *Point*, a cape on the east coast of Java. S. lat. 7° 55′. E. long. 114° 33′.

Water *Sound*, a strait of the North sea, between South Ronaldsha and Barra, two of the Orkney islands.

WATERBOROUGH, a town in the district of Maine, and county of York, containing 1395 inhabitants; 15 miles N.W. of Wells.

WATERBURY, a town of the state of Connecticut, containing 2874 inhabitants; 20 miles S.W. of Hartford.

WATEREE, a river which rises in the Allegany Mountains, then runs southerly into South Carolina, and changing its name to Wateree; after a course of about 120 miles, it joins the Cangaree, and then takes the name of Santee.

WATERFORD, a maritime county of Ireland, in the province of Munster, having the county of Cork on the west, the counties of Tipperary and Kilkenny on the north, the county of Wexford on the east, and St. George's Channel on the south. It extends from east to west 40 Irish, or 51 English miles; and from north to south 23 Irish, or 29 English miles. Its breadth, however, varies much, and is in one part not more than six miles. The area is stated to be 262,800 acres, or 410 square miles Irish, which are equal to 425,692 acres, or 665 square miles English. Dr. Beaufort states the number of houses to be 18,796; and the number of inhabitants at least 110,000. The number of parishes is 74, in which there were 21 churches, divided between the sees of Waterford and Lismore. Waterford returns four members to the imperial parliament, two for the county, one for the city of Waterford, and one for the borough of Dungarvan. The county of Waterford is in general hilly, and the northern part is particularly rough and mountainous; in the south and east the soil is rich and productive. In the west of the county, on the north of the Blackwater, there is a ridge called the *Knockmeledown* mountains, many parts of which are very high, though Mr. Twiss is mistaken in calling them the highest in Ireland. The Commeragh mountains cover a great extent of country between Dungarvan and Clonmell. These hills, except in a few desolate and craggy spots, afford pasture to small cows, which produce a great quantity of butter. In the eastern part agriculture has been much improved, and the farms are not surpassed in any part of Ireland.

The river Blackwater flows through the west of this county into the bay of Youghal, and is navigable to Cappoquin. The banks of this river are peculiarly beautiful, especially near Lismore. The river Bride, which joins the Blackwater, passes near the town of Tallow, and is so far navigable for large boats. The gentle and majestic Suir forms the northern boundary, dividing it from the counties of Tipperary and Kilkenny, and running east till joined by the Barrow; when, turning south, they form an estuary, 9 miles long, and 2 broad, which is the harbour of Waterford. At Dunmore, near the extremity of this, on the Waterford side, a very fine pier is building, for the protection of the packets, and of such vessels as may put into this harbour.

Dr. Charles Smith published "The ancient and present State of the County and City of Waterford," in the year 1745, which was reprinted in 1772. In this work, he states the Menapii to have been inhabitants of this county and Wexford in the time of Ptolemy, which Menapii he supposes to have been a colony from the Belgic Menapii, mentioned by Cæsar. The Desii are stated to have been a powerful clan at the time of the English invasion. These came from the county of Meath, and gave name to the baronies of Desies within and Desies without Drum, and their descendants are now called Deasy. Though the power of the Desii was abolished by the English, yet, for many years after, the O'Feolains, kings of the Desii, are occasionally mentioned in the Irish annals. Henry II. in 1177 made a grant of the city of Waterford, with all the circumjacent province, to Robert Le Poer, his marshal, from whom are descended not only the family of Le Puer, the head of which was created, in 1535, earl of Tyrone, but also the several respectable families of Power, settled at Clashmore, Gurteen, &c. By marriage, the estates and honours of the Le Poers came to the family of Beresford, the head of which is now marquis of Waterford, and has a noble seat at Curraghmore, in this county. In the civil war, Waterford had its share of disturbance, and Cromwell himself was engaged unsuccessfully in the siege of its capital. Dr. Smith's Topography is still interesting to the reader, from the various information he collected respecting the different families settled, though many of them are now extinct or removed. His natural history is very defective, yet it is the best hitherto published. He drew attention to the fisheries, and to the Nymph bank, yet even now, though employment is so much wanted, the fisheries remain without encouragement. In his enumeration of eminent men born in this county, we find the names of Congreve the poet, and of Robert Boyle, who was born in the castle of Lismore. The duke of Devonshire, as descendant of the eldest branch of the Boyle family, possesses the towns of Dungarvan, Lismore, and Tallow, with a great tract of land, which gives him a preponderating influence in the county. Beaufort's Memoir of Ireland, &c.

Waterford, a city and sea-port town on the south side of the river Suir, in Ireland, capital of the county of the same name. This river is embanked by a noble quay, extending the whole length of the town, to which vessels of great burden can come up, though the largest ships generally lie a few miles lower down. Like most of the other sea-ports of Ireland, it was originally built by the Ostmen or Danes; and is said to have been founded A.D. 853, nearly at the same time as Dublin and Limerick. Waterford seems to have been the chief settlement of this people, for we find the kings of the Danes of Waterford often mentioned in the old annals. Strongbow, soon after his landing in Ireland, took Waterford by assault in 1171, and in 1172 he gave it up to king Henry II., who landed at Waterford, and received there the submission, not only of his English subjects, but also of many Irish chiefs. King John also landed at this city, and made it his residence for some months. The steady adherence of Waterford to the English caused it to be engaged in almost constant warfare with its neighbours; and in return it received many marks of royal favour. Richard II. landed twice at Waterford. When Simnel was crowned king by the earl of Kildare, the lord deputy, the citizens of Waterford refused to admit him, adhering steadily to Henry VII., in consequence of which he addressed a letter to them, thanking them for their adherence, and giving them power to seize the rebels and their effects, and to employ the latter for their own advantage. They behaved with the same loyalty against Perkin

Warbeck, who had many adherents in Ireland, in confequence of which the king gave them this motto, which is ftill ufed, "Intacta manet Waterfordia." In the reign of James I., Waterford appears to have become turbulent in confequence of its attachment to the Roman Catholic religion, and in confequence was deprived of many privileges, but thefe were reftored by Charles I. In the civil war, Waterford was on the fide of the Catholics, and a meeting of the popifh clergy was held there by the pope's nuncio in 1646. It was befieged by Cromwell without fuccefs; but was afterwards taken by Ireton. It has been already mentioned that Waterford was built by the Danes; it was at firft called *Portlargie*, from *lairge*, a thigh; the courfe of the river Suir, near this place, refembling that part of the human body. The Englifh gave it its prefent name, as it is faid, from a ford in St. John's river, which empties itfelf into the Suir. The city chiefly faces the north and eaft, which, though feemingly a fituation not fo defirable, being expofed to the chilling blafts of thefe winds, yet the healthinefs of it makes amends for the bleaknefs of the expofure. A further advantage is its noble fituation, near the confluence of three large and navigable rivers, the Suir, the Nore, and the Barrow, by which inland commodities may be fupplied at a very inconfiderable expence of carriage, from the very centre of the ifland, and from feven different counties wafhed by thefe rivers, and other counties adjacent to them. Over the river Suir, a fine wooden bridge has been erected within a few years, to facilitate the communication with other places. A very flourifhing commerce with England and other countries is the happy confequence of fuch a fituation. Its exports of beef, butter, hides, tallow, pork, and corn, are confiderable. The number of large hogs weekly flaughtered during the feafon exceeds 3000 on an average. The quantity of butter annually exported exceeds 80,000 cafks.

This city is alfo largely concerned in the Newfoundland trade. The population is fuppofed to exceed 40,000, and it ranks as the fourth town of Ireland in extent, and the fifth in commercial importance. Packet-boats are eftablifhed between this port and Milford Haven, for the convenient intercourfe of the fouth of Ireland with England. This city fends one member to the united parliament, elected by the freemen and freeholders. This election is free, and, to the honour of the electors, fir John Newport, one of the moft fteady friends of Ireland, has been repeatedly returned. The cathedral of Waterford, adorned with an elegant fteeple, is a fine ftructure. There is alfo a very fuperb Catholic chapel, with feveral other places of worfhip. The other public edifices are conftructed with much elegance, and effentially contribute to ornament the city. It is, however, of more confequence to obferve, that its numerous charitable inftitutions are well conducted, and liberally fupported. Its houfe of induftry may ferve as a model for others. Its fever hofpital was the firft in Ireland, and nearly the firft in the united kingdom, and has been carried on with uniform fuccefs. Without any wifh to take from the merit of other worthy individuals, much of this praife is due to the exertions of the *Society of Friends*, who are numerous in Waterford. This city is $74\frac{1}{2}$ Irifh miles S.S.W. from Dublin. Smith's Waterford. Carlifle's Dictionary. Wakefield, &c.

WATERFORD and LISMORE, *Bifhopric of.* The firft of thefe fees, which is confined to the eaftern part of the county of Waterford, and is very fmall, was founded by the Oftmen in the 11th century; but that of Lifmore, which includes the greateft part of Waterford county, and a confiderable portion of Tipperary, was founded in the feventh century. The union took place in 1536. The extent of the union is, in Irifh miles, 39 by 29, and in Englifh 49 by 37. The number of Irifh acres 354,800, which are divided into 106 parifhes. Forty-four of thefe are impropriate, and the reft form only 44 benefices, of which, when Dr. Beaufort publifhed his account, only 30 had churches, and only 8 glebe-houfes. Many churches and glebe-houfes have been built throughout Ireland within a few years. Beaufort.

WATERFORD, a populous and compact incorporated poft-village, in the S.E. corner of Half Moon, Saratoga county, on the W. bank of the Hudfon; 10 miles N. of Albany. It is the moft populous town in the county, and has the greateft fhare of trade. It is handfomely laid out, in 5 E. and W. ftreets, interfecting at right angles. It has 190 houfes and ftores, 2 houfes of worfhip, and fome other buildings, together with three fchools on the Lancafter plan. It is well fituated for a manufacturing town; and in 1812 a wharf, 320 yards long, was conftructed, and a canal along it to the channel of the Hudfon.

WATERFORD, a town of the ftate of Vermont, in the county of Caledonia, on the W. bank of the Connecticut, formerly called Littleton, containing 1289 inhabitants; 40 miles N. of Norwich.

WATERFORD, a poft-town in the diftrict of Maine, and county of Oxford, containing 188 inhabitants; 95 miles N. of York.

WATERFORD, a poft-town of Virginia; 20 miles N.W. of Wafhington.

WATERFORD, a town of Connecticut, in the county of New London; containing 2185 inhabitants.

WATERFORD, or *Le Beuf*, a poft-town of the ftate of Pennfylvania, in the county of Erie, containing 162 inhabitants; 370 miles N.W. of Wafhington.

WATERFORD, a townfhip of New Jerfey, in Gloucefter county, containing 2105 inhabitants; 40 miles S. of Trenton.—Alfo, a town of Ohio, in the county of Wafhington, containing 701 inhabitants.

WATERGUCHEE, or WATERQUECHIE, a river of Vermont, which runs into the Connecticut, N. lat. 43° 34'. W. long. 72° 18'.

WATERING, in *Gardening*, the practice or means of rendering feeds, plants, fhrubs, and trees, as well as garden-grounds, properly and fuitably moift for the purpofe of their better, more ready, and more healthy germination, growth, and taking root, when fown, planted out, or fet, and afterwards for continuing them in the neceffary ftates of vegetation, growth, and increafe, efpecially when the weather is dry, hot, and parching. It is alfo occafionally ufeful in preventing fome forts of fruit-trees from being deftroyed by the attacks of different forts of infects, as well as for the clearing them of other kinds. It is occafionally equally effential for the feeds and plants in the full ground, as for thofe in pots in it, and thofe in green-houfes, glafs-cafes, hot-beds, hot-houfes, ftoves, and other fimilar fituations; fuch, for inftance, in the former kinds, as the feeds in drills, beds, and other open places, different young plants in the fame fituations, numerous others of the cutting, flip, offfet, and other fimilar kinds, which have been newly pricked out, planted, or tranfplanted, not only at the time of firft putting them out, but now and then afterwards, when dry hot weather is prefent; alfo in many kinds of newly-planted young trees and fhrubs in the fpring and early autumnal plantings; and to all the plants which are in pots in the open air, whether they may be of the more or lefs hardy kinds, during the droughty feafons of fpring, fummer, and early autumn; and in the latter defcription, to all the fine tender kinds

kinds of potted plants and trees under any ſort of covering or protection of the houſe or other kind.

There are many ſorts of plants which cannot exiſt without watering in either a ſmall or plentiful manner. Some ſtand in need of it only in a ſlight degree, and at particular ſeaſons of the year, while others demand it in very full proportions at all times. Some are very nice in the quantities which are required at any one time; but others are leſs particular in this reſpect. Some too are under the neceſſity of having it thrown over their leaves as well as to their roots; others only have occaſion for it to the root part. And there are ſome other methods of adminiſtering and applying it, which are peculiar to certain kinds of plants, trees, and other vegetable products, as ſhewn under their particular individual modes of culture.

In all caſes, the moſt proper water for this uſe is that which is contained in any ſort of pond, reſervoir, or other ſimilar kind of excavation, for the purpoſe of containing it in a ſtate of conſtant expoſure to the atmoſphere, in gardens or other places, as it is not only more convenient and ready for being employed, but, at the ſame time, a great deal more ſalutary, and better adapted to promote the growth and increaſe of the different ſorts of plants and vegetables, than that of the raw, ſharp, cold, hard kind, which is drawn from wells or raiſed by pumps for immediate uſe, as being more ſoft in its nature, and more ſuitable in its temperature.

The moſt ſuitable time of applying it is in the evening, after the diſappearance of the ſun, and when the exceſſive heat of the day is gone off, and in a great meaſure abated, as its effects are then more beneficial and laſting; and beſides the work can be performed with more eaſe and convenience, as well as in a more agreeable manner.

When once the buſineſs of watering has been commenced, it ſhould always be regularly proceeded with, or the plants or vegetables may ſuffer much, and be greatly injured by the omiſſion or neglect. It is conſtantly better never to attempt it, than to juſt begin and then leave it off again, as is much too frequently the caſe, in the practice of horticulture, with ſome gardeners, who have not fully conſidered the matter.

The work of watering ſeeds, plants, ſhrubs, and trees, is uſually performed, either by means of common watering pots and cans, large ſyringes contrived for the purpoſe, forcing engines for throwing it up over the plants, or by ſome other contrivance of a ſimilar nature. The water being moſtly brought to the places where it is wanted, either in tubs hung in a ſort of barrow-frame, or by their being placed on the barrows themſelves.

The water is commonly applied in a fine divided ſtate, over the plants, where it is not required in any large quantities, and for clearing away and deſtroying ſmuts: but where it is demanded in large proportions, it is often poured in full ſtreams to their roots or other parts.

But in uſing it upon a large ſcale for garden-grounds, Mr. London has ſuggeſted that it may be accompliſhed by a practice ſomewhat ſimilar to that of overflowing tillage-land, or by means of ſubflooding; this laſt may, he thinks, be effected by having a ſtratum or layer of gravel underneath the whole garden, which by having a trench ſurround-it, or, if upon a ſlope, at the upper ſide of it only, may have the ground wholly ſaturated with the water let into it, which will ſoon be abſorbed and taken up by the incumbent ſurface containing the vegetables that are under cultivation. And, in the former of theſe methods, by having pipes, open-cuts, or rather ſmall wooden troughs, which may ſerve to convey and conduct the water upon the ſurface of every quarter of the ground; it may there diſtribute itſelf in the intervals between the beds or drills, as well as over the general ſurface of the broad-caſt crops. It is further ſuggeſted that the former method could be put in practice at any period of the ſpring or ſummer; the latter, for the moſt part, in moiſt weather, or in the night ſeaſon. See Watering *of Land*.

In the watering of both ſeeds, plants, and garden grounds, much care ſhould, however, be taken, in every inſtance, that injury inſtead of good be not done, by employing too large quantities, or continuing them for too great a length of time.

On the whole, it will be evident, from what has been ſaid above, that the practice of watering in garden culture may be beneficial in different ways, as in exciting and promoting a better and more ſpeedy vegetation in newly-ſown ſeeds and tranſplanted vegetables; in forwarding the growth and increaſe in a proper manner of different crops, plants, and trees; and in the deſtruction or removal of inſects, ſuch as the *aphis*, red ſpider, and ſome of the *coccus* tribe.

Watering-*Barrow*, in *Gardening*, ſuch as is employed in conveying water to gardens or other places. They have uſually a tub fixed upright in the frame by means of pivots, hooks, and gudgeons, or ſome other way, one-half of which is below and the other above it, the water being, in a great meaſure, prevented from ſpilling while it is carrying. See Quendon *Water-Barrow*.

Watering *Forcing-Engine*, an engine contrived for the purpoſe of forcing water in a ſort of ſhower over ſome kinds of fruit-trees, garden vegetables, and plants, and which commonly effects the buſineſs in an eaſy, convenient, and effectual even manner, being well adapted to particular modes and purpoſes of watering.

Watering *of Land*, in *Agriculture*, the practice of overflowing it artificially in the graſs ſtate, with the water which is diverted from an adjoining or neighbouring river or ſtream, which has a higher level than the ground to be covered, or where there is a proper fall. In this way, by the new-formed water-courſes being kept nearly on the level, the ſpaces of land between the new and the old channels may be watered, the water being brought upon the ground by the former, and diſcharged or taken away by the latter; and thus a conſtant ſucceſſion of the water be retained and removed without ſuch an accumulation of it as would be injurious, or ſuch a deficiency as would leave any part imperfectly ſupplied. In different diſtricts different names are applied to this practice, ſuch as thoſe of floating, flooding, drowning, ſoaking, and ſome others.

It is, without doubt, a practice of great antiquity, which it is probable the extraordinary fertility afforded by the annual overflowings of the river Nile, in Egypt, may have firſt ſuggeſted as the means of improving the lands of other countries. In this country, indeed, it would ſeem to have been had recourſe to, for the purpoſe, at a very early period, as in the county of Hereford, it appears to have been practiſed more than two hundred years ago, as is evident from a work on the ſubject written by Rowland Vaughan, and publiſhed in the year 1610, entitled "Moſt improved and long-experienced Water-Works; containing the manner of ſummer and winter drowning of meadow and paſture, by the advantage of the leaſt river, brook, fount, or water-mill adjacent; thereby to make thoſe grounds, eſpecially if they be dry, more fertile ten for one." And the practice is probably ſtill more ancient in the county of Wilts than in the above or any other diſtrict, in conſequence of its poſſeſſing naturally watered graſs lands, which perhaps firſt led to to the notion of forming them in an artificial manner. The general want of good pafture-grounds in the high lands of this county might, it has been fuppofed, be a great inducement to improve fuch watery valley-tracks, which muft ever have difplayed the moft pleafing and interefting appearances of early and luxuriant vegetation and growth.

However, in whatever way the practice originated in this country, it is unqueftionably a method that is deferving of the attention of the land proprietor and the farmer in a very high degree.

It has been ftated by different writers on the practice of watering land, that the moft proper qualities of the grounds for being watered, are all thofe which are of a fandy or gravelly friable open nature, as on fuch the improvement is not only immediate, but the effects produced more certain and powerful than on other kinds of them. There are alfo fome ftrong adhefive four wet lands, which are alfo capable of being improved by watering.

There are ftill fome other forts of lands, as thofe which contain different kinds of coarfe vegetable productions upon their furfaces, fuch as heath, ling, rufhes, boggy and other aquatic plants, which may likewife be much improved by watering. It fhould, however, be conftantly kept in mind, in attempting this fort of improvement, that the more ftiff and tenacious the foil or land is, the greater the command of water fhould be, in order to effect the purpofe.

The lands which admit of this fort of improvement with the moft fuccefs and benefit are, for the moft part, all fuch as lie in low fituations on the banks and borders of brooks, rivers, and ftreams, or in floping directions on the fides of hills, to which water can be conducted in an eafy and ready manner.

The writer of a late ufeful tract on the fubject, however, feems inclined to fuppofe that there are only a few foils or forts of land to which watering may not be advantageoufly applied; the experience which he has had, it is faid, has determined, that the wetteft land may be greatly improved by it, and likewife that it is equally beneficial to that which is dry. But that as many perfons, unacquainted with the nature of watering land, may be more inclined to the latter fuppofition than the former, the reafon of wet land being as capable of improvement by watering as that which is completely dry before it is ufed, is explained. It is that, in the conftruction of all watered meadows or lands, particular care muft be taken to render them perfectly dry when the bufinefs of floating or covering them with water fhall terminate; and that the feafon for floating or watering is in the winter and not in the fummer, which thofe who are unacquainted with the procefs have too commonly fuppofed. All bogs of the peat kind are certainly, it is faid, of vegetable origin, and thofe vegetables are all aquatic in their nature. It therefore follows that the fame water which has produced the vegetables of the bog would, under due management upon the furface, produce fuch graffes or other vegetables as are ufually grown by the farmer; and the writer has hitherto had reafon to think, that this may be confidered as a general rule for determining the fituation for any experiments or trials with water. The writer having fucceeded in the attempt to make good watered lands, upon foils which have been thought unfit for the purpofe, and floated or watered them with water that was equally condemned, in point of quality, he is now, it is faid, fufficiently emboldened to recommend the trial of watering land by means of machinery, and that the moft flattering hopes of fuccefs are entertained from it. It is noticed that the graffes produced by the firft year's floating or watering of a peat-bog, or any wet land, will be much more like what will become the permanent herbage of a water-meadow, than the firft or fecond year's crop from a newly-floated or watered piece of dry land. The herbage of the former being, it is faid, previoufly ftored with aqueous plants, is in fome degree fuited to this new ftate, whereas the herbage of dry land is generally of quite a different nature, and often produces an exceeding great crop of grafs the firft year, which does not appear the next; for the fame water which caufed thefe graffes to grow fo very luxuriantly the firft year, will totally deftroy them in the courfe of the enfuing winter, and produce an herbage much more congenial to that degree or ftate of moifture. The utility of watering in all thefe cafes has been fully eftablifhed in feveral different diftricts, fo that proper examples of the forms and crops may always be readily had for the trials of others in the fame way. This has been done, it is faid, in the counties of Bedford, Norfolk, and Kent, in the firft and laft of which upon foils that are very different from thofe of moft water-meadows in the county of Wilts; and that the floating or watering of them has been effected with water which was always before confidered to be wholly unfit for that purpofe, even by thofe fuppofed to be the beft acquainted with the practice: it is now, however, fully proved and fhewn to be the cafe, not only by the accurate inveftigations of the moft able chemifts, but by the extraordinary growth of graffes in particular boggy fituations, that waters of the ferruginous kind are not at all hurtful to vegetation; but, on the contrary, very friendly to it, when they are properly applied. Such facts being eftablifhed beyond all poffibility of doubt, afford, it is faid, a much greater fcope for the improvements by water, than was ever expected or thought of by the moft fanguine advocates of watering, and enables the writer, from his great experience and obfervation, in different parts of the kingdom, to fay that there are few diftricts to which they are not applicable.

It is, however, fuppofed by fome, that the quality of the water, like that of marl or other manures, is a matter of the firft importance, and fhould be particularly afcertained. And it has been remarked by the author of the "Treatife on Landed Property," that it is univerfally known that water which flows out of a dung-yard poffeffes a fertilizing quality. It is generally admitted, too, that the wafhings of fheep-walks, frefhly-manured arable lands, ftreets of towns, roads, and other fuch places, after a long drought, have the quality of fertilization. And it is equally evident, it is thought, that the waters iffuing in different parts of the kingdom from chalk, lime-ftone, marl, or other calcareous ftratum, though they are perfectly limpid, poffefs the power of fertility; and thofe of fome diftricts, as of Wiltfhire, Dorfetfhire, and fome others, to an aftonifhing degree. And a fimilar, though lefs powerful, effect is produced by the limpid waters, which iffue from the flate-rocks of Devonfhire and Cornwall. On the other hand, waters that ooze out of peat-bogs, and iffue from particular mines, are well known to be injurious to the growth of agricultural vegetables.

It is added, that chemiftry points out tefts and proceffes whereby waters, as well as marls and other grofs manures, may be tried and analyfed. But the virtue of water, when confidered as a manure, does not refide in a fingle principle, like that of lime-ftone. Water is capable of fufpending, not only calcareous earth, but various other matters,—of animal, vegetable, and foffil origin: fome of them friendly, others inimical, to vegetation. It would, therefore, it is thought, be imprudent in a practical man in this bufinefs to commit himfelf to theoretic guidance alone, while the theory of manures, and efpecially of watering land, remains fo much in-

 volved

volved in obfcurity; and while trials in the field, on the very land which is defired to be improved, may be made with facility and prompt decifion.

The effects of watering are remarkable in many inftances: in Wiltfhire, it is not uncommon to fee, it is faid, lands, where water has been diverted for the purpofe of improvement, divided by a hedge or a ditch only, the grafs on one fide of which is of the moft luxuriant nature and abundant growth, but on the other fo diminutive that the ftrongeft blades have never reached the height of three inches. The fame is the cafe in other fituations, which fufficiently marks the importance of the practice.

It will be neceffary, before we ftate the different methods of performing the bufinefs of watering in different circumftances, to give fome account of the implements which are requifite for the purpofe, as well as fome explanation of the terms employed in carrying on the work in the different modes. The firft and principal inftrument in the execution of the work is a proper level, of which the fpirit one is perhaps the beft. It is neceffary for taking the level of the land at a diftance, compared with the part of the river or other ftream, from whence it is intended to take the water, to know whether it can or cannot be made to float the part defigned to be watered. It is particularly ufeful in works of this fort on a large fcale, though the labourers too frequently neglect the ufe of it, bringing the water after them to work by in-cutting the feveral parts that are to convey the water. It fhould, however, be moftly ufed as being more certain and correct. See LEVEL, and WATER-*Level.*

A proper line and reel and cutting-iron are likewife abfolutely neceffary, as well as a breaft-plough, which fhould be of the beft kind, as being of great ufe in cutting turfs for the fides of the channels and other parts. See WATER-*Line and Reel*, WATER *Crefcent*, and BREAST-*Plough*.

The fpades ufed in this fort of work fhould have the ftems or handles confiderably more crooked than thofe in common ufe, the bit being of iron, about a foot in width, in the middle, terminating in a point, a thick ridge running down the middle part, from the top to near the point; the edges on both fides being drawn very thin, and kept quite fharp by frequent grinding and whetting: when they are become thin and narrow by wearing, they are ufed for the fmaller trenches and drains. By means of the handles being made fo crooked, the workman, ftanding in the working pofition in the bottom of the drain or trench, is enabled to make it perfectly fmooth and even without any difficulty.

Both fhort and narrow fcythes are alfo neceffary, in order to mow and cut away any weeds or fuperfluous grafs that may be prefent, during the running of the water in the trenches or other cuts; as well as forks, and long four or five-tined crooks or drags for pulling out the roots of the fedges, rufhes, reeds, and other fuch matters, that may be in the large mains or other channels. Thefe crooks fhould be made light, and have long fhafts to reach wherever the water is fo deep that the labourers cannot work in it, fo as to remove fuch obftructions.

Wheel and hand-barrows, too, become neceffary and ufeful, the former for removing the clods and earths to the flat or hollow places, for this ufe they may be made open, without fides or hinder parts; the latter are ufed where the ground is too foft to admit the former, and where the clods or other matters require to be removed during the time the land is in water. But when large quantities of earth are wanted to be removed, efpecially when to be conveyed to fome diftance, three-wheeled carts are proper.

And in all cafes a ftout large water-proof pair of boots is abfolutely requifite, having the tops made fo as to draw up half the length of the thigh; they fhould be large enough to admit a quantity of hay or other fuch materials to be ftuffed down all round the legs, and be kept well tallowed, in order to refift the running water for any length of time.

The terms ufed in the practice of watering are very numerous. A weir is a work thrown over or acrofs a brook, river, rivulet, ftream, main, or other fuch parts, the ufe of which is to divert the water; and when the hatches are all properly adjufted and in their places, to ftop the whole current, in order that the water may rife high enough to overflow the banks, and fpread over the adjoining land; or, by ftopping the water in its natural courfe, turn it through mains or channels, cut to convey it another way, to fome diftant lands that are to be watered. See WEIR.

A fluice differs from the above fimply in having but one thorough or opening, as when there are more than one it becomes a weir. It is applicable in fmall ftreams in the fame way that the weir is in large ones. See SLUICE.

The covered fluice or trunk is conftructed and had recourfe to in all fuch cafes, as where two ftreams of water are to crofs each other at the point of difcharge, and to ferve as a bridge. The drain-fluice or trunk is that which is placed in the loweft part of a main, as near to the head as it can be formed, and put low enough to drain the main and other parts. It is put with the mouth at the bottom of the main, being let down into the bank; and from the other end of which a drain is cut to communicate with fome trench-drain that is the neareft. It is ufed for carrying off the leakage through the hatches when fhut down, to convey the water to other grounds, and for fome other purpofes. See SLUICE.

Hatches are flood-gates, and ufed for the fame purpofes: they are confequently differently formed in different cafes; but fuch as have about a foot to take off, and let the water pafs over fo much of them, are thought ufeful by fome in different cafes of watering. Others fuppofe them the beft when made whole and of good timber. See HATCH.

A carriage is a fort of fmall wooden or brick paffage, built in an open manner, for the purpofe of carrying or conveying one ftream over another, and is ufeful in many cafes, though very expenfive in the practice of watering.

Head-main in watering land implies that part of the principal cut or channel which takes the water firft out of a river or ftream, and conveys it to fuch lands as are laid out for the purpofe, by means of fmaller mains and trenches. It is neceffarily formed of various breadths and depths, according to the quantity of land to be watered; and to the length, or the fall of the ground it is cut through. Small mains are the next order of cuts for the diftribution of water on lands, as connecting between the head-main and trenches. Thefe fmaller mains are moftly taken out of the head-main; and the only difference between them is, the one being much lefs than the other; they are commonly cut at, or nearly at, right angles with the other, though in fome cafes at many degrees lefs. The ufe of both thefe forts of mains is to feed the various trenches and gutters that branch out in all parts of the land with water, and to convey it for floating the ground in an equal manner. By fome thefe fmaller mains are termed carriages, but improperly, as it is confounding them with the open trunk fo named, as already feen.

The trench, in watering, is a fhallow narrow cut or ditch made to take the water out of the mains for floating the land. It fhould always be drawn in a ftraight line from angle to angle, with as few turnings as poffible. It is never

never made deep, but the width of it muſt be in proportion to the length it has to run, and the breadth of the pane of ground between that and the trench-drain. It ſhould conſtantly be cut gradually narrower and narrower, in the wedge-form, to the lower end, in order to force over the water more equally.

The trench-drain is conſtantly cut parallel to the trench, and as deep as the tail-drain water will permit when neceſſary. It ſhould always, where poſſible, be cut ſo as to come down to a firm ſtratum of ſand, gravel, or clay. If the laſt, a ſpade's depth into it will be of great benefit. The uſe of it is to take away the water immediately after it has run over the panes of the land from the trench. It is not neceſſary to be brought up to the head of the land by five, ſix, or more yards, as the nature of the ſoil may be. The form of it is the reverſe of the trench, being narrower at the head, or upper part, and gradually wider and wider, until it comes to the lower end, and empties itſelf into the tail-drain, which is a receptacle for all the water that comes out of the other drains, that are ſituated ſo as not to empty themſelves into the river; and, conſequently, it ſhould run nearly at right angles with the trenches; but it is, in general, preferable to draw it in the loweſt part of the ground, and to uſe it for conveying the water out of the ground where there is the greateſt deſcent: this is commonly found in one of the fence-ditches; for which reaſon a fence-ditch is moſtly made uſe of for the purpoſe, as anſwering the double uſe of a fence and drain at the ſame time.

The pane of ground is that part of the land which lies between the trench and the trench-drain, and is the part on which the graſs grows, which is cut for hay: it is watered by the trenches, and laid dry by the trench-drains; conſequently there is one on each ſide of every trench. The term pane is alſo applied to the part which is uſed, for taking off the produce.

The bend implies a ſtoppage made in different parts of ſuch trenches as have a quick deſcent, in order to obſtruct the water. It is effected by leaving a narrow ſlip of greenſward ground acroſs the trench where the bend is deſigned to be, and cutting occaſionally a ſmall part out of the middle of it in the wedge form. It is uſeful for checking the water, and forcing it over the trench on to the panes; which, if it were not for ſuch bends, would run rapidly on in the trench, and not flow over the land as it paſſes along. The great art of watering land conſiſts in giving to every part of each pane of ground an equal quantity of water, which is greatly promoted in this way.

The gutter is a ſmall groove cut out from the tails of theſe trenches, where the panes of ground run longer at one ſide or corner than the other. The uſe of it is to carry the water to the extreme point of the panes. Thoſe panes which are interſected by the trench and tail drains, meeting in an obtuſe angle, want the aſſiſtance of theſe gutters to convey the water to the longeſt ſide. And another uſe of them is, when the land has not been ſo perfectly levelled but that ſome parts of the panes of ground lie higher than they ſhould, a gutter is then drawn from the trench over that high ground, which would otherwiſe not be overflowed. Without this precaution, unleſs the flats were filled up, which ſhould always be the caſe when materials are to be had, the water will not riſe upon it; and after the watering-ſeaſon is paſt, thoſe places would appear of a ruſty-brown, while a rich verdure would overſpread the others; and at hay-time the graſs in thoſe places would ſcarcely be high enough for the ſcythe to touch it; while that around them, which has been properly watered, will, from its luxuriance, be laid down. This neglect is, therefore, to be reprobated in moſt caſes, as the great art of watering land is that of throwing the water regularly over all parts, thoſe where it cannot riſe of itſelf as well as others, and in carrying it off from thoſe in which it would otherwiſe ſtagnate and be hurtful.

The catch-drain is an occaſional ditch, ſometimes cut for the purpoſe of carrying the ſame water into a ſecond main or other part, for watering lower lands or panes of ground with the water that has been before uſed. It is made uſe of too in ſome other caſes, as catching the water that is thrown forward.

Pond is uſed to ſignify any part where the water ſtands on the ground in watering, or in the tail-drain, trench-drains, or others, ſo as to injure the lands near them; and is occaſioned by flats and irregularities in the ſurface of the grounds, as well as by other cauſes.

The turn of water means the ſpace of land that can be watered at one time in any caſe; and is accompliſhed by ſhutting down the hatches in all thoſe weirs where the water is deſigned to be kept out, and opening thoſe that are to let the water through them. The quantity or extent of land to be watered by one turn, muſt of courſe vary with the ſize of the river, brook, main, and other ſuch parts, and by the plenty or ſcarcity of the water.

The bed of a river, main, trench, or other ſuch part, is the bottom of any of them.

The head of any watered land is that part into which the river, main, or other ſuch part, firſt enters. And the tail of it is that part where the water laſt paſſes off by the tail-drain into the courſe that is to take it away.

The upper ſide of a main or trench is that which, when they are made at nearly right angles with the river or other ſuch part, fronts the place where the river, &c. entered. And, of courſe, the lower ſide is the reverſe.

The upper pane of the land is that which lies upon the upper ſide of the main or trench when made at right angles with the river, &c. running north and ſouth. Where, however, theſe run parallel with the river, &c. the panes on either ſide are not diſtinguiſhed from each other.

Some other terms, which are uſed by the more modern writers on watering land, will be explained as we proceed in pointing out the nature of the buſineſs.

After noticing the manner in which water is artificially brought on and taken away from the land in watering, as already ſeen, the writer of the tract before alluded to remarks, that the art of watering land may properly be called floating, not ſoaking or drowning. Soaking the ſoil, ſimilar to the effects produced from a ſhower of rain, is not ſufficient for the general purpoſes of watering; nor will damming up the water, or keeping it ſtagnant upon the ſurface, like that in a pond, or on the fens, produce the deſired effect. The latter, it is thought, may properly be termed drowning, becauſe it drowns or covers all the graſſes, thereby rendering the plants beneath it certainly aquatic, or the herbage diſpoſed to take on ſuch a change; whereas the herbage of a watered meadow or land ſhould, from the form and circumſtances of the ground, enjoy the full benefits of air and water. Practice has proved, it is ſaid, that there is no better method of effecting this, than by keeping the water paſſing over the ſurface of the land with a briſk current, but not ſo briſk as to waſh away the ſoil, and yet in ſufficient quantity to cover and nouriſh the roots, but not too much to hide the ſhoots of the graſſes: hence appears the nicety of adjuſting the quantity of water; and hence it appears, too, that one main-drain, to bring the water on the upper ſide of the land, and another on the lower

lower ſide to take it away, will not be adequate to all the purpoſes of ſuch an accurate regulation. If the ſpace between the upper channel, or *main-feeder*, and the lower one, or *main-drain*, ſhould therefore be wider than what is proper for the due adjuſtment of the water, that is, ſo that every part of the ſpace may have enough of water paſſing over it, and no part too much, then that ſpace muſt be divided into ſmaller ſpaces by intermediate drains, which may catch and re-diſtribute the water. Theſe, and the ground capable of being watered in this way, have this term applied to them, as they *catch* or collect the water and re-diſtribute it, being in well-formed lands never made more than eight or ten yards apart. As the water is brought by the main-feeder upon the higher ſide of a piece of ground, which ſlopes towards the main-drain, and down which ſloping ſurface the water will very readily run, to perſons unacquainted with watering, it does not at firſt ſight appear neceſſary to make ſuch a number of intermediate catch-drains; but it is proved by experience, that however regular the ſlope of ground may appear to the eye, the water will find a number of irregularities, force itſelf into gutters or channels, and defeat the purpoſes of watering, in the hollow places by exceſs, and in the high ones by the want of water. Hence the water that was ſcattered over the ſurface of the firſt ſpace, being all collected in the catch-drain, may, by the ſkill of the floater, be let out upon thoſe parts of the bed of ground below, which ſeem to need the greateſt aſſiſtance.

As it is eſſentially neceſſary to poſſeſs full and complete command of the water in all caſes of improvements of this nature, the works for the purpoſe ſhould always be well-formed at firſt. Temporary means of making dams and hatches to divert the water out of its uſual channel may, it is ſaid, by the writer of the tract on watering land, ſuffice to try an experiment, or for a tenant who has but a ſhort term in the grounds to be watered; but every land-owner, or other proprietor, who enters upon or undertakes ſuch works in this temporary manner, ſadly miſtakes his own intereſt; indeed, it is frequently more difficult to repair than to renew upon large ſtreams, where the foundations are not ſeldom deſtroyed or very greatly injured by the force of the water. The ſame principle holds good upon ſmall ſtreams, and even in the feeders and drains of watered land. Wherever the channels are ſo contracted as to make a fall, or much increaſe the rapidity of the ſtream, it is conſtantly diſpoſed to wear away the ſides of its channel, or undermine a dam. The repair of theſe defects will ſtand in need of land to be dug away and waſted each time, they are replaced with the loſs of labour. The conſequent ill-management of the water renders it more adviſeable, and perhaps cheaper, to make all ſuch works of maſonry. When works are well done at firſt the owner ever finds a pleaſure and ſatisfaction in viewing them; and even the labourers feel much more intereſt in their good management, which is a circumſtance not to be overlooked.

In the undertaking of buſineſs of this kind, it is neceſſary, before entering upon its execution, to fully conſider whether the ſtream of water to be made uſe of will admit of a temporary weir or dam to be formed acroſs it, ſo as to keep the water up to a proper level for covering the land without flooding or injuring other adjoining grounds; or if the water be in its natural ſtate ſufficiently high without a weir or dam, or to be made ſo by taking it from the ſtream higher up, more towards its ſource, and by the conductor keeping it up nearly to its level until it comes upon the meadow or other gound. And ſtill further, whether the water can be drawn off from the meadow or ground in as rapid a manner as it is brought on. Having, in addition to all theſe, too, an attention to all ſuch other difficulties and obſtructions as may preſent themſelves, from the lands being in leaſe through which it may be neceſſary to cut or form the mains or grand carriers, from the water being neceſſary for turning mills, from the rivers or brooks not being wholly at the command of the floater, and from ſmall necks of land intervening, ſo as to prevent the work from being performed to the greateſt advantage, the operator may be in a ſituation to commence his works.

The water being thus under full command and regulation in every part of the land to be watered, by a proper direction, uſe, and form of the works, it is ſuppoſed neceſſary, in order to have an equal diſtribution, and prevent the waſte of it, that no part of the meadow or land, either in the bed or catch-work mode, ſhould be ſo formed as to be floated or watered directly from the main-feeder; but that all the main-feeders ſhould be kept high enough to diſcharge the water into the ſmall feeders with conſiderable velocity, and through a narrow opening. The motion of water is ſaid to be truly mechanical; and that it requires a great deal of ingenuity, and a perfect knowledge of lines and levels, to make it paſs over the ground in a proper manner. Each meadow or portion of land requires a different deſign, unleſs the land-owner or tenant makes up his mind to the heavy expence of paring off banks, and filling up ſuch hollows as may be neceſſary to reduce it to ſome regular method, the conſtruction to be varied according to the nature of the ground. This conſtitutes the difference between the watered meadows or lands of Berkſhire and thoſe of Devonſhire. Thoſe of the latter county being upon ſmall ſtreams carried round the ſides of the hills, and are chiefly in catch-work; thoſe of the former are near large rivers and boggy ground, being thrown up into ridges to create a briſk motion in the water; and alſo for the eſſential purpoſe of drawing off the ſuperficial moiſture which might be injurious to the graſſes when ſhut up for feeding or mowing. Where there is much floating to be done with a little water, or rather where the great fall of a ſmall ſtream will admit of its being carried over a great quantity of ground, and uſed ſeveral times, it is deſirable to employ it in ſuch a way, though meadows or land ſo watered are not to be conſidered as perfect models. If it ſhould anſwer the purpoſe of a coat of manure upon ſuch an extent of ground, it is all that can be expected, and will amply repay the expence. In all caſes, loſing fall is waſting water. All the drains of watered meadows or lands require no greater declivity than is neceſſary to carry the water from the ſurface; therefore, the water ſhould be collected and uſed again at every three feet of the fall, if it be not catch-work. It is ſometimes difficult to do this in bed-work lands; but where the upper part of the land is catch-work, or in level beds, and the lower part not too much elevated, it may be done. By collecting and uſing the water again in the ſame piece of ground before it falls into the brook or other courſe, a ſet of hatches is ſaved, and it is not neceſſary to be very particular about getting the upper part into high ridges, ſince that part of land which is near the hatches generally becomes the beſt, and the lower end of the field being often the wetteſt or moſt boggy in its natural ſtate, requires to be thrown up the higheſt. If the land be of a dry abſorbent nature before floating or watering, it is not neceſſary that it ſhould be thrown up into high beds. There are many good meadow lands in the county of Wilts that have little work in them, and ſome that have neither feeder nor drain: but theſe are extraordinary ſituations that do not occur in almoſt any

other

other county, or they muſt, it is thought, have ſuggeſted the ideas already ſtated as to the origin of floating or watering. There is ſome reaſon, it is thought, from the natural warmth of peat-ground, which keeps it from freezing, that ſuch land will produce an earlier crop of ſpring-feed than any other. At all events, it will firſt ſhew the advantages of watering, and gravel or ſand may the next to it.

It has been ſuggeſted that if graſs-land of the heavier kind could be ploughed in ſuch a manner as to ſet the two furrow-ſlides or ſods in a leaning poſition againſt each other with the graſs ſides outwards, the roots of the graſſes would be perfectly dry all winter; the ſhoots would have the full benefit of the ſun, and great advantage from mutual ſhelter. Upon wet land, this ploughing ſhould be done the way the water runs. If the ground ploughed in this form before winter could be watered toward the ſpring, ſo as to give it a good ſoaking, it might be preſſed down again to a level ſurface with a heavy roller. If theſe narrow ridges, too, were croſſed with level trenches at every forty, fifty, or one hundred yards diſtance, according to the fall of the ground; and theſe trenches made to communicate with other main trenches, which ſhould run up and down the ſlope, and ſupply or diſcharge the contents of thoſe which are horizontal, ſuch ground might be laid dry or wet at pleaſure. And it is believed, that land ſo ſhaped might be floated or watered all winter with ſtagnant water to its great benefit, and probably in the ſpring too, if the water be changed at frequent and proper periods; for the water would remain only in the furrows, where there would be little or no vegetation, and the newly looſened ſoil of the ridges could not fail to abſorb moiſture, ſuch as would promote the growth of the graſs without any danger of putrefaction. The levels muſt be taken before a piece of ground be ploughed in this ſhape, and the earth taken out in cutting the croſs-drains, be uſed in ſtopping the furrows on the lower ſide of them. Perhaps upon wet lands it would be neceſſary to re-plough them every autumn, or the ſtrong lands might become too ſolid to receive the ſame benefit from the practice; and it will be neceſſary to level the ridges every ſpring, if the ground be mowed, but if ſummer-fed, it may as well remain in this form as any other. This eaſy method of getting land up into ridges, which are very narrow, gives to the ſurface all that inclination which is neceſſary for drawing off water, and is certainly ſo far likely to anſwer the purpoſe of watering. The water is thus under the ſame command as in any of the beſt-formed meadows or lands, and a much leſs quantity will be ſufficient than under any other plan of watering. It is ſuppoſed that it might, probably, anſwer the purpoſe to float young wheat, or any other ſort of grain, in ſome caſes, by a ſimilar method. It is thought that flat peaty ground, ſuch as the level fens in Norfolk, which are ſubject to be covered a few inches deep every winter with ſtagnant water, would be much benefited by ploughing in this way before the floods commence. Some parts of it would thereby be raiſed above the water, and vegetate quicker in the ſpring, and the ſedgy matter growing up in the furrows, would in a few years raiſe them to the ſame level. The croſs-drains, where on a declivity, would ſerve to catch and re-diſtribute the water, and the fall from one to the other muſt be very little. If this method be found not to do for watering, it is thought that four furrow-ridges of turf, with a ſmall feeder upon each, would anſwer all the purpoſes of a more expenſive ſyſtem. There is always good graſs by the ſide of the feeder, whether the water ruſhes over it or not, and a meadow or land of this nature would be nothing but feeders. It requires ſo little elevation of ridge and fall in the feeders, that the water might ſoon be uſed again; therefore a very ſmall quantity would ſuffice; and if there was a ſcarcity in the winter, the whole diſcharge might be ſtopped, and gradually lowered in the ſpring. This method would anſwer all the purpoſes of complete ſaturation, which ſeems to be one of the moſt eſſential parts of watering, and might be applied more or leſs, according to the time of the year. When the water is put on, it is ſuppoſed no graſſes would ſuſtain any injury by excluſion from the air for a day or two at the firſt application. If theſe ridges could be elevated but four or ſix inches above the furrows, it would give the ſurface nearly the ſame ſlope as the wider ridges of common meadows or lands; perhaps it would be better to begin ploughing the furrows wide at the ridge, and very narrow at the furrow, which would leave but narrow ſpaces for drains. If a piece of turf-ground were ploughed in ſuch ridges by the common way of turning over the furrow, if it were ſet pretty much on edge, it is thought the graſs between would ſoon cover the whole ſurface.

Ridges, too, might perhaps be made by beginning the two firſt furrows more apart than the uſual width, thus leaving the width of one furrow between the two firſt to conſtitute the channel of the feeder. Theſe ridges ſhould be ploughed up and down, with only three or four inches fall between the croſs feeders; and the water may be brought into uſe again at every other ſet of beds. If the ground require to be looſened every year, or every other, or two years or more, it will not be attended with much expence, and there will be no very great inconvenience in mowing ground in this ſhape, if the ſides of the ridges be about a ſwath wide. It is thought that meadows or lands of this ſort might be made for twenty-five or thirty ſhillings the acre, floated or watered with leſs water than catch-work, and have many advantages over it; namely, the water would lie more above the ſurface, would be more at command, and therefore changed more readily, and it may be pent up better to get a good ſoaking when ſcarce. This may be done more effectually in turns, and will run drier when the water may be taken off. It does not require much ſkill in the making or management. All the water will be let through nicks inſtead of running over a nice level edge, which in the firſt place is ſeldom made well, and in the next is difficult to keep in repair. This ſort of work would, it is thought, have all the advantages of drains and feeders, whereas the ſame channels are obliged to ſerve for both in the common catch-work; it would require but very few or no ſtops, and conſequently want but little attendance. It might be practiſed where there are ſix or eight inches of fall between the croſs-feeder and croſs-catch, as the water of each ridge, which ſhould be ſhort, may be led out by a ſod with leſs trouble in the regulation than catch-work. See Weir.

The whole of the channels and drains for carrying the water on or off the land, in the conſtant courſe and regular quantity which practice proves to be neceſſary, have two very diſtinct uſes. The firſt ſort or feeders bring a continued ſupply of water to make the ſlopes wet; and the latter by carrying it away, prevent the land from getting too wet in the time of floating or watering, and ſerve to render it dry when that operation is over, and to remove any ſuperfluous moiſture which may leak from the ſoil or fall from the clouds. The large ones which convey the water to the land, and along the main ridge to ſupply the others, are ſometimes ſaid to be the *main feeders;* and the branches that run along each ridge and diſtribute the water down the ſides, the *floating feeders*. The firſt operation of floating or watering begins, or ought to begin, at the edges of theſe feeders; the main feeders being nothing more but channels or courſes

along

along which the water muft pafs, from the places where it can be found to the places where it is to have its effect. The place of its ufe lies between the floating feeder and the foot of the flope or drains, which are made in every furrow, for the purpofe of catching the water; and which are faid to be catch drains, and the large ones, which collect the water from thefe, main drains.

It is fuppofed that all floating or watering, in large rivers, may be done without conftructing hatches, which are often attended with heavy expences and many inconveniences. If the proprietor has the land far enough up the river, nothing more is neceffary, than to go thither and cut a channel out of it, which fhall be deeper than the bottom of the ftream. The water, which will be taken out in this new channel, may be dammed up by the hatches in it, at any place moft convenient for getting it out upon the furface. To turn it into its old courfe down the river, nothing more is neceffary than a hatch at the upper end of the feeder. Feeders conftructed in this way will be extremely ferviceable in time of floods, for by drawing both the hatches an entire new channel will be opened, which is generally much ftraighter than the old one. To contrive the fhorteft poffible way to get the water upon the ground, it is evident that an obtufe angle is the beft calculated for that purpofe; it fhortens the length of the feeders, facilitates the motion of the water, increafes the velocity, and confequently preferves that natural warmth or motion which keeps it from freezing in the winter or ftagnating in the fummer. It alfo prevents the accumulation of fcum, or whatever floats upon the furface, and enables the floater to diftribute the water much more equally on every part of the work than if it went in a more circuitous courfe. The wind has lefs power to retard the motion of the furface, and the fediment which fhould go out upon the beds is lefs liable to lodge in the bottom of the feeders, and confequently the feeders will be cleared out with much lefs trouble and expence, efpecially if there be proper plugs or fmall hatches to draw up for the purpofe of fending a ftream through them. It may appear to fome that thefe hatches are too expenfive, or unneceffary, but practice proves that it is beft to have them well done at firft, which is doing them for a length of time. Inclined planes, too, are abfolutely neceffary for the purpofe of watering. To form thefe between ftraight and parallel lines, it is requifite to dig away land where it is too high, and move it to thefe places where it is too low, to make fuch an uniformity of furface. The new-made ground will, of courfe, fettle in hollows proportioned to the depth of the loofe matter which has been lately put together, but fuch fettlement will not take place until the new ground has been completely foaked with wet and dried again; confequently, thefe defects cannot be removed before the fecond or third year of watering; it will therefore require more fkill to manage watered land for a few of the firft years, than may be the cafe at any time afterwards.

In conclufion it is noticed, that however fimple the conftruction of a watered meadow or land may appear upon a fuperficial view, thofe who enter particularly into the concern will find it much more difficult than is commonly fuppofed. It is no eafy tafk to give an irregular furface that regular yet various form which may be fit for the overflowing of the water. It is quite neceffary for the defigner to have juft notions of lines, levels, and angles; the knowledge of fuperficial forms will not be fufficient. Accurate ideas of folid geometry, fomehow acquired, are abfolutely neceffary to put fuch a furface into the proper form for the reception of water, without the trouble and expence of doing much of the work twice over.

Divifion of Watering.—The practice of watering land may be divided or diftinguifhed into two principal heads or modes; as thofe of performing it in flat work or flat-flooding, and in floping or catch work. Each of thefe divifions has, however, many varieties in the methods of executing the bufinefs, as will be feen below.

In the former, or that of watering lands in flat-flooding, there muft be a full fupply of water, which ferves only one turn, and is then carried off the field. There fhould be a very moderate but uniform declivity in the furface of the land, and the requifite expence be incurred by the undertaker. But though in fuch works a very fmall gradual declination will moftly be fufficient, there will be confiderable variety in this particular, according to the actual form of the land. The moft defirable and perfect declivity for this purpofe has been found to be in the ridges, from the upper to the lower extremities of the field, one inch in every nine yards. With this gentle fall, the water paffes over by the mere contraction of the feeder, without any ftop; but fuch exact declivities are feldom had. It is alfo found that the declivity of the fides of the ridges, from the crown to the furrow, fhould be about two inches for every yard; fo that, fuppofing the ridge to be ten yards broad throughout, and every fide to be in the form of an inclined plain, declining in this proportion, the crown may be ten inches raifed above the furrow, meafuring by the furface at each part. In thefe proportions, however, there is great actual variety. It is by no means uncommon to find the ridges fourteen yards wide; and when the water is very fcanty, they are fometimes twenty yards in width. Where there is a full ftream of water, the narrow ridges are found to produce the greateft crops in proportion; but the expence of forming them is likewife greater. Where the field or land has an uniform furface, and the declivity fuits, one principal feeder may ferve the whole. It is to be cut fo as to be the wideft at the upper end, contracting all the way as it defcends. Notches are to be cut in the bank on the fide next the land; and a notch oppofite to and communicating with each of the leffer feeders, in order to fupply them all in fucceffion with water. Thefe fmaller feeders, too, are to be formed fo as to be the largeft at the heads, contracting gradually as they defcend, until near the lower end of the ridge, when the fmall feeder entirely difappears. The correfponding fmall drains are made fomewhat lefs than the feeders, though not much lefs, and the proportions of the drains are reverfed, being formed the largeft at the lower ends, and diminifhing into fcarcely any thing at the upper ends.

But though the furface of the field or land fhould be uniform, yet if the defcent in the line of the principal feeder be too rapid to admit of its giving fupply to the leffer feeders, in a regular manner, without great ftops or hatches, the method below may in that cafe be had recourfe to. The main ditch may act as a conductor only, not as a feeder; and parallel to it the main feeder may be formed in feveral different parts, each of which is eafily levelled up, fo as to fupply five or fix ridges, and is itfelf fupplied from the conductor, by fimply adjufting a ftop or hatch for every fubdivided feeder. If the furface fhould confift of feparate and gently rifing fwells, there muft be a main feeder branching away from the conductor to fupply every afcent, on the top of which this feeder is formed; while a correfponding drain is cut at the bottom, and the refpective ridges are marked out and formed between the feeder and the drain.

If it fhould be neceffary, fome catch-work may be intermixed, fo as to water the irregular portions of furface, which poffefs a degree of declivity anfwering to that mode

of

of watering; and too much of it to be conveniently and properly watered in flat flooding.

The ridges being formed, and all the feeders and drains cut out, and their materials placed and difpofed in fuch a way as to render the furface as regular and correct as can at firft be done; the feeds of proper graffes fhould in fome cafes be fown, but in others it will be unneceffary. When the land is ready in the fpring, the feeds may be fown with a thin crop of fome early grain kind, but it may be as well to fow the feeds alone towards the beginning of the autumn if the land be then ready.

In the latter mode of watering, or that of catch-work, the principle confifts in floating as much of the furface, as can be done, in the way moft fuited to the form of the grounds; taking care to prevent the water from finking or ftagnating; and collecting it again to be a fecond time, or more frequently thrown over new furfaces of the land. In order to put it in the power of the floater to receive the water, and to throw it again over fome other portions of the ground, there muft be a declivity fufficient for fuch purpofes. A fmaller quantity of water may be enough for watering, according to this method, than is neceffary in flat flooding; and as the water is accommodated to the form of the ground, and no ridges required, the expence of watering in this way is generally very moderate, in comparifon with that of watering flat meadows or lands. It is well adapted, too, to thofe gentle declivities which produce very little in the ftate of nature, but may become highly valuable at little expence, when properly watered. On thefe and fome other accounts, it would feem that all the preference to flat meadows or lands, that has been commonly claimed for them, is not due. At leaft, it admits of no queftion, that watering in catch-work, when properly executed, is a very beneficial and advantageous method.

The principal objection to this mode of watering is, perhaps, in the feeming unequal diftribution of whatever nutriment the water may contain, which has certainly fome weight in it; as the firft furface over which the water paffes, muft of neceffity have the advantage. It fhould not, however, be entirely forgot, that in moft cafes of land in fuch declivities the confiderate farmer beftows moft manure where the foil or land is the moft thin and poor; and the water of catch-work meadows or lands does the fame; the higher fituated grounds receiving it and its benefits the firft, and afterwards thofe which are lower, and, for the moft part, richer, and deeper in point of earthy ftaple.

In this mode of watering, the feeders and drains are cut in a direction paffing acrofs the flope of the furface of the land; and having no greater fall, as the water flows in them, than to caufe it to move gently and freely, without either ftagnating, or acquiring fuch a rapidity, as might endanger the works. In order to accomplifh the work in this eafy way, the water may be introduced at an upper corner, where it paffes gently, and by a very fmall declivity in the feeder acrofs the flope, and overflows the furface below its tract. A drain, at a proper diftance below, receives the water, and tranfmits it into another feeder, cut on the fame plan as the former, where it again overflows, and is again taken up in a drain to be fent over new furfaces.

In this manner, a moderate quantity of water may float a fet of different fpots lying in a diagonal direction, until it arrive at length at the bottom of the watered grounds, and reach a drain which carries it off completely. An entirely new fet of different fpots may then be watered in the fame manner, the drains in the firft procefs, or cafe, acting as feeders in the fecond, and the contrary in other cafes. But catch-work watering, fo far as regards the method of performing it, admits of almoft an endlefs variety. A conductor with ftops may be formed, pointing directly down a declivity, if the rapidity of the current be not fufpected as dangerous for forcing up the channel in which it flows. From this conductor, feeders may be formed at right angles, to the right and to the left, or in either direction; and the ftops in the conductor fend the water into thefe feeders; which, being formed only a very little off the level, foon fill and overflow the grounds below them. The furplus water is collected in drains parallel to thefe feeders, which reftore it to the conductor, whence it can again be diffufed to right and left, in order to float a lower fituated furface, from feeders conftructed in the manner already feen.

There are many other ways of watering in different cafes of this nature; but where the lands are neceffary to be laid down into permanent meadows, the works fhould evidently be fubftantially executed at once, and with proper care and defign, whether the method be catch-work or flat meadows or grounds.

Regular plans of this mode of watering may be feen in the laft editions of Wright's tract on the "Art of floating Land," and of Young's "Farmer's Calendar."

The writer of the work on "Landed Property" has given practical directions for four different methods of applying it artificially on the furfaces of grafs lands, which may be ufeful in guiding the practice of the inexperienced.

1ft. Flooding or covering low flat Lands with ftagnant or flowly-moving Water.—This is a mode which, it is thought, was formerly, perhaps, the only one in ufe, in this country, for enriching the bafes of valleys by the means of water. In the midland diftricts, tradition, it is faid, fpeaks of it with familiarity. And the remains of works that have been ufed in practifing it, are ftill evident. Even in the weftern diftricts of the fouthern range of chalk hills, which have long profited more by watering, than all the other diftricts of the ifland, this, it is more than probable, has been heretofore the only method in ufe. It is indeed an interefting fact, it is faid, that the far-famed long-grafs mead of Orchefton, in the county of Wilts, is ftill watered in this manner. But it is conceived that there are now, however, few fituations in which this method can be practifed with the beft effect. The one for which it is the moft applicable is, it is fuppofed, a *drained* morafs, or other flat moory ground, through which a ftream naturally paffes, or to which a fufficient fupply of enriched waters can be led. A body of water, refting on a light fpongy furface, tends to comprefs and confolidate it; while the fediment of foul waters, let fall in paffing from an agitated to a ftagnant ftate, further promotes this tendency. The rich moory meadows and pafture grounds, which are feen in various parts of the kingdom, were doubtlefsly, it is thought, brought to their prefent profitable ftate, by being flooded with ftagnant or flowly moving waters.

Another, and perhaps the only other, fort or clafs of lands, to which this method can now be properly applied, is *dry* valley grounds, which are compofed of a fufficient depth of foil for the pafture of herbage, with a fubfoil of flints, pebbles, or rough gravel, to draw off quickly the fuperabundant moifture that may be left in the foil, after its furface has been freed from water; and, thereby, to give vegetation the immediate freedom of action. But lands of this fort, having a fufficient command of water to flood them, are much lefs common, in this country, than thofe of the former clafs or kind. The valley of Orchefton is, however, in itfelf, it is thought, a fufficient ftimulant for fearching narrowly for lands of fo valuable a formation, and which can command fertilizing water to flood them; as they may generally

nerally be watered at lefs expence by this, than by any other method.

The method of flooding flat or difhing lands artificially with ftanding water, is fimply, it is faid, that of raifing a dam acrofs the lower end of the fite of improvement, of a fufficient height to overflow the land, and proper ftrength to fuftain the weight of the water; with a channel at each end, to carry away the overflow; and with a valve in the middle or loweft part to draw at pleafure.

Where the fubfoil is not fufficiently abforbent and open to free the upper foil of fuperfluous moifture, prefently after the body of water has been drawn off, a main drain fhould be run up into the area of the fite, and lateral ones be branched off from that, to wherever the water is found to hang; whether on the furface or in the fubfoil. But where the fubfoil throughout is retentive, though but in a fmall degree, the land may be confidered as improper for this mode of watering, as will be feen below.

2d. Watering flat Lands with running Water, when raifed into Ridges.—This is a method of practice which is conceived to be modern when compared with that of flooding, drowning, or covering the entire furface with ftanding water, as being a fpirited mode which is ftill, as a general practice, confined to one part of the kingdom. Among the chalk-hills of Wiltfhire and Dorfetfhire, but efpecially the former, there are large tracts of water-formed valley lands, which have long been watered with fcientific accuracy and correctnefs. Thefe lands, it is probable, were firft brought to a firm ftate of fward, by flooding them, during a great length of time, with ftanding water; and have been fince moulded into their prefent form; been raifed into ridges, or other inequalities, in fuitable manners, and properly watered.

It is proper and neceffary, however, before fo expenfive a practice be recommended, to explain the principles on which it proceeds, and on which it may be profitably purfued and had recourfe to; where fuitable ground, and a fufficient fupply of water, which is proper, can be employed. It is noticed that plants, as well as animals, have their natural elementary matters. That water plants, aquatics which root beneath the water, live but in this fluid, where they are fecluded, in a certain degree, from air and heat. On the contrary, the agricultural vegetables of this country, among which are to be reckoned the more nutritious meadow plants, require a free communication of atmofpheric air and heat, to every part of them: they cannot live with their roots immerfed in water, nor flourifh while water is lodged immediately beneath them. And between thefe two oppofite tribes of plants, is found an intermediate one, which is fomewhat amphibious, or partakes fomething of the nature of both,—the plants of which delight in water, yet can live, though not flourifh, on dry land,—provided it be of a cool nature or quality.

It is ftated that where the foil of low flat meadow lands of this nature, refts on a retentive bafe, the paluftrean fort of plants feldom fail to intermix with the meadow herbage. In a feafon which is favourable to dry land plants, the fuperaquatics are kept in a dwarfifh underling ftate. On the contrary, in a wet feafon they flourifh; while the better herbage becomes weak and unproductive. If, through neglect, the foil or land be fuffered to remain faturated for fome length of time with water, the meadow plants dwindle, or die, and the ranker wet-land weeds take poffeffion. Hence, in the practice of watering, the propriety of quickly relieving the foil or land from fuperfluous moifture or wetnefs, in order that the better herbage may gain the afcendancy; efpecially in the fpring, when a few days of warm weather at the critical juncture may give the one or the other a fuperiority during the early fummer months. Even in meadows where the fuperaquatics do not abound, the fame principle of practice holds good; for it is well known to common obfervation, that flat retentive meadows, which do not readily fhoot off furface-waters, are materially injured by a cold wet fpring: by which the finer more nutritious herbage is cut off, or wholly checked; fo that the hay-crop proves thin, is of fmall bulk, and of an inferior quality. But further, though it be evident that water, even ftanding water, may remain for a fhort time upon dry land-plants with impunity, efpecially in a cold feafon; yet wherever it is fuffered to lie long on the furface, particularly during warm weather, there, dry land-plants, in general, are deftroyed, are probably fuffocated for want of that fupply of air which *ftanding* water is incapable of affording them. Hence, it is fuppofed, appears to arife an advantage of watering with *running* water; and hence, too, the propriety of watering by *intervals*; in order to enable the plants to recover their ftrength, and to exert their natural powers of imbibing the nourifhment the water may have provided for them, and thereby increafing their ftrength. Befides, the warmth which moving bodies, even agitated liquids, naturally generate, may be fuggefted as another advantage of watering with running water.

Thefe confiderations may, it is fuppofed, fufficiently explain the reafon for laying up cool flat lands into ridges for the purpofe of watering. Experience has well afcertained, it is faid, that where calcareous water, at leaft, is fpread over a fufficiently floping furface of grafs-land, the fuperaquatic plants difappear, while the more nutritious graffes luxuriate. On the contrary, where the fame fort of water is fuffered to loiter on a flat foil, lying upon a retentive bafe, the groffer wet-land plants prevail. And further, that the fame or fimilar water in its nature, thrown over the fame or a fimilar fort of foil, with the fame turn of furface, but with a dry abforbent bafe, produces luxuriant crops of valuable herbage. And, from long continued obfervations on facts of this nature, has doubtlefsly arifen, it is thought, the prefent *practice* of Wiltfhire and its neighbourhood.

The work of raifing flat lands into water-mead ridges in thefe cafes, is directed to be performed in this manner. In a fuitable fituation, where the ftream of water can be properly received to begin and mark out a plot of the green fward, or land, of the proper length and breadth for the purpofe. Then if to be done by the fpade, to roll back the turf after it has been cut, and form the earth of the foil into the proper fhaped convex ridge, being careful in forming it, to keep the beft of the mould conftantly toward the furface, and leaving the opening on the ridge eight or nine inches or more deep, and nearly level; the end towards the ftream being made fomewhat higher and rather wider than the other, that the water may flow evenly over every part of the ridge. The turf is then to be returned, being careful to replace it evenly and firmly along the fides of the trench in the middle; and cut a drain on each fide of the ridge thus formed, with proper outlets to carry away the wafte water. Laftly, raife a channel between the ground and the fource of the water, to conduct it into the watering-trench; and continue to adjuft the ground until the well flow evenly over every part of it. The moft proper forms, and the degrees of convexity which are the moft fuitable in different cafes, will be feen below.

This work may be performed either with the fpade or with the plough. The former is the more expenfive method, but it is the more accurate, and fooner brings the improvement to profit. By the fpade, the natural earth and foil are again diftributed on the furface. By the plough much of them is buried

buried under the ridges, while the furrows are left deftitute. Where there is a great depth of fertile foil, the plough may be ufed with better effect than where the foil is fhallow.

The next confideration is the elevation and convexity of thefe meadow ridges. On the principle offered, it is faid, the fteeper the fides are formed, the more beneficial will be the effect of the work. But it is not lefs certain that the expence of it will be proportionally great. Something may depend on the nature of the materials of which the ridges are to be formed, and the method of forming them. If, in moving the materials, a regular ftratum of flints or gravel can be buried, at a proper depth, as an open fubfoil, a fmall degree of elevation will be fufficient. In ordinary cafes, one foot of rife to fixteen feet and a half, or a ftatute-pole of bafe, will fuffice ; provided the drains between the beds be funk to a fufficient depth. One foot of rife to five feet and a half of flope, or eleven of bafe, may be confidered as the maximum of elevation in thefe cafes. On thefe premifes, it is concluded, that a ridge fet out one ftatute-perch in width at the bafe, requires an elevation of from nine to eighteen inches at the ridge ; one of two perches in width, an elevation of from eighteen inches to three feet, according to the nature of the materials by which it is formed. In refpect to the *turn* of furface, or form of the flope, there are fufficient reafons why it fhould be convex, not a regular inclined plane, nor of a concave or hollow caft. A regular fheet of water fpread over a floping furface has a natural tendency to break into ftreamlets, and to collect into partial currents. In the procefs of watering, this effect is produced in part, by the unevennefs of the furface it is fpread over, and the obftructions it meets with in its defcent, as well as by the natural propenfity of falling waters to collect into a body ; and the fteeper the defcent, the greater freedom of action this propenfity acquires. Hence, the propriety of giving the water a gentle defcent on the upper part of the flope, in order to preferve the entirety of the fheet as far down the fide of it as may be ; and this is effected by the convex form, which alfo gives firmnefs to the fides of the trench. Befides, a convex furface, while it leffens the defcent at the ridge, increafes it at the foot of the flope, and thereby haftens the drying in that part ; to which the fuperfluous moifture of the entire flope tends, and where noxious plants are moft liable to gain a footing ; the earth or foil being there kept the longeft in a ftate of faturation.

The width of thefe convex beds is a matter of much confideration. In what has been faid of their elevation, it plainly appears that the expence of forming them is in proportion to their width. An acre of ground may be raifed into beds of a rod wide, with the mentioned flope, at half the expence that another acre can be formed into thofe of two rods in width, and the fame flope : the latter requiring to be raifed at the ridge twice the height of the former ; befides the work in this cafe being within a fmaller compafs. And from what has been faid of the form of the flope, it is equally clear, that water may be more evenly fpread over a narrow than over a wide or deep flope ; and that a narrow bed will dry more quickly than a wide one of the fame foil and fubftrata. Neverthelefs, there is an advantage of wide ridges, which, in fome fituations, may more than over-balance all their inconveniences. A given quantity of water will float twice the quantity of ground, though perhaps not with twice the profit, when raifed into beds of two poles wide, that it will in thofe of one perch in width, befides the current expences of management being lefs. If, however, the quantity of water be great in proportion to the extent of ground, or if it can be collected again, and fpread over other lands belonging to the fame owner, which lie below thofe that have been watered, narrow ridges may claim a fuperiority. Hence, the proper width of watered meadow ridges depends much on foil and fituation, and on the quantity of water proportionate to the quantity of ground. In the neighbourhood of Salifbury, the prevailing width, it is faid, is ten yards, nearly two perches. In the vicinity of Amefbury, there are fome of three times that breadth or width, but they are nearly flat. From one to three poles may fairly, it is thought, be fet down as the ordinary limits of width.

In refpect to the arrangement of thefe meadow beds, and the general economy of watered meadows or lands of this nature, almoft every thing may be faid to depend on the particular circumftances of the given fite. But fuppofing a copious ftream of good water to pafs through a flat of water formed land, in a dilatation of the bafe of a valley ; and fuppofing the fituation of it to be nearly level from fide to fide of the fame, or to have a gentle defcent, the banks of the ftream towards the outer margins ; a cafe which often occurs where flat lands have long been liable to the overflow of foul waters. In this cafe, the beds require, it is faid, to be run acrofs the valley in a direct or oblique manner, as the defcent may point out ; and the water to be conducted to them by an artificial channel, winding on each fide of the natural ftream, with a main-drain near each outer margin, leaving room for a carriage-way between it and the foot of the bank of the valley ; and where the grounds to be watered are wide, other road-ways may be left between the conducting trenches and the bed of the brook or rivulet. Thefe dry flips of land are ufeful, not only in conveying away the crop, but in furnifhing comfortable lodging-grounds for pafturing ftock when the area of the land is moift. It follows, of courfe, that thefe road-flips fhould be watered with caution, late in the fpring and during the fummer months. The moft eligible method of *raifing* the water high enough to fill the trenches, is that of placing folding-gates, like thofe in ufe for navigable canals, acrofs the ftream, at the upper end of the ground to be improved. In fummer, or when the water is not wanted for ufe, the gates may be thrown open, and faftened back, to give free paffage to floods. But during the time of watering they are kept fhut, to throw a conftant fupply of water into the main trenches. If the defcent downward of the valley be confiderable, the main trenches or conducting channels require to have ftops, or rather checks, placed acrofs them, at diftances proportioned to the defcent, in order to fill with due effect the working trenches, the mouths of which open into the conducting channels ; and, to gain more perfect command of the water, the mouth of each acting trench fhould be furnifhed with a regular valve, to admit juft water enough to fupply the given ridge while under watering, and to clofe the entrance effectually when it is laid. A lifting-board in the form of a fhovel, with a fhort handle, and fliding in upright grooves made in the faces of two flender pofts, joined together within the ground, becomes a fimple and defirable regulator for the purpofe. And where a meadow ridge happens to be long and much declining, a circumftance which fhould, as much as poffible, be avoided : checks are likewife requifite to be placed in the working-trenches, to affift in diftributing the water evenly over its furface. Thefe checks are formed in different ways. Two thick tough fods placed in the trench, fo as to leave an opening between them narrow enough to force a fufficient quantity of water over the fides of the trench above them, and wide enough to let the remainder pafs down freely into the lower part of the trench, form a ready and not ineligible check for this purpofe ; as the opening may be eafily widened or narrowed

rowed at pleafure. If the defcent ftraight acrofs the valley be not fufficient, where the defcent down it is confiderable, it is advifed to direct the beds obliquely acrofs it, and by this eafy mean gain the required fall. But where the bafe of the valley is wide, fo that the length of the beds, if run out from the natural ftream to the outer bank, will be too great, as from fifty to a hundred yards, wind a conducting trench along the foot of the bank, as well as by the fide of the brook or rivulet, and fink a deep drain in the midway between them. As to what regards the dimenfions of working trenches, they fhould vary according to the breadths and lengths of the beds to be watered. The wider and deeper they are formed, the more freely a large body of water will pafs along them. Hence it is evident, that the upper end of a long trench fhould have the larger dimenfions, in order that a fufficient fupply of water may pafs freely to the further end, where the dimenfions are required to be lefs; as the uniform contraction ferves as a continual check to the water, and thus tends to force it in its paffage over the fides of the trench. From fix to fifteen inches wide, and from four to ten inches deep, may ferve to give a general idea, it is faid, of their dimenfions.

3*d*. *Watering by fpreading running Water over naturally uneven Surfaces.*—In the more weftern counties of this country, but particularly in Devonfhire, this practice has been eftablifhed time immemorial. Even tradition there fpeaks not of its origin. The fpring-waters that iffue from the flate-rocks, which are there the prevalent fubftructure, are of a fertilizing nature; and the fteep valleys that there abound are moftly covered with a rich deep foil, fit for hay-ground. Such circumftances may well ferve, it is faid, to account for the prevalence and antiquity of the practice in that part of the kingdom. Something of this practice, on a fmall fcale, too, has been long in ufe in different parts of the country for fpreading the overflowings of dung-yards and pits, and the wafh of home-ftalls over grafslands lying below them. Of late years, alfo, it has been employed in different diftricts, in diftributing the waters of more copious ftreams; and numerous inftances ftill remain in which the practice may be extended with great and valuable effects.

If the quantity of water be fmall, whether it flow from a farm-ftead, or a fpring of fuperior quality, it fhould, it is faid, be collected in a proper place, whenever it is not employed on the ground; more efpecially in the fpring months, while the hay-crop is growing, in order to be able to liberate it, fhould its growth be arrefted by a dry feafon, and to meliorate the foil as foon as the crop is off the ground for the benefit of the after-growth. The ground or fituation of improvement is moftly given in the fource of the water, or the point at which it can be commanded. Where this is a matter of choice, it is generally advifable to run the channel of fupply along the brink or brow of a flope, as above: thus giving the flatter lands above it to the plough, to which in upland fituations they are beft fuited, and the fteeper to the fcythe, as watered hay-grounds, for which they are the moft eligible; extending the ground downward to the foot of the flope, and to the flatter lands beneath it, provided their fubfoil be abforbent and open, and the given quantity of water be fufficient for the whole extent. The canal or artificial water-courfe from the natural ftream or other fource of the water, to the ground of improvement, requires a certain fall, to give a due degree of current to the water it may convey. If the motion of water in a fupplying channel be fluggifh, part of it is liable to fink, and be loft by the way. Slowly moving water does not tend to make the bottom of the channel firm and water-tight, like a living ftream: nor will a channel of the fame fize convey an equal quantity of water in the fame time; nor will it clear itfelf fo well from obftructions, as with a quicker current. On the contrary, dead water gives the fufpended matter, which fhould be conveyed as nourifhment to the plants, an opportunity of being depofited by the way in the form of mud, for want of agitation, and thereby fouling the channel. On the other hand, if the current be made too rapid, it is liable to wear the channel, and to caufe unneceffary repairs. Befides, where all the height that can be properly got is required, every foot of fuperfluous fall contracts, unneceffarily, the field of improvement. On the grounds of practical experience, it is fuppofed, that one *per cent.* as one inch, foot, or yard of fall, in every hundred inches, feet, or yards of diftance, is, in ordinary cafes, the proper fall: this giving an active but inoffenfive current. Under the above circumftances, and where the length of channel required is great, one-half *per cent.* may be made to fuffice. Two-thirds of the ordinary fall gives a degree of life to the ftream, and may, in many cafes, be eligible and proper.

In fetting out water-courfes of this nature and fort, the ufe of the level is neceffary; and the beft forms of fuch courfes, whatever the fize may be, are thofe of inverted arches, as clearing themfelves better when low in water, and giving firmer banks on the lower fides than is the cafe with fquare flat-bottomed fteep-fided trenches. The modes of performing the work, and of laying them out properly, muft be directed by the particular turn of the furface of the grounds.

In the low lands which lie at the feet of the floping grounds, the natural furfaces of which are fufficiently uneven to admit of running water being fpread over them, without the affiftance of art; and the fubftrata of which are fufficiently abforbent and open, to permit them to dry quickly, after the water is taken off: the method of watering, where they lie pretty regularly fhelving, is to lead the water along the higher fide of the land, and to draw it off by a main-drain on the lower fide; ftraight working trenches and correfponding drains being cut, downward of the area, fo as to fpread the water over the whole, without fuffering it to lodge on any part of the furface. This is that which may be diftinguifhed by the Devonfhire practice, or manner of watering.

Where, however, the furface is more irregular, lying in natural fwells and ridges, with dips and hollows between them, the water is to be led along the tops of fuch higher parts, without regard to the ftraightnefs or regularity of the trenches; and the drains to wind up the hollows and loweft ground with the fame irregularity. There are two ways of afcertaining the true lines of the trenches and drains in cafes of this nature. The one is by flooding the entire area, where it can be done, and driving down levelling-pegs over every part of it, fo as to leave their heads uniformly level with the furface of the water; which being let off, the fhorteft pegs fhew the proper lines for the trenches, the longeft thofe of the drains. This method was ufed by Bakewell, in Leicefterfhire. The other, which has occurred in the writer's experience, is attended, it is faid, with lefs trouble and inconvenience. The higher parts are readily afcertained, and the lines of the trenches accurately traced by a proper levelling implement; artificial mounds being raifed between the detached knolls when wanted. After the frefh-made ground has properly fettled, and the trenches have been duly formed, the water is turned on; and by this ready mean, the proper lines of the drains are accurately given. This is an eafy way of watering valley lands; and where

where the irregularities of furface are fufficiently great, and the fubfoil abforbent, it is very eligible; efpecially, if in making the trenches and drains, the turf and foil fo raifed be applied in adjufting the natural defects of the furface.

In the watering of more fteeply floping grounds, as the fides of hills, and the lower banks of valleys, in what may be termed the Devonfhire practice, as having been long there and thereabouts chiefly eftablifhed; as there, the fides of the valleys lie in or nearly in their natural ftates; many of them appear as if they had never been fubjected to the plough; and thofe which have been in tillage, have been laid down again to grafs with nearly their natural furfaces. The practice of laying up foils into high arable ridges, has never, perhaps, gained a footing in that part of the kingdom. In thefe cafes, the conducting channel being led along the brink, and acrofs the upper part of the flope, as advifed, the working trenches are to be fupplied from it by means of checks and valves, as already feen. The diftances between the working trenches are to be regulated by the fteepnefs and evennefs of the furface. Wherever the fheet of water is feen to break, and to divide into numerous ftreamlets, there a trench is required to catch and refpread it; the working trenches, in this manner of watering, acting in the two-fold capacity of trenches and drains: frefh fupplies of water being let down from above, to the lower trenches, as occafion may require.

Where the depth or downward length of the flope is great, or where an additional fupply of water offers itfelf, and where refervoirs are formed at different heights, an additional main-channel is required, to lead a frefh fupply acrofs the midway of the flope. This main-trench likewife receives the wafte water from above; and, like the working-trenches, acts at once as a fupplying-channel, and as a receptacle of the wafte water: hence, a given quantity of water will float a much larger extent of ground in this manner of watering, than in watering ridges, raifed on level ground; though, it may be prefumed, not with equal benefit.

In forming the trenches of whichever fort, the turf and loofe earth that are raifed out of them, and which are not wanted to make their lower fides firm and level, are to be ufed in filling up the channels and dimples that naturally happen in the face of the flope; in order that the water may fpread more evenly over it, and thereby to leffen the requifite number of trenches. To the fame end, if hillocks or fmall protuberances occur, as they generally do on natural furfaces, they are to be lowered by turning back the turf, ufing their contents as above, and returning the fods to fmoothed furfaces. But, where the knoll is large, water may be led by a narrow branching trench to its top, and be thus fpread evenly over its fides. The proper defcent or decline of the working trenches depends, in fome meafure, on the prefs of water that enters them. One quarter *per cent.* may ferve as a guide in fetting them out: firft making them of inferior dimenfions, and then turning on the water: afterwards enlarging them, and in doing this, adjufting them in fuch a manner, that the water will flow evenly out of them, from end to end. The fhorter the acting trenches are made, the more eafily they may be regulated without the incumbrance of checks, which fhould be avoided as much as poffible.

4th. Watering floping Grounds that have been raifed into Ridges by Cultivation, and are in the State of Grafs.—In watering ridges on flopes, or fuch fhelving grounds as have formerly been in a ftate of aration, in which they have been raifed into high wide convex beds, refembling thofe advifed above, for flat meadowy furfaces, and have been laid down to grafs in that form; a practice which, it is fuppofed, has been common to many parts of the kingdom, efpecially where the common-field fyftem prevailed; the direction of the ridges being moftly directly downward of the flope. In this cafe, it would be in vain to attempt to fpread water over the furface, in the manner ufually practifed on more even flopes. And if it be thrown into open trenches, cut along the tops of the ridges, agreeably to the practice in ufe for level grounds, and according to the ordinary practice of watering the lands now under confideration, the operation becomes very imperfect. For, if the defcent be confiderable, the water will unavoidably flow out of the trenches in ftreams immediately above the checks; and the fides of the ridges will confequently be watered partially. Thefe difficulties in fpreading water evenly over ridges on fteeply fhelving furfaces, have led fome induftrious managers to throw down the ridges, and return the flopes to their natural ftates. But this, where the ridges are high and wide, is very troublefome and expenfive if done by hand; and if performed by the plough, is greatly injurious and hurtful to the land for many years. A better method has therefore been had recourfe to by the writer. Inftead of leading the water down the ridges, it is thrown into the furrows, and fpread over the fides of the beds by means of crooked trenches, winding, in the feftoon manner, horizontally, or nearly fo, acrofs them, and led more effectually over their tops by pointed trenchtels depending from the feftooned parts. Thefe winding trenches, like thofe acrofs plain floping furfaces, act both as feeding-trenches and as drains, or collecting trenches, to refpread the water evenly over the ground, immediately below them: thus keeping the entire ridge covered with an even fheet of brifkly moving water. When the upper ends of the ridges are fufficiently watered, the water is to be let down the furrows to the parts below; or if the ridges are fhort, their whole length may be watered at once, by letting the water partially down the furrows to the lower parts, by the means of cuts of proper widths, made with a fharp tool acrofs the lower fides of the trenches, where they crofs the furrows: thefe fimple regulators acting as checks in the common modes of watering. The diftances between the trenches, as well as their form, muft always vary with the fteepnefs of the flope or defcent, and the fhape of the ridge.

Confiderable tracts of land in North Wales have been watered in fomewhat this manner of late years.

In concluding, it may be ftated on the beft authority, that the beneficial practice of watering, by fome of the methods which have been fuggefted above, may be greatly extended and applied in different parts of the country where it has yet been but little tried, as on the fenny lands of the counties of Lincoln, Norfolk, Cambridge, Northampton, and, perhaps, fome others, where it is particularly defirable, as well as the bottoms of the chalk-hills in different diftricts, as Yorkfhire and Suffex, and the vales of Hertfordfhire, the chalky parts of Buckinghamfhire, Oxfordfhire, and Suffolk, which are peculiarly fitted for the purpofe; befides many others where good waters are afforded for making fuch improvements on grafs-lands.

WATERING *Live-Stock*, in *Agriculture*, the bufinefs of giving and providing them with water. The work is effected in different ways, and by different means. See DRINKING-PONDS, *Made* STREAMS, WATER-*Cifterns*, WATER, *Rain, Collecting of*, SPRING, *Artificial*, WELL, *Field*, &c.

WATERING *Plants and Fruit-Trees, in Hot-houfes, Stoves*, &c. in *Gardening*, the practice of throwing water over them in different intentions. The common modes of applying water have been fpoken of in confidering the general practice

of

of garden-watering, and under the heads of the different plants, as they may require it; but the nature of its application, in these cafes, may be explained in the prefent place.

For plants in thefe fituations, Mr. Fordyce has advifed the ufe of fimple water only, in clearing them from different nuifances to which they are expofed, though lime-water in other cafes may be more powerful and have a better effect, as will be feen below. It is directed to be applied in this manner. About four o'clock in the afternoon a barrow-engine is to be filled with foft water, or fuch as has been expofed to the fun through the day, and wheeled along the foot-paths of the houfes, where they are wide enough to receive it, and the whole of the plants fprinkled with the fluid, by preffing the finger on the top of the pipe of the engine, in order to fpread the water fomewhat in the manner of a fine fhower of rain, playing the engine and throwing the fluid likewife againft the top-lights and fhelves of the houfes, until the water ftands an inch deep in the paths of the houfes. A fmall copper engine may be made ufe of, and anfwers very well, when a barrow-engine cannot be got into the houfes. It may be had in moft places. But if an engine fhould not be conveniently at hand, which can be got into the houfes, the front-lights may be opened, or, where there are no front-lights, the top-lights may be flided down, and the water be thrown in at the fronts or tops. When this operation is begun, if in the infide, every light muft be clofe fhut down; and if the water be thrown in at the fronts or tops, one light only is to be kept open, which is immediately to be fhut, when that part of the houfe, which is oppofite to it, is fufficiently watered; then proceeding to open others until the whole be properly watered. The houfes after this are to be kept clofe until the next morning; which will caufe fuch an exhalation from the glafs of the houfes, and the beds that may be in them, if there fhould be any, that the plants will, it is faid, be covered all over with fteam or vapour; which will infallibly deftroy and clear them of the vermin and other hurtful matters that may be upon them, efpecially thofe of the plant-loufe and coccus kinds. This fort of watering is, however, to be repeated every afternoon, in the time of hot weather only. By it a great deal of labour in watering will be faved; but fuch plants as ftand in need of much watering, fhould have the water given them before the fprinkling of the houfes is begun. In moft cafes, the plants will have imbibed all the moifture before morning, and the paths of the houfes will be perfectly dry.

As it fometimes happens that in hard winters, when ftrong fires are under the neceffity of being kept in the ftoves or other houfes night and day, that the plants which ftand on fhelves in thofe of the dry kind, are fo parched up, that the leaves drop off, as from deciduous trees in the autumnal feafon, which renders them very difagreeable in their appearance; it fhould be prevented or remedied by watering, in the manner directed below by the fame writer. About eight o'clock in the morning, when the fun fhines out, and there is the appearance of a fine day, water is to be thrown into the houfes until the floors are covered to the depth of nearly two inches; they being kept fhut the whole day, unlefs the heat rifes very high, which is feldom the cafe at fuch a feafon of the year, but when it does happen, the doors may be opened to admit a little air. By the middle of the day, the water becomes entirely exhaled, and the floors quite dry. The operation may be repeated two or three times in a week in funny weather. The plants in the courfe of a week's time begin to recover, or throw out new foliage, and in a fortnight or three weeks become in full leaf again, difplaying themfelves in a fine manner.

This fort of watering is greatly ufeful on many other occafions, as in the growth of plants in the pits of fuch houfes.

Fruit-trees in fuch houfes may alfo be watered in the fame manner with much benefit in fome cafes; but for thofe againft walls, a lime-water prepared by putting thirty-two gallons of foft water to half a peck of unflaked lime is recommended to be ufed in this manner. With the clear liquid, after the lime has fubfided, the engine is to be filled, and a good watering given to the trees, throwing a confiderable part of it forcibly under the leaves, and fpreading it finely by the means directed above; at the fame time, wheeling it backwards and forwards, that no parts of the trees may be miffed. This fhould be performed when the weather is cloudy, or when the fun is off the wall that contains the trees. Where the trees are on an eaft wall, the watering may be begun about half paft eleven o'clock; if on a north wall, the watering may be done the firft thing in the morning; and when they are on a fouth wall, it may be executed about four o'clock in the afternoon: it is to be repeated once a day for fix or feven days in fucceffion. If, however, there fhould be cold northerly or eafterly winds, or frofty nights, fuch watering fhould be difcontinued until the weather becomes more mild and temperate. Care is conftantly neceffary that the trees get dry before night, and that no watering takes place while the fun is upon them. Care is likewife to be taken not to water them with any of the grounds of the limey liquid, which would injure the leaves, and make the trees look very unfightly.

This fort of watering, with the ufe of lime and wood-afh duft to the under-fides of the leaves, are found extremely effectual in deftroying and clearing away every thing noxious about the trees, and in rendering them healthy and productive. See Watering, in *Gardening*.

Watering-*Pots*, *Pans*, *or Cans*, are fuch contrivances of this nature as are fuited for pouring water over feeds, plants, trees, &c. in pots or otherways in a fine fhowery divided ftate, they being provided with ftrainers or rofes of a finer or coarfer kind for the purpofe, well adapted to their fpouts. They are particularly convenient for potted plants of all forts, as well as many other kinds. They form the principal mode of hand-watering.

Watering *Sheep*, in *Agriculture*, the fupplying them with water. This is particularly neceffary in the management of flocks in fome fituations, as on the South Downs; and as there is there no other water than what is to be collected by fome artificial method, ponds are conftructed for retaining fuch water as falls in rain; thofe, for this ufe, are commonly made circular, and very gently floping to the centre; the bed very ftrongly rammed down to prevent any lofs by foaking through the chalk. As ponds are liable to become leaky, and to be fpoiled by a hard froft, they are made by lining them with chalk, puddled and trod down until it makes a fort of plaifter floor. If a little good ftone lime were fifted evenly over the whole and trod well in with the chalk, it would probably effect the bufinefs of rendering them perfectly retentive of the water under all circumftances.

In Italy the fheep-flocks were regularly watered morning and evening, as is evident from Columella, and the practice has probably confiderable utility, efpecially in dry fituations.

Watering-*Syringe*, in *Gardening*, a large kind of garden fyringe employed for throwing water to fome height over trees or plants, in rather a forcible manner, in the way of a ftream, for clearing away infects and other matters, as well as fome other purpofes.

Watering *the Soil of Tillage Land*, in *Agriculture*, the practice of improving ploughed ground, and the crops upon it, by the application of water.

The outlines of a plan for watering arable or tillage crops and lands, that has long been familiar to the writer on the Management of Land, are firſt to form the ſoil into flat beds or ridges, with intervals, or trenches, directed ſomewhat obliquely acroſs the ſlope, or general deſcent of the field or ground; namely, ſo as to dip from one quarter to one half *per cent.* beneath the dead level; this declination being equally calculated to communicate and carry off water. The width of the beds is to be regulated by the nature of the land. Abſorbent ſoils may be laid into wider beds than thoſe which are repellent, or of the ſtiff heavy kind, that are leſs prone to draw away the water.

The depth of the trenches ſhould vary according to the quality of the water, and the intention of uſing it. For merely moiſtening the land, in a dry ſeaſon, with ordinary water, the trenches, it is conceived, ſhould be deep, ſo as to lodge the water in the ſubſoil, rather than the ſoil above it. But when an enriched water is to be uſed to fertilize the ſoil, and encourage the growth of the crop during its early ſtages, it requires to be communicated immediately to the paſture of the plants; conſequently, in this caſe, the beds ſhould be narrow, and the trenches no deeper than juſt to prevent the water from overflowing.

When the water is neceſſarily required to be conducted to the uppermoſt corner of the field or open ground, to be continued and conducted down the ſlope, acroſs the higher ends of the beds, and to be forced into the trenches, by the means of regulated checks, placed below their mouths, as occaſion may require; it ſhould be either ſuffered to run with moderate ſtreams along the trenches; or, if the quantity be ſmall in proportion to the extent of ground, it may be checked at proper diſtances, ſo that the whole of it ſhall be abſorbed, thus going over the ground, and repeating the watering as the quantity of water, or the ſufficiency of moiſture may direct.

Watering, in the *Manufactures.* To water a ſtuff is to give it a luſtre, by wetting it lightly, and then paſſing it through the preſs, or the calender, whether hot or cold. See Tabbying.

WATERLAND, Daniel, D.D. in *Biography*, was born in 1683, at Waſely, in Lincolnſhire, where his father was rector, and ſent to Magdalen college, Cambridge, in 1699, for the completion of his education; of this college he was elected a fellow in 1704, took his degree of M.A. in 1706, and became a private tutor. His tract, entitled "Advice to a young Student, with a Method of Study for four Years," publiſhed at this time, was popular, and paſſed through ſeveral editions. In 1713 he was nominated maſter of his college, and preſented to the rectory of Ellingham in Norfolk. On occaſion of taking his degree of B.D. in 1714, he diſtinguiſhed himſelf by defending before the regius profeſſor of divinity the negative of his theſis, "Whether Arian ſubſcription be lawful?" Being choſen chaplain in ordinary to king George I., he was nominated, on his majeſty's viſit to Cambridge, D.D., and incorporated in the ſame degree at Oxford. Diſtinguiſhed as a champion of orthodoxy by his "Vindication of Chriſt's Divinity, being a Defence of ſome Queries relating to Dr. Clarke's Scheme of the Holy Trinity," printed in 1719, he was appointed in the following year the firſt preacher of lady Moyer's lecture in favour of the divinity of Chriſt. He alſo publiſhed an anſwer to Dr. Whitby on the ſame ſubject, and in 1721 he was preſented by the dean and chapter of St. Paul's with the rectory of St. Auſtin and St. Faith. His "Hiſtory of the Athanaſian Creed," vindicating it againſt the objections of Dr. Clarke, was publiſhed in 1723, and his preferments to the canonry of Windſor, the vicarage of Twickenham, and the archdeaconry of Middleſex, kept pace with his publications of this nature. His remarks on Dr. Clarke's "Expoſition of the Church Catechiſm," printed in 1730, engaged him in a controverſy with Dr. Sykes on the ſacrament of the Lord's ſupper. Againſt Tindal's "Chriſtianity as old as the Creation," he publiſhed his "Scripture Vindicated," and his "Chriſtianity Vindicated againſt Infidelity." On theſe treatiſes, Dr. Middleton publiſhed remarks, and they were defended by Dr. Zachary Pearce. In 1734 Dr. Waterland made an attempt for refuting Dr. Clarke's opinions in a "Diſcourſe of the Argument *à priori* for proving the Exiſtence of a Firſt Cauſe;" and in this year, having declined the office of prolocutor of the lower houſe of convocation to which he was choſen, he publiſhed his treatiſe "On the Importance of the Doctrine of the Trinity," which he regarded as fundamental, avowing his high reſpect for the authority of the fathers in this and other articles of faith. In 1736 he commenced a ſeries of archdiaconal charges on the ſubject of the euchariſt, arguing againſt the opinion of Hoadley on the one hand, that it was a mere communicative feaſt, and againſt that of Johnſon and Brett, on the other, that it was a proper propitiatory ſacrifice. But a complaint under which he laboured, and which required repeated ſurgical operations, endured by him with exemplary patience, at length terminated his life in December 1740, in the 58th year of his age. A collection of his ſermons was publiſhed after his death. "As a controverſialiſt," ſays one of his biographers, "though firm and unyielding, he is accounted fair and candid, free from bitterneſs, and actuated by no perſecuting ſpirit." Gen. Biog.

Waterland, in *Geography*, an iſland in the South Pacific ocean, diſcovered by Le Maire and Schouten, in the year 1616. It is repreſented as a low uninhabited iſland, ſandy, and full of rocks, with plenty of trees on the border, but neither cocoa-nuts nor palmettoes. Some creſſes and Indian ſalad were found, and ſome freſh water in ditches. No ſoundings for anchorage were diſcovered. S. lat. 14° 46′. W. long. 149° 30′.

WATERLANDIANS, in *Eccleſiaſtical Hiſtory*, a ſect of thoſe that were called the groſs or moderate Anabaptiſts, conſiſting at firſt of the inhabitants of a diſtrict in North Holland, called *Waterland;* whence their name. They were alſo called Johannites from John de Reis, who, aſſiſted by Lubert Gerard, compoſed their confeſſion of faith in 1580. This confeſſion far ſurpaſſes, in reſpect both of ſimplicity and wiſdom, all the other confeſſions of the Mennonites; though it has been alleged, that it is not the general confeſſion of the Waterlandians, but that merely of the congregation, of which its author was the paſtor.

This community, ſays Moſheim, has abandoned the ſevere diſcipline and ſingular opinions of Menno, whom, nevertheleſs, they generally reſpect as their primitive parent and founder. They are, however, divided into two diſtinct ſects, which bear the reſpective denominations of Freislanders and Waterlandians; and are both without biſhops, employing no other eccleſiaſtical miniſters than preſbyters and deacons. Each congregation of this ſect is independent on all foreign juriſdiction, having its own eccleſiaſtical council or conſiſtory, which is compoſed of preſbyters and deacons. The ſupreme ſpiritual power is, nevertheleſs, in the hands of the people, without whoſe conſent nothing of importance can be carried into execution. Their preſbyters are, generally ſpeaking, men of learning, and apply themſelves with ſucceſs to the ſtudy of phyſic and philoſophy; and there is a public profeſſor, feffor, fupported by the fect at Amfterdam, for the inftruction of their youth in the various branches of philofophy, and facred erudition. One of thefe Waterlandian fects was divided, in 1664, into two factions, of which the one were called GALENISTS, and the other APOSTOOLIANS, from their refpective leaders. Mofheim's Eccl. Hift. vol. iv. vol. v.

WATERLOO, ANTHONY, in *Biography*, a Flemifh landfcape painter of great abilities, is generally fuppofed to have been born at Utrecht, about the year 1618; it is certain that he refided there the greater part of his life, and the fcenery of his pictures is found in the environs of that city.

His landfcapes are characterized by the greateft fimplicity of compofition; the entrance into a foreft, a broken road with a bank and a few trunks of trees, a folitary cottage, a mill, &c. are made interefting by the exquifite touch, and beautiful colour and chiaro ofcuro, with which he treated them. His fkies are clear, and his clouds float in air; his colouring, however, is fometimes too ftrongly contrafted with yellow foregrounds and blue diftances, and offend the eye for want of being more broken. He marked the characters of his trees admirably, in form and colour. His pictures are by no means common, as they are not numerous. He occupied himfelf very much in etching his own defigns and views, and his productions in that art are as valuable as his pictures, in point of truth and fkill; and will always continue to be a fource of pleafure and improvement to the artift and the connoiffeur. His plates, according to Bartfch, amount in number to 150, not entirely completed with the point, but finifhed with the graver, to foften and to invigorate them. It is to be lamented that he funk an early prey to habits of intemperance.

WATERLOO, in *Geography*, a village of the Netherlands, between 12 and 13 miles from Bruffels, fituated behind the fkirts of the fine beech foreft of Soignies, rendered famous by one of the moft fevere and fanguinary battles which modern hiftory of war records, fought in its vicinity on Sunday the 18th of June, 1815, between the duke of Wellington, who commanded the Britifh, Hanoverian, German, and Belgic army, and Napoleon Buonaparte, who conducted the operations of the French forces. The ground on which the battle was fought is faid not to exceed two miles from north to fouth, including the whole from the rear of the Britifh to the rear of the French pofition; and from eaft to weft, from the extremity of the left to that of the right wing of the contending armies, is about a mile and a half in extent; fo that the fanguinary refult of the battle has been attributed in fome degree to the limited fpace in which they were engaged, and the confequent intermixture of the two armies. The pofition of the French troops is reprefented as the beft, becaufe the eminence occupied by them was higher, and the afcent fteeper than ours, and better adapted to attack and defence. The village of Waterloo, which is not feen from the field of battle, was occupied on the Saturday night previous to the battle by the duke of Wellington, the principal officers of his ftaff, the prince of Orange, lord Uxbridge, fir Thomas Picton, fir William de Lancey, and other general officers. The French army in the Netherlands, is faid to have amounted to 130,000; and after the loffes of the 15th and 16th, and the detachment of two corps under marfhal Grouchy, there muft have remained at leaft 90,000 men, with which Napoleon took the field on the 18th of June; while, after allowing for the loffes of the allies on the 16th, which were very ferious, it muft appear that there was a great difparity in regard to numbers; as it may be deduced from a ftatement, founded upon the lateft return to the Horfe Guards, previous to the battles of the 16th and 18th, that the extreme force Britifh and German was 46,221 men, under the duke of Wellington, to which we may add 22,000 for Brunfwickers and Dutch, fo that the whole could not exceed 68,221 men; or, as it is elfewhere ftated, there could not be in action a greater number than 64,000 men to fupport the attack of the whole French army. From the adjutant-general's office, 6th November 1816, it appears that the effective ftrength of the Britifh army, prefent at the battle of Waterloo on the 18th of June 1815, was 74,040, including the army of obfervation. It is moreover obferved, that the hoftile army confifted of the beft troops of France; that it was a regular and difciplined army, even before the Bourbons quitted France, and that from the return of Buonaparte every thing had been done to render it effective; it was indeed the force which had been felected and combined to act upon the northern frontier. Whereas the allied army, the Britifh part excepted, was almoft wholly a green army; the allies, particularly the Dutch, Belgians, Hanoverians, and troops of Naffau, being chiefly young foldiers.

Previoufly to the grand and decifive battle of Waterloo, the campaign had commenced on the 15th of June by an attack upon the outpofts of the Pruffian army, commanded by field-marfhal prince Blucher. The points of concentration of the feveral corps of his army were, Fleurus, Namur, Ancy, and Hannut. Buonaparte advanced the fecond corps of his army by Thuin, along the banks of the Sambre, upon the town of Charleroi, and drove the advanced pofts of general Ziethen's corps back upon the bridge of Marchienne. After a very fmart action, the Pruffian general was obliged to retire behind the river, and collect his corps near Fleurus: and as he confidered Charleroi untenable, the troops ftationed in that town were withdrawn, and the French cavalry entered it about mid-day. The Pruffians defended their advanced pofts with bravery; and it was only the overwhelming force that was brought againft Ziethen's corps, which induced that general to withdraw his advance, in order that he might concentrate his whole force near Fleurus.

On the evening of this day an officer arrived at Bruffels from marfhal Blucher, to announce that hoftilities had commenced. The duke of Wellington received his difpatches, whilft he was fitting after dinner with a party of officers. The troops were ordered to hold themfelves in readinefs, to march at a minute's notice. Before midnight a fecond officer arrived from Blucher, and the difpatches were delivered to the duke of Wellington in the ball-room of the duchefs of Richmond; and he gave his orders to one of his ftaff-officers, who inftantly left the room. In the midft of the repofe that feemed to reign over Bruffels, the drums fuddenly beat to arms, and the loud call of the trumpet was heard from every part of the city. The whole town became inftantly an univerfal fhow of buftle. The foldiers affembled with their knapfacks, and every kind of warlike preparation threw the town into a ftate of agitation. But before eight in the morning, the ftreets, which had been filled with bufy crowds, were empty and filent; the great fquare of the Place Royale, which had been filled with armed men, and with all the appurtenances of war, was now quite deferted. The duke of Wellington had fet off in great fpirits, obferving, that as Blucher had moft probably fettled the bufinefs, he fhould perhaps return to dinner.

When the direction by which Buonaparte intended to penetrate into Belgium had been afcertained, the duke of Wellington immediately gave orders for the army under his command

command to concentrate on the extreme of its poſition, near the great road from Bruſſels to Charleroi, and in a line between Nivelles and Namur. The fifth diviſion of the Britiſh army, with the corps of the duke of Brunſwick-Oels, left Bruſſels about 2 A. M. on the 16th, and advanced towards the poſition where the whole army was ordered to aſſemble.

One brigade of the Dutch troops, which was in advance towards Charleroi, had been attacked, when the Pruſſians fell back on the 15th, and driven from its advanced poſition near Fraſnes; but the prince of Orange having moved up another brigade of the ſame army, they were able to repulſe the enemy, and in the evening they regained the greater part of the ground which had been loſt throughout the day. On the morning of the 16th, prince Blucher, who was determined to meet Buonaparte with all his ſtrength, had poſted the army under his command on the heights between the villages of Brie and Sombref, and to ſome diſtance beyond Sombref. In front of this line, he occupied the villages of St. Amand and Ligny with a very conſiderable force.

Buonaparte, as ſoon as he had paſſed the Sambre, directed the great body of his force againſt the Pruſſian line. Marſhal Ney, who commanded the left wing, was directed to advance by Goſſelies and Fraſnes, and attack the Britiſh poſition; his force conſiſting of the firſt and ſecond corps of infantry, and four diviſions of cavalry.

The third, fourth, and ſixth corps, with the guard in reſerve, were ordered to attack the Pruſſian poſition in front, while the fifth corps under Grouchy, and a diviſion of cavalry, were detached towards Sombref, on the Namur road, with the view of manœuvring on that flank.

On debouching from Fleurus, Buonaparte had an opportunity of reconnoitring the poſition of marſhal Blucher with more preciſion. He immediately placed the firſt corps belonging to the left wing under Ney, with two diviſions of heavy cavalry, behind the village of Fraſnes, on the right, and at a little diſtance from the Bruſſels road, where it was to form a reſerve, that could be brought up to ſupport either his attack upon the Pruſſians, or Ney's attack upon the Britiſh. The third corps was ordered to advance in column to carry the village of St. Amand, while the fourth corps, ſupported by the guard and the cavalry, was ordered to attack Ligny.

The enemy advanced in overpowering maſſes upon St. Amand, where the action firſt commenced on the morning of the 16th. The brave Pruſſians defended this part of their advanced poſition with great firmneſs, and it was not till after a long and ſanguinary conflict, that they were obliged to yield for a time to ſuperior numbers. The fourth corps commenced its attack upon the village of Ligny about mid-day, and by one o'clock P. M. the action may be ſaid to have become general throughout the whole of the extended line of the allied Britiſh and Pruſſian armies. Grouchy by that time had attacked the extreme left beyond Sombref, and Ney had come in contact with the advance of the army under the duke of Wellington, near Fraſnes. But it was in the villages of St. Amand and Ligny, that the greateſt ſtruggle for victory took place, between the contending armies. There the battle continued for five hours, it may be ſaid, almoſt in the villages themſelves, as the movements forwards and backwards, during that period, were confined to a very narrow ſpace. Freſh troops were conſtantly moved up on both ſides; and as each army had immenſe maſſes of infantry behind that part of the village which it occupied, theſe ſerved to maintain the combat, as they were continually receiving reinforcements from the rear. Upwards of 200 pieces of cannon were directed againſt the villages, and they were frequently on fire in many places.

About 4 o'clock, prince Blucher placed himſelf at the head of a battalion of infantry, and charged with them into the village of St. Amand. After a dreadful ſtruggle, he gained poſſeſſion of the greater part of it. The enemy were panic-ſtruck, and the victory ſeemed ſo doubtful, that Buonaparte was obliged to ſend in all haſte for the firſt corps, which he had left in reſerve near Fraſnes; at the very moment too, that it had become equally neceſſary to marſhal Ney, whoſe columns, having been repulſed by the fifth diviſion of Britiſh infantry, were retiring in great confuſion.

The advantage which Blucher had ſo nobly gained, was of little importance to the general action in which his troops were engaged. At Ligny, the battle ſtill raged with unabated vigour; and though the evening was far advanced, the victory remained undecided. The badneſs of the roads, and the difficulties which general Bulow had to encounter in his march, prevented his corps from getting up on the 16th; ſo that Blucher had only three corps of his army in poſition; and though they had repulſed every attack which had been made upon them, the danger was becoming urgent, as all the diviſions were engaged, or had already been ſo, and there was no reſerve at hand.

As the night advanced, the enemy, favoured by the darkneſs, made a circuit round the village of Ligny, with a diviſion of infantry on one ſide; and, without being obſerved, got into the rear of the main body of the Pruſſian army, at the ſame moment that ſome regiments of cuiraſſiers forced their paſſage on the other ſide of the village. This movement decided the day, and field-marſhal Blucher was obliged to commence his retreat; yet his brave columns, though ſurpriſed, were not diſmayed. They formed themſelves into ſolid maſſes, and, repulſing every attack which the enemy made upon them, retired in perfect good order to their original ground, upon the heights above the village, and from thence continued, unmoleſted, their retrograde movement upon Wavre.

This movement of the marſhal's rendered neceſſary a correſponding one on the part of the duke of Wellington; and he retired from the farm of Quatre Bras upon Genappe, and thence upon Waterloo, the next morning of the 17th at 10 o'clock.

The duke of Wellington, having given orders for the army under his command to concentrate on the left, proceeded with the fifth diviſion and the duke of Brunſwick-Oels' corps, in the direction of Charleroi. About two o'clock on the afternoon of the 16th, the head of the Britiſh column reached the farm of Quatre Bras, ſo named from its ſtanding near where the roads from Bruſſels to Charleroi, and from Nivelles to Namur, croſs each other. The advance of the enemy under Ney, who had again driven the Dutch troops from their poſition near Fraſnes, had nearly reached the ſame ſpot; and general Kempt's brigade had ſcarcely time to deploy from the great road, before it was attacked by the enemy's cavalry, ſupported by heavy maſſes of his infantry. Nothing could exceed the daring intrepidity of the French troops at this moment; their ſucceſs on the 15th, and confidence in their leader, added to the natural bravery of the troops, made them advance with almoſt a certainty of victory. The ſudden appearance of overwhelming maſſes of cavalry, and the rapidity with which they charged our infantry, before they had time to throw themſelves into ſquares, created ſome little confuſion in one or two regiments. Indeed, ſo daring were the

French

French cuiraffiers, that a regiment actually cut into the fquare of the forty-fecond Highlanders; but they paid dear for their temerity, as few ever returned to their lines; and the Highlanders had ample revenge for the lofs of their brave colonel fir Robert Macara. The third battalion of the Royal Scots, twenty-eighth, and firft battalion of the ninety-fifth, were warmly engaged for feveral hours on the left of the Bruffels road; while general Pack's brigade, confifting of the forty-fourth, feventy-ninth, and ninety-fecond regiments, with the forty-fecond already mentioned, fucceeded completely in repelling the enemy on the right, after an equally arduous conteft.

About 4 o'clock, the firft divifion under major-general Cooke, and third under lieutenant-general fir Charles Alten, came up, and were alfo immediately engaged. The enemy was now driven from his ground, and obliged to retire to the pofition which he had occupied the night before, and where he had fome difficulty in maintaining himfelf, until the darknefs put an end to the combat. The troops of the duke of Brunfwick diftinguifhed themfelves very much on the afternoon of the 16th; and his ferene highnefs was unfortunately killed at the head of his brave huffars.

At day-light on the morning of the 17th, the duke fhewed his whole force, and challenged the enemy to fight; but they did not feem difpofed to accept the challenge; and therefore both he and prince Blucher took up their refpective pofitions; their movements having been communicated to each other, and Blucher having been requefted to fupport the duke in cafe of an attack on the next day with two divifions of his army. On the 17th no movement of any confequence took place.

The pofition which the Britifh army now took up, had been chofen with great judgment, from its proximity to the extenfive foreft of Soignies. The village of Waterloo lies upon the great road from Bruffels to Charleroi, embofomed in the foreft; and a few fcattered houfes extend to another fmall village called Mont-Saint-John: about a quarter of a mile in front of this latter village, there is a rifing ground which croffes the great road already mentioned, and extends from a farm-houfe called Ter-la-Haye on the left, to the village of Merbe-le-Braine on the right, croffing alfo the road from Bruffels to Nivelles, which diverges from the road to Charleroi at the village of Mont-Saint-John. It was on this rifing ground that the allied army, commanded by field-marfhal the duke of Wellington, or more properly the firft corps of that army, took up its pofition on the evening of the 17th of June. The fecond corps, under the command of lord Hill, (with the exception of the fourth divifion and the troops of the Netherlands, under prince Frederick of Orange, who were left to guard an important pofition at Halle,) was placed in referve on the right of the pofition, and in front of the village of Merbe-le-Braine, with its right refting on Braine-la-Leud. The infantry bivouacked a little under the ridge of the rifing ground, and the cavalry in the hollow ground in rear of the infantry. Excepting a few round fhot which the enemy occafionally fired while our troops were deploying into their pofition, nothing of any moment occurred during that afternoon or the whole of the night.

It had rained almoft inceffantly during the greater part of the 17th, and the weather was very tempeftuous during the night. The ground afforded no cover for the troops; fo that generals, officers, and men, were equally expofed to the rain, which fell in torrents. Buonaparte flept at the farm-houfe of Caillou near Planchenois; and his army halted in the neighbourhood of Genappe. The duke of Wellington flept at a fmall public houfe in the village of Waterloo.

As foon as day-light appeared on the morning of the 18th, the Britifh army could perceive, from its pofition, immenfe maffes of the enemy moving in every direction, and before two o'clock the whole of his force appeared to be collected on the heights and in the ravines, which ran parallel with the Britifh pofition.

The French army, when concentrated in front of the pofition of the allies, confifted of four corps of infantry including the guard, and three corps of cavalry, the whole number of men being uncertain, and probably overrated by thofe who ftate them at 120,000.

At 11 o'clock every thing feemed to indicate that the awful conteft would foon commence;—a conteft in which victory was obftinately and valiantly difputed on both fides, but which at laft terminated in the complete triumph of the duke of Wellington, and total defeat and political annihilation of Buonaparte. The weather had cleared up, and the fun fhone a little as the battle began, and the armies within 800 yards of each other, the duke of Wellington, with his ufual quicknefs, had foon perceived the nature of the attacks that would be made upon his line; and when the troops ftood to their arms in the morning, he gave orders that they fhould be formed into fquares of half battalions, and in that ftate await the enemy's attack.

Marfhal Ney, as foon as Buonaparte's order was communicated to him, directed the divifion of infantry commanded by Jerome Buonaparte, to advance upon Hougomont; and about half paft eleven o'clock, the firft columns of this divifion made their appearance upon the ravine, or rather hollow ground, which leads down from the public-houfe of La Belle Alliance to the Chateau. The two brigades of artillery belonging to general Cooke's divifion had taken up a pofition on the ridge of the hill in front of the line of infantry, and the moment the enemy made his appearance, our nine-pounders opened upon his columns. The artillery officers had got the range fo accurately, that almoft every fhot and fhell fell in the very centre of his maffes; fo great was the effect produced by thefe few guns, that all Jerome's bravery could not make his fellows advance, and in a moment they were again hid by the rifing ground from under cover of which they had but juft emerged. This, which was the commencement of the action, was confidered a very favourable omen by our brave fellows who witneffed it; and for a fhort time they were much amufed with the manœuvres of Jerome's divifion, and the cautious manner in which it feemed to emerge from its hiding-place.

This ftate of things, however, did not continue long, as other great movements were obferved to be preparing throughout the enemy's line. A powerful artillery was brought to bear upon our guns that had fo annoyed his firft advance, and general Jerome's troops gained the outfkirts of the wood, where they became engaged with our light troops. By mid-day the cannonade was general.

The great object of Buonaparte, in this important battle, was evidently to force our centre, and at the fame time turn our right flank; fo that by furrounding and taking prifoners, as it were, one half of our line, he might completely paralyfe and deftroy the effect of the other half. Unfortunately, our centre was the weakeft part of our pofition, and upon that part he directed his firft grand attack to be made about noon.

An immenfe mafs of infantry, followed by a column of upwards of twelve thoufand cavalry, advanced upon the points occupied by the third and fifth divifions, and the left of the Guards, covered by a fire from upwards of one hundred pieces of artillery. Thefe columns, which feemed to advance with a certainty of fuccefs, were led by count d'Erlon in perfon. They advanced almoft to the muzzles of our mufkets; but here they foon found they had Britons to contend with; our fellows gave them a volley; and, cheering, rufhed on to the charge, which they did not ftand to receive, and our cavalry emerging from the hollow ground where they had hitherto been concealed from the enemy's view, paffed through the openings between the fquares, and charging the enemy's cavalry, fucceeded completely in difperfing them, and driving them back upon their own line.

In this conflict, which was dreadful while it lafted, the enemy was baffled in all his attempts, and, befides the killed and wounded, loft feveral thoufand prifoners and an eagle; but the Britifh army had alfo to lament the lofs of its brighteft ornaments, and his majefty, one of his beft officers. The gallant fir Thomas Picton fell, mortally wounded, in leading on the fifth divifion.

About 3 o'clock, when Buonaparte found that Jerome's divifion could not drive the guards from Hougomont, he ordered the chateau to be fet on fire. The fhells from feveral mortars which were brought to bear upon the houfes, foon had the defired effect: but our troops, retiring into the garden, did not yield one inch of their ground; and the only thing which the enemy gained by this cruel meafure, was the deftruction of a few of our wounded, who were too ill to be removed, and who fell a prey to the flames. The troops in La Haye Sainte, having expended their ammunition, were obliged to retire for a moment from that point, and the enemy got poffeffion of the houfe and garden; but as foon as a reinforcement of our troops could be moved up, he was driven from that as well as from every other point which he had attacked: and at no period during the day, notwithftanding the heavy maffes of infantry and cavalry which were advanced againft our centre, time after time, was he ever able to force our pofition; and the poffeffion of the advanced poft of La Haye Sainte for a few minutes, may be faid to have been the greateft advantage he ever gained. The battle continued to rage with unabated fury, and the number of brave men who were continually falling on both fides was very great, while the rapidity with which the columns of attack fucceeded each other, feemed to indicate for a time, that the refources of the enemy were inexhauftible. The artillery on both fides was well ferved: but Buonaparte had upwards of two hundred and fifty pieces in the field; while the train of the allied army under the duke of Wellington did not exceed one hundred guns, nine-pounders and fix-pounders. Notwithftanding our inferiority in this arm, which was ftill more apparent from the fize of the enemy's guns (being twelve-pounders) than from their numbers, ours were fo well fought, that it is allowed by all, they did equal execution.

About 2 o'clock, the duke of Wellington difpatched an officer of his ftaff to the head-quarters of field-marfhal Blucher, to afcertain his movements, and to know when it was probable his advance would come in contact with the enemy. This officer found the Pruffian general at the village of Lafnes, where he gained the information required.

At half paft 7 o'clock, the iffue of the battle was ftill doubtful. The greater part of lord Hill's corps of the Britifh army had been moved up at different periods to the fupport of the firft corps. The whole of Bulow's corps, and part of the fecond corps of the Pruffian army, had arrived at their pofition near Frichermont, and their attack in that direction was fufficiently powerful to oblige the enemy to give way on his right; which Buonaparte having obferved, conceived that the moment was now arrived when he muft put an end to the engagement. He informed his generals that the firing on the right was occafioned by the arrival of Grouchy's corps. This gave frefh hopes to his troops already beginning to defpair, and immediately he gave orders to form the laft column of attack. This column was compofed principally of the guard, which had hitherto fuffered but little; he gave directions for the whole of the line to fecond this effort, upon which he faid the victory depended, and placing himfelf at their head, they advanced in double quick time.

Thefe veteran warriors, fo long efteemed the firft troops in Europe, advanced acrofs the plain which divided the two armies, with a firmnefs which nothing could exceed; and though our grape and canifter fhot made dreadful havoc in their ranks, they were never difconcerted for a fingle moment. Our infantry remained firm in their pofition, until the enemy's front line was nearly in contact with them, when, with the ufual falute of a well-directed volley, and a Britifh cheer, they rufhed on to the charge with bayonets. This charge even the Imperial guard could not ftand againft, and thofe undaunted troops, who at one time confidered themfelves the conquerors of the world, were obliged to give way. In this attack the Britifh and French guards were, for the firft time, perhaps, fairly oppofed to each other. The fhock for a moment was dreadful. The enemy refufed to take or give quarter, and the carnage was horrible. At laft the whole of their ranks was broken, all difcipline was at an end, and they began to give way in the utmoft confufion. The duke of Wellington, who was on the fpot, was not inattentive to the manner in which the enemy retired from this attack, and, though his left was ftill preffed, he ordered the whole line of infantry, fupported by the cavalry and artillery, to advance. This order was no fooner given, than our brave fellows rufhed forward from every point. In a moment they carried the enemy's pofition, and obliged him to retire in great diforder, leaving in our poffeffion a number of prifoners, and upwards of one hundred and fifty pieces of cannon, with their ammunition, befides two eagles. Before the diforganized maffes of the French had cleared the ravine by which they retired, the right and left of the Britifh line were nearly in contact, and the enemy in a manner furrounded. What added greatly to the confufion of the beaten foe, was a gallant charge by general Ziethen's corps upon his right flank, at the moment the Britifh advanced in front. Blucher, who had joined with his firft corps at the time this decifive charge was going on, advanced with his gallant troops; and about nine o'clock the two field-marfhals met at the fmall public-houfe called La Belle Alliance, and mutually faluted each other as victors.

The Britifh army, which had been fo warmly engaged for upwards of nine hours, was now halted, and the purfuit left to the brave Pruffians. Though they had already marched many leagues, all fatigue was forgotten when in the prefence of their enemy. About half-paft nine field-marfhal Blucher affembled the whole of his fuperior officers, and gave orders for them to fend every man and horfe in purfuit.

It is not eafy to afcertain the number of thofe who were killed and wounded, from the 15th to the 18th days of June inclufively. The lofs of the guards, in killed and wounded, in the defence of Hougomont, amounted to 28 officers, and about 800 rank and file. The foreign corps (Naffau and Brunfwickers) loft about 100. Within half an hour, it is faid, 1500 men were killed in the fmall orchard

of

of about four acres at Hougomont. The loſs of the French was enormous. The diviſion of general Foy alone loſt about 3000, and their total loſs in the attack of this poſition is eſtimated at 10,000 in killed and wounded. Above 6000 men of both armies periſhed in the farm of Hougomont; 600 French fell in the attack on the chateau and the farm; 200 Engliſh were killed in the wood; 25 in the garden; 1100 in the orchard and meadow; 400 near the farmer's garden; 2000 of both parties behind the great orchard. The bodies of 300 Engliſh are buried oppoſite the gate of the chateau; thoſe of 600 French have been burnt at the ſame place. The wounded at Quatre Bras, 16th of June, are ſtated upon the report of the adjutant-general, to be 5000; but no eſtimate is given of the killed, who muſt have been very numerous. On occaſion of Blucher's retiring to Wavre, he is ſaid to have had 14,000 men killed and wounded. The loſs of the Britiſh, as ſtated in a letter dated June 19th, ſince the 16th, muſt have exceeded 5000. In the battle of Ligny and Quatre Bras, Napoleon is ſaid to have loſt 10,000 men. The total of the killed and wounded of the Britiſh ſoldiers, as returned from the War-office July 1815, amounts to 9755 perſons. The total of the killed, wounded, and miſſing of the royal artillery in the battles of the 16th and 18th of June 1815, comprehends 32 officers, 15 ſerjeants, 285 rank and file, and 529 horſes. The loſs of the Dutch in killed, wounded, and miſſing, is ſtated to be 4136. The Pruſſians are ſaid to have loſt 33,120.

According to the French accounts their loſs, at the battle of Fleurus on the 15th, was 10 killed and 80 wounded, and that of their enemy 2000, of whom 1000 were priſoners. The loſs of the Pruſſians on the 16th could not be leſs, as they ſay, than 15,000 men, and their own 3000 killed and wounded. At Quatre Bras they ſay, that the Engliſh loſt from 4 to 5000 men; and that theirs, which was very conſiderable, amounted to 4200 killed and wounded. They make no ſtatement of that of the 18th.

The total loſs of the Britiſh, Hanoverians, and German legions from official reports, from June 16th to the 26th, 1815, is 11,084; and the computed loſſes of the Dutch and Pruſſians during the campaigns in the Netherlands were, that of the Dutch as above ſtated 4136, and that of the total Pruſſian loſs 33,132.

It appears from the liſt of killed and wounded from the official returns, June 16 to June 26, 1815, that an immenſe number of officers, ſeveral of whom were high in rank, is included in one or other of theſe claſſes. In the former, are the names of the duke of Brunſwick-Oels, colonel Cameron, lieutenant-colonel Canning, lieutenant-colonel ſir F. d'Oyly, colonel ſir H. W. Ellis, lieutenant-colonel ſir A. Gordon, colonel ſir W. de Lancey, and colonel ſir R. Macara, lieutenant-general ſir T. Picton, major-general ſir W. Ponſonby, &c. &c.; and in the latter we find the prince of Orange, the earl of Uxbridge, colonel Hon. A. Abercromby, lieutenant-general ſir C. Alten, major-general ſir E. Barnes, major Beckwith, lieutenant ſir H. Berkeley, lieutenant-colonel ſir H. Bradford, major Cameron, lieutenant-colonel Cameron, lieutenant-colonel R. H. Cooke, colonel ſir J. Ellay, captain Hon. E. S. Erſkine, lieutenant-colonel ſir R. C. Hill, lieutenant-colonel Macdonald, colonel Hon. F. Ponſonby, lieutenant-colonel Fitzroy Somerſet, earl of Uxbridge, &c. &c.

After the moſt diligent reſearch, amidſt confuſed and contradictory accounts, it is difficult, if not impoſſible, to aſcertain the exact number of the killed and wounded, on both ſides, in this ſanguinary and deciſive conflict.

Honourable and proſperous as was the iſſue of this battle, we cannot forbear regretting that ſo many valuable lives ſhould be ſacrificed on occaſions of this kind, and we alſo lament the condition of thoſe who are wounded and maimed, and rendered helpleſs for the reſidue of their years. We applaud the ſpirit that has actuated ſuch multitudes, and diſpoſed them to confer honour on the name and memories, or to impart to the ſuccour and ſupply, of thoſe who have fallen or ſuffered in the ſervice of their country.

The ſingular importance of this victory, the pre-eminent talents of the commander-in-chief, and the heroiſm diſplayed by the officers, commiſſioned and non-commiſſioned, and by all the privates, on this intereſting occaſion, entitled them to the gratitude of the government and of the country, and to ſuch tokens of reſpect as were thought to be moſt appropriate to the occaſion. Accordingly, it was reſolved on the 23d of June, that the thanks of both houſes of parliament ſhould be given to his grace the duke of Wellington, prince Blucher, and the allied armies, officers and ſoldiers. The prince regent alſo granted the dignity of a marquis to earl Uxbridge and his heirs. The houſe of commons agreed June 29th 1815, in an addreſs to the prince regent, requeſting him to direct a national monument to be erected in honour of the ſplendid victory of Waterloo, and to commemorate the fame of the officers and men of the Britiſh army, who fell glorioufly upon the 16th and 18th of the ſaid month; and more particularly of lieutenant-general ſir Thomas Picton, and major-general the Hon. ſir William Ponſonby; and that funeral monuments be alſo erected in memory of each of theſe two officers in the cathedral church of St. Paul, London. The prince regent has alſo been pleaſed, in the name and on behalf of his majeſty, to grant promotion to 52 majors, recommended for brevet-rank, for their conduct in the battle of Waterloo, to be lieutenant-colonels in the army; and to 36 captains to be majors, with commiſſions reſpectively, dated from June 18, 1815. His royal highneſs has alſo appointed major-general ſir James Kempt, to be knight grand croſs of the moſt honourable military order of the Bath; and major-generals G. Cooke, Maitland, and F. Adam, to be knights commanders of the ſaid order, and a number of other officers to be companions of the moſt honourable military order of the Bath, upon the recommendation of the duke of Wellington. The king of the Netherlands has given the duke of Wellington the title of prince of Waterloo, and the ſtates-general have ſettled upon his family an eſtate annually producing 20,000 Dutch florins, (2000*l.*) conſiſting of woods, &c. in the neighbourhood of La Belle Alliance, Hougomont, &c. The king of Saxony has alſo conferred upon the duke his family order of "The Crown of Rue:" and the grand duke of Baden has conferred upon him his order of "Fidelity" of the firſt claſs, accompanied with a gold ſnuff-box, enriched with diamonds of great value. The emperor of Auſtria has conferred upon a number of officers the croſs of a commander, and of a knight reſpectively of the order of "Maria Thereſa." The emperor of Ruſſia has alſo conferred decorations of different claſſes of the orders of St. George, Anne, and Wladimir, on a number of officers. The king of the Low Countries has alſo conferred decorations of different claſſes of the "Wilhelm's" order upon certain officers. The king of Bavaria has conferred decorations of the different claſſes of the order of "Maximilian Joſeph," on certain officers; all theſe in teſtimony of their reſpective approbation of their ſervices and conduct. The prince regent has granted the dignity of a baron of the United kingdom of Great Britain and Ireland unto the right honourable lieutenant-general Rowland baron Hill and to his heirs; and in token of his high approbation of the diſtinguiſhed bravery and

and good conduct of the firſt and ſecond life-guards at the battle of Waterloo, he has declared himſelf colonel in chief of both theſe regiments. He alſo declares that he ſhall approve all the Britiſh regiments of cavalry and infantry which were engaged in the battle of Waterloo, being permitted to wear on their colours and appointments, in addition to all other badges and devices, the word "Waterloo," in commemoration of their diſtinguiſhed ſervices on the 18th of June 1815; and he alſo approves of all the enſigns of the three regiments of foot-guards having the rank of lieutenants, and that ſuch rank ſhall be attached to all the future appointments to enſigncies in the foot-guards, in the ſame manner as the lieutenants of thoſe regiments obtain the rank of captain; and he alſo approves of the firſt regiment of foot-guards being a regiment of grenadiers, and ſtyled "The Firſt or Grenadier Regiment of Foot-Guards." An alteration has alſo taken place in regard to the penſions allowed to wounded officers in favour of thoſe who have ſerved in the battle of Waterloo; and it is alſo ordered that henceforth every non-commiſſioned officer, trumpeter, drummer, and private man, who ſerved in the battle of Waterloo, or in any of the actions which immediately preceded it, ſhall be borne upon the muſter-rolls and pay-liſts of their reſpective corps as "Waterloo Men;" and that every "Waterloo Man" ſhall be allowed to count two years' ſervice in virtue of that victory, in reckoning his ſervices for increaſe of pay, or for penſion when diſcharged.

It is alſo ordered, that the lieutenants of cavalry and infantry, who had ſerved more than five years as ſuch, on the 18th of June 1815, or who may ſubſequently have completed that period of ſervice, are to receive one ſhilling *per diem* for every day's ſervice as lieutenant beyond five years, it being fully underſtood that the retroſpect is, in no inſtance, to exceed two years. In like manner, the corporals and privates, diſtinguiſhed as "Waterloo Men," are to receive the benefit of the two years' ſervice retroſpectively, in caſes in which, by the addition of the two years, they would have completed their reſpective terms of ſervice, on or previouſly to the 18th of June 1815, and the two years' ſervice will, of courſe, be reckoned in all claims ſubſequently accruing.

Sir Charles Alten is honoured with the title of count, and the Hanoverian troops, who were preſent in the battle, may bear on their colours and uniform the word "Waterloo." Other regiments alſo that are particularly ſpecified, are to have the word "Waterloo" in commemoration of their diſtinguiſhed ſervices, June 18th, 1815. The prince regent has commanded, that in commemoration of the brilliant and deciſive victory of Waterloo, a medal ſhall be conferred upon every officer, non-commiſſioned officer, and ſoldier of the Britiſh army, preſent upon that memorable occaſion. It is alſo appointed, that from the date of the battle of Waterloo, 18th June 1815, the penſions to officers and widows ſhall increaſe according to the officer's further advance.

It is a farther inſtruction with regard to the Waterloo grant, that lieutenants of cavalry and infantry, who had ſerved more than five years on the 18th of June, are to receive one ſhilling *per* day for every day beyond five years' ſervice, provided the retroſpect be not beyond two years: non-commiſſioned officers and privates are alſo to benefit proportionately from the ſame retroſpect. The charge for officers is to be made in their ordinary accounts; thoſe for men diſtinct in a pay liſt ſupplementary, according to a preſcribed form.

Prize-money was alſo granted by parliament to the army which ſerved under the command of field-marſhal his grace the duke of Wellington in the battle of Waterloo and capture of Paris. This was advertiſed in the London Gazette, June 21, 1817. Thoſe ſhares that have not been claimed before the 24th of September 1817, may afterwards be received from the deputy treaſurer of Chelſea hoſpital, if claimed within the period of ſix years.

The ſhares of each individual in the following claſſes are:

Commander-in-chief's proportion is eſtimated at	£61,000	0	0
Claſs 1. General officers	1,274	10	10¾
2. Field-officers and colonels	433	2	4¼
3. Captains	90	7	3¾
4. Subalterns	34	14	9½
5. Serjeants	19	4	4
6. Corporals, drummers, and privates	2	11	4

Notice has alſo been given in the Dutch, Flanders, and German papers, that his highneſs the prince of Waterloo, duke of Wellington, has given orders for the payment of the prize-money to all the allied troops, who fought under his command at Quatre Bras and Waterloo, at the taking of Paris.

His highneſs has fixed the proportions into claſſes as above. This diſtribution includes the Dutch, Belgic, Naſſau, Hanoverian, and Brunſwick troops.

The total amount of receipts for the Waterloo ſubſcription to May 31, 1817, has been 518,288*l.* 9*s.* 11*d.* The total expenditure for payments and donations, and incidental charges, leaves a balance at the bankers 18th of June 1817 of 1,222*l.* 13*s.* 5*d.*

Statement of the appropriation is as follows:

Annuities granted for Life.

To the widows of officers, non-commiſſioned officers, and privates killed	£9,594	
To the wounded non-commiſſioned officers, and privates totally diſabled	1,649	
To dependent relatives	540	
Amount of annuities for life		11,783

Annuities granted for limited Periods.

To the children of officers, non-commiſſioned officers, and privates	8,314	
To orphans	895	
Amount of annuities for limited periods		9,209
Total amount of annuities		20,992

Voted in Money.

To the wounded officers, non-commiſſioned officers, and privates		71,126
To the parents and dependent relatives of officers, non-commiſſioned officers, and privates killed, leaving no widows or children		28,577

To the Foreign Troops, viz.

Pruſſians, Brunſwickers Hanoverians, and Netherlanders	45,000	
Additional for the excluſive benefit of their orphans rendered ſuch by the campaign of 1815	17,500	
		62,500
Total amount voted in money		162,203

A conſiderable ſubſcription, amounting to 3905*l.* 14*s.* 9*d.* received

received from Demerary, has been lately announced, February 24, 1818.

On the ſecond anniverſary of the battle of Waterloo, the noble ſtructure of the bridge over the Thames from Surrey to the ſcite of the Savoy, was firſt opened for public accommodation; and with a view of commemorating the ever-memorable victory of Waterloo, its name was changed from that of the "Strand Bridge," to the more dignified and triumphal appellation of "Waterloo Bridge." The ceremony was conducted with great dignity and ſplendour.

This bridge exhibits a very ſtriking diſplay of the eminent abilities and taſte of Mr. Rennie, the engineer, as well as of the liberality of the proprietors, who have provided the funds neceſſary for its conſtruction. Its ſituation is judiciouſly ſelected, as, independently of the advantage which commerce and the convenience of perſonal intercourſe may derive from it, it gives the grandeſt view we have of the river in its beautiful meander, diſplays the riſing creſcent of buildings on the north ſide, and brings out Somerſet Terrace in the moſt favourable way; while on the ſouth it opens the beautiful proſpect of the Surrey hills.

The following are ſome detailed particulars of the bridge, which is conſtructed of Corniſh granite; the baluſtrades are of granite from Aberdeen.

Dimenſions of the Bridge.

		Feet.
The length of the ſtone bridge within the abutments		1,242
Length of the road ſupported on brick arches on the Surrey ſide of the river - -		1,250
Length of the road ſupported on brick arches on the London ſide - - - - -		400
Total length from the Strand, where the building begins, to the ſpot in Lambeth where it falls to the level of the road - - -		2,892
Width of the bridge within the baluſtrades -		42
Width of pavement or foot-way on each ſide -		7
Width of road for horſes and carriages -		28
Span of each arch - - - -		120
Thickneſs of each pier - - -		23
Clear water-way under the nine arches, which are equal, 120 ft. each - - -		1,080
Brick arches on the Surrey ſide -	40	
Ditto on the London ſide - -	16	
Granite ditto for the water-courſe -	9	
Total number of arches from the Strand to the Lambeth level - -	65	

In building the arches, the ſtones (ſome of which weigh upwards of ſix tons) were ſo accurately jointed and carefully laid, that upon the removal of the centres, none of the arches ſunk more than an inch and a half. In ſhort the excellency of the workmanſhip vies with the beauty of the deſign, and with the ſkill and arrangement, to render the "Bridge of Waterloo" a monument of the public ſpirit, taſte, and glory of the age, of which the metropolis, and the Britiſh empire, have abundant reaſon to be proud.

We ſhall cloſe our account of the battle of Waterloo, with ſtating a fact not unworthy of being recorded. The ſtates-general deſiring to give to his royal highneſs the prince of Orange a teſtimony of the national gratitude, for the bravery which he employed, as well in the defence of the poſition of Quatre Bras as at the battle of Waterloo, have propoſed to his majeſty, to purchaſe at the expence of the State a palace, ſituated in the city of Bruſſels, which, after being properly furniſhed, may be given in full property to his royal highneſs the hereditary prince, as well as the park of Toweuren, in the foreſt of Soigné, with a hunting-ſeat; and that theſe eſtates be transferred to the prince of Orange, free of all charges and expence. His majeſty approved of this propoſal. See Battle of Waterloo, &c. 2 vols. 8vo. London, 1817.

WATERMEN are ſuch as row in boats, or ply on the river Thames, ultimately ſubject to the direction and government of the lord-mayor of London, and court of aldermen, who ſettle their fares, and, as well as other juſtices of peace, have authority to hear and determine offences, &c.

The names of watermen are to be regiſtered; and their boats muſt be twelve feet and a half long, and four and a half broad, or be liable to forfeiture; and watermen, taking more than the fares aſſeſſed, ſhall forfeit 40*s.*, and ſuffer half a year's impriſonment; and refuſing to carry perſons for their fare, ſhall be impriſoned for twelve months. None ſhall ply on the river, but ſuch as have been apprentices to watermen for ſeven years. 2 & 3 P. & M. cap. 16. 29 Car. II. cap. 7.

The lightermen and watermen conſtitute a company; and the lord-mayor and aldermen yearly elect eight of the latter, and three of the former, to be rulers, and the watermen chooſe aſſiſtants; the rulers and aſſiſtants being empowered to make rules, which are required to be obſerved, under penalties. The rulers on their court-days ſhall appoint forty watermen to ply on Sundays, for carrying paſſengers acroſs the river, who pay them for their labour, and apply the overplus to the poor decayed watermen; and no perſons are allowed to travel on a Sunday with boats, unleſs they are licenſed and allowed by a juſtice, on pain of forfeiting 5*s.* 11 & 12 W. III. cap. 21.

No apprentice ſhall take upon him the care of a boat, till he is ſixteen years of age, if a waterman's ſon, and ſeventeen, if a landman's, unleſs he hath worked with ſome able waterman for two years, under the penalty of 10*s.*; and if any perſon, not having ſerved ſeven years to a waterman, &c. row any boat in the river Thames for hire, he ſhall forfeit 10*l.*, gardeners' boats, dung-boats, fiſhermen's, wood-lighters, weſtern barges, &c. excepted. No apprentice is to be taken under fourteen years, who ſhall be bound for ſeven years, and inrolled in the book of the watermen's company, on pain of 10*l.* No tilt-boat, row-barge, &c. ſhall take more than thirty-ſeven paſſengers, and three more by the way; nor any other boat above eight, and two by the way, on forfeiture of 5*l.* for the firſt offence, and 10*l.* for the ſecond, &c. And in caſe any perſon be drowned, where a greater number is taken in, the waterman ſhall be deemed guilty of felony, and tranſported. 10 Geo. II. cap. 31.

Tilt-boats uſed between London-bridge and Graveſend ſhall be fifteen tons, and the other boats three tons. Rulers of the watermen's company are required to appoint two officers, one at Billingſgate at high-water, and another at Graveſend, to ring a bell for the tilt-boats, &c. to put off; and thoſe which do not immediately proceed with two ſufficient men, ſhall forfeit 5*l.* The fares of watermen, aſſeſſed by the court of aldermen, are, from London-bridge to Lime-houſe, Ratcliffe-croſs, &c. for oars 1*s.*, and ſcullers 6*d.*; Wapping-dock, Rotherhithe-church ſtairs, &c. for oars 6*d.*, and for ſcullers 3d.; from either ſide of the water above the bridge to Lambeth and Vauxhall, for oars 1*s.*, and ſcullers 6*d.* For all the ſtairs between London-bridge and Weſtminſter, oars 6*d.*, and ſcullers 3*d.*

WATERS, among *Farriers*, the name given to a diſtemperature of horſes. See WATERY *Sores.*

WATERSAY, in *Geography*, one of the Weſtern iſlands of Scotland, about one mile ſouth from South-Uiſt, from which it is ſeparated by a channel, called "Chiſamul Bay." This iſland is about three miles long, and one broad. N. lat. 56° 54'. W. long. 7° 30'.

WATERTIGHT STUFF denotes clay, or any other tenacious and compact ſoil, which will hold water.

WATERTOWN, in *Geography*, a town of Maſſachuſetts, in the county of Middleſex, containing 1531 inhabitants; 7 miles W.N.W. of Boſton.—Alſo, a town of Connecticut, in the county of Litchfield, containing 1714 inhabitants; 26 miles N.N.W. of New Haven.

WATERTOWN, a poſt-townſhip of New York, the capital of Jefferſon county, and a place of depoſit for the military ſtores of the ſtate of New York. It lies near the mouth of Black river, about 80 miles N.W. of Utica, and was firſt created into a town in March 1810, from a part of Mexico, then in Oneida county, and compriſed alſo Rutland and Hounsfield. Its extent is about ſix miles ſquare. The inhabitants are principally emigrants from the eaſtern ſtates. Here are about 200 dwelling-houſes, eight ſchool-houſes, a court-houſe and gaol, together with a lodge and arſenal for military ſtores. Here are alſo eight griſt and ſaw-mills, one paper-mill, one wool-carding machine, five diſtilleries, two breweries, a printing-office and weekly paper, a ſmall air-furnace, and many common mechanics. It promiſes to be a place of much buſineſs. Pot and pearl aſhes are manufactured in abundance, and ſent in boats to Montreal. By the cenſus of 1810, the population conſiſts of 1849 perſons; and here are 308 ſenatorial electors.

WATERTOWN, or *Jefferſon Village*, is a flouriſhing poſt-village of Watertown, in Jefferſon county, on the ſouth bank of Black river, four miles from Brownville, and at the ſame diſtance from navigable water communicating with lake Ontario. The village contains about 50 dwelling-houſes, ſome of which are elegant. In its vicinity are a quarry of good building lime-ſtone, clay, and ſand. Pine and other timber are plentiful.

WATERVILLE, a town of the diſtrict of Maine, and county of Kennebeck, containing 1314 inhabitants.

WATERVLIET, a large townſhip of New York, in the north-eaſt corner of Albany county, 6 miles N. of Albany; extending 10 miles along the Mohawk, and 6½ miles along the Hudſon, and having an area of about 52 ſquare miles, excluſive of ſeveral iſlands in the Hudſon. Much of the land is poor and barren, and the population is very unequally diſtributed. Along the Hudſon are ſome fine flats, and in many places the river-hills are moderately ſteep, and afford good farming lands. The interior abounds with ſandy ridges, ſome marſhes, and wet land, wooded with pine and a variety of dwarf ſhrubbery, of little value. In this townſhip are two ſmall villages, *viz.* Waſhington, five miles north of Albany, and Gibbon's Ville, oppoſite Troy, ſix miles. The Cahoos, which are the principal falls of the Mohawk, are between Watervliet and Halfmoon, in Saratoga county. The whole river Mohawk deſcends in one ſheet at high water, about 70 feet; and below the falls the ſpreading branches form iſlands, which are attached to this town: theſe are Haver iſland, Van Schaick's iſland or Cahoos iſland, and Green iſland In this town are 1092 white males, 1070 white females, 128 ſlaves, and 75 other perſons; in all 2365; and 215 ſenatorial electors. The ſettlement of the people called "Shakers" lies in the north-weſt part of this town, at a place called Niſkayuna, 8 miles N.W. of Albany. They have a houſe of worſhip, and the village contains about 150 houſes. A manufactory of iron ſcrews has lately been erected on the Mohawk, near Cahoos bridge.

WATERVLIET, a town of Flanders; 12 miles E. of Sluys.

WATERY HEAD. See HYDROCEPHALUS.

WATERY *Humour*. See AQUEOUS and HUMOUR.

WATERY *Lands*, in *Agriculture*, all ſuch as are largely impregnated with and retentive of moiſture or wetneſs.

Wherever water reſts much upon lands, it ſours them, and deſtroys the finer herbage; the remaining plants being made to become coarſe and ſtrong, but moſtly unpalatable, and of little value for ſtock. They ſhould, of courſe, have the ſuperabundant water removed from them, and then be improved by ſuitable ſubſtances applied as manures, and by other means, ſuch as being flooded, in ſome caſes.

By ſuch methods, according to the nature of their wetneſs, ſuch lands may moſtly be brought into a good ſtate of improvement. See BOG, FEN, MORASS, MARSH, and SWAMP; alſo the lands of their ſeveral natures.

WATERY *Poke*, a name ſometimes given to a diſeaſe in ſheep, from their having a ſort of poke or bag hanging below the top of their throats, ſuppoſed to be cauſed by water. See SHEEP and ROT.

WATERY *Sores*, diſeaſes of the legs and paſterns of horſes and ſome other animals, in which there are watery ſwellings and ſores, which diſcharge an acrid watery fluid. They moſtly ariſe from bad feeding, and improper management in dreſſing and the uſe of exerciſe.

The cure will commonly be effected by giving ſtrengthening remedies, with calomel and ſquills in moderate doſes, and by the gradual uſe of elaſtic bandages to the parts.

WATFORD, in *Geography*, a market-town in the hundred of Caſhio, and county of Hertford, England, is 8 miles S.E. from St. Alban's, 20 miles W.S.W. from the county-town, and 14 miles N.W. from London. Previous to the Conqueſt, Watford formed part of Caſhio, and under that appellation was given by king Offa to the abbey of St. Alban's, to which it continued attached till the time of the diſſolution, when the ſtewardſhip of this and other adjacent manors was given to John, lord Ruſſel. James I., in the ſeventh year of his reign, granted Watford to the lord chancellor Egerton, in whoſe deſcendants, the dukes of Bridgewater, it remained veſted till about the year 1760, when it was purchaſed by the then earl of Eſſex, and is now the property of the preſent earl. The town conſiſts principally of one ſtreet; the houſes being ranged on the ſides of the high road, and extending in a north-weſterly direction rather more than a mile. The buildings are chiefly of brick, and many of them very reſpectable. The police is under the direction of the reſident and neighbouring magiſtrates. A market, which is now held on Tueſdays, was granted to the abbots of St. Alban's for Watford by Henry I.; and Edward IV. gave them liberty to hold two annual fairs, which are now increaſed to four. The market-houſe is a long building, rough-caſt above, and ſupported on wooden pillars beneath. Corn is ſold here in very large quantities; and the number of cattle, ſheep, calves, and hogs, is proportionable. Employment for the labouring claſſes is chiefly derived from agriculture; but an additional ſource is furniſhed by the throwing of ſilk, three ſilk mills having been eſtabliſhed in or near the town. The pariſh of Watford comprehends, with the town, the hamlets of Caſhio, Leveſdon, and Oxhey. In the population return in the year 1811, the number of inhabitants was ſtated to be 3976, occupying 766 houſes. The church, a very ſpacious edifice, conſiſts of a nave, three aiſles, and a chancel; with a maſſive embattled tower at the weſt end, about 80 feet high. The church contains ſeveral fine monuments, among which are two by Nicholas Stone. At the ſouth ſide of the church-yard is a free-ſchool, founded and endowed in the year 1704, by Mrs. Elizabeth Fuller, for the education and clothing of forty boys and twenty girls: the government is veſted in nine truſtees, choſen out of the principal inhabitants of the town. Here are alſo eight alms-houſes, for the maintenance of ſo many poor widows.

About

About one mile north-west of the town is *Cashiobury*, the seat of the earl of Essex. The mansion is a spacious edifice, situated in an extensive and well-wooded park, through which flows the river Gade; and to which is the line of the Grand Junction Canal. The house was originally begun in the time of Henry VIII. by Richard Morison, esq., and completed in the style of that age by his son, sir Charles Morison. It has since been greatly altered and improved, particularly under the direction of the present noble owner, and contains a number of elegant apartments, together with a kind of cloister, the windows of which have been recently ornamented with painted glass, executed in a very superior style. In its general appearance, the whole mansion, with its offices, has the character of a monastic dwelling. The rooms are adorned with numerous portraits, and other pictures of the first degree of merit. The park is between three and four miles in circumference, and affords rich scenery and noble timber; the pleasure-grounds and gardens are extensive, and have lately undergone some judicious alterations. A particular description of this splendid seat, by Mr. Britton, is contained in Havell's "Views of Gentlemen's Seats," &c. which also contains a print of it.—Salmon's History of Hertfordshire, fol. 1728. Beauties of England and Wales, vol. vii. Hertfordshire, by E. W. Brayley, 1808.

WATH, in *Rural Economy*, a term often used provincially to signify a ford.

WATHULT, in *Geography*, a town of Sweden, in the province of Smaland; 47 miles W.N.W. of Wexio.

WATKIN's POINT, a cape on the S.W. coast of Maryland, in the Chesapeak. N. lat. 37° 59′. W. long. 76°.

WATLING's ISLAND, one of the Bahama islands, about 18 miles long, and 4 broad. N. lat. 23° 50′. W. long. 74° 16′.

WATLING-*Street*, in *Roman Antiquity*. See WAY.

WATLINGTON, in *Geography*, a small market-town in the hundred of Pirton, and county of Oxford, England, is situated between the two high roads leading from London to Oxford, about half a mile N. by W. from the Ikeneild-street, at the distance of 5 miles S. from Tetsworth, 15 miles S.E. from Oxford, and 46 miles W. by N. from London. The streets are narrow, and the houses, with a few exceptions, mean and ill built. There is no staple manufacture of any consequence: the making of lace, however, prevails to some extent, and forms the chief employment of the labouring females. A school has been formed expressly for the purpose of teaching this art, and is usually attended by from forty to fifty pupils. The town is watered on the south side by a brook, rising in the vicinity, which now works, within two miles from its source, four corn-mills. A weekly market is held on Saturdays, which was originally granted to Roger Bigod, earl of Norfolk, in the reign of Richard I. But this market is thinly attended; and the business of the day is invariably conducted in the parlours of the principal inn. Here are likewise two annual fairs. In the centre of the town is the market-house, a substantial building, erected by Thomas Stonor, esq. in the year 1664: he also founded and endowed a grammar-school for ten boys; according to the will of the donor, the master was to be a graduate of one of the universities; but imperative circumstances have caused this article to be dispensed with: four boys have been added to the original number, and the whole are taught in a commodious room above the market-house, in which are likewise held the courts leet and baron of the manor. The magistrates hold a petty sessions once in a fortnight during the winter, but in summer not so often. According to the population return of the year 1811, this town then contained 239 houses, the number of inhabitants being 1150, which was a decrease of 156, since the enumeration of the year 1801. The church is a respectable ancient building, situate N.W. of the town: in the chancel are several neat monuments, and a handsome burial-place of the Horne family. Lands and tenements have been left by will for the repairs of the church, without any parish-rate for that purpose; and there have also been considerable sums bequeathed for the use of the poor. Previous to the Reformation, the abbot and canons of Osney were patrons, to whom the church was appropriated in 1263, by the bishop of Lincoln. In this parish was anciently a chapel, founded by the lord of the manor of Watcomb; but on a complaint made by the abbot and canons of Osney, pope Urban III. dissolved it: no traces can now be discovered of the scite occupied by this structure. Wesleyan Methodists and Baptists have each a place of worship in the town; but the number of these societies is comparatively small. The Methodists were established here during the life of John Wesley, who occasionally preached in the open street: a substantial meeting-house has lately been erected, but not more than thirty persons are in the habit of attending. The Baptists are scarcely so numerous; and their meetings are held in a very humble building. The manor of Watlington was given by Henry III. in 1231, to his brother Richard, earl of Cornwall. By Edward II. it was granted to Piers Gaveston. On his disgrace it reverted to the crown, and was given by Edward III. to sir Nicholas De la Becke, who obtained permission, in 1338, to build a spacious castle, some traces of which were discernible within the last century. The building stood on a slightly elevated spot to the south-east of the church, and it may yet be perceived that the structure was encompassed by a moat. King Charles I. granted the manor, in 1628, to four citizens of London, who sold it in the following year. Soon after this period it became so divided and parcelled out, that in the year 1664 there were about fifty persons participating in the manorial rights; and previous to the enclosure of the parish, which took place in 1809, the shares of the manor were sixty-four in number.

On *Britwell-hill*, about a quarter of a mile east of the Ikeneild-street, some remains of trenches point out the scite of an ancient encampment.

Within half a mile from Watlington is one of the most complete agricultural establishments to be found in the county. The whole of the very extensive farm-yard is encompassed by buildings covered with slate, and presents the spectacle of a new and handsome village. This noble range was erected under the immediate inspection of William Hayward, esq., and was completed in the space of one year. His primary object appears to have been to produce utility on the simplest and most scientific plan.

About a mile to the north of Watlington is Pirton, an inconsiderable village, though it gives name to the hundred. Near Pirton is *Shirbourn-Castle*, the seat of the earl of Macclesfield. A castellated edifice was first erected on this spot in the fourteenth century by sir Wariner de l'Isle. The castle and manor were purchased at the beginning of the eighteenth century by Thomas, earl of Macclesfield. The building forms an oblong square, and is encompassed by a broad and deep moat, over which are three draw-bridges; the chief entrance is guarded by a portcullis: at each angle of the edifice is a circular tower. The interior is disposed in a style of modern elegance and comfort that contains no allusion to the external character of the structure, except in one long room fitted up as an armoury, and containing coats of mail, shields, tilting-spears, and offensive arms of a modern as well as ancient date. A park of about sixty acres is attached

attached to the manſion.—Beauties of England and Wales, vol. xii. Oxfordſhire. By J. N. Brewer, 1813.

WATO, a town of Sweden, on an iſland in the Baltic, near the coaſt of the province of Upland; 10 miles E.N.E. of Nortelge. N. lat. 59° 54′. E. long. 18° 43′.

WATOLMA, a town of Sweden, in the province of Upland; 10 miles N. of Upſal.

WATRAP, a town of Hindooſtan, in Madura; 33 miles S.W. of Madura.

WATSCH, or VATSCHE, a town of the dutchy of Carniola; 16 miles S.E. of Stein.

WATSNESS, a cape on the weſt coaſt of the iſland of Shetland. N. lat. 60° 19′. W. long. 2° 6′.

WATSON, ROBERT, D.D., in *Biography*, a Scottiſh hiſtorian, was born at St. Andrew's about the year 1730, commenced his courſe of education for the miniſtry at the ſchool and univerſity of St. Andrew's, and with ſingular aſſiduity proſecuted his ſtudies at the univerſity of Glaſgow, and alſo in that of Edinburgh. He paid particular attention to grammar and eloquence, and with the advice of lord Kaimes, delivered a courſe of lectures on theſe ſubjects, which gained the approbation of Mr. Hume, and other men of genius and learning. Having failed in his endeavours to ſupply a vacancy in one of the churches of St. Andrew's, he was ſoon after made profeſſor of logic, and by a patent from the crown, profeſſor of rhetoric and belles lettres. In his lectures on logic and metaphyſics, he deviated from the old plan of ſyllogiſms, modes, and figures, and introduced ſubſtantial improvement by furniſhing his pupils with an analyſis of the powers of the mind, and by leading them to inveſtigate the various kinds of evidence, of knowledge or truth. His hiſtory of Philip II. advanced his reputation during the period of his life; and it was farther enhanced by his hiſtory of Philip III., which was publiſhed after his death; of which latter he only wrote the firſt four books, the other two being ſupplied by Dr. William Thomſon, the editor, at the deſire of the guardians of his children. He ſucceeded Tulideph as principal of the univerſity by the intereſt of the earl of Kinnoul; but his death, in 1780, ſoon deprived him of this honour. By his wife, who was daughter of Mr. Shaw, profeſſor of divinity in St. Mary's college, St. Andrew's, he had five daughters, who ſurvived him. Gen. Biog.

WATSON, RICHARD, an Engliſh prelate, eminently diſtinguiſhed by his talents, acquirements, and character, was born at Haverſham, in Weſtmoreland, in Auguſt 1737. He was the deſcendant of an ancient family, deriving its remote origin from Scotland, and occupying, for ſeveral generations, a ſmall eſtate at Hardendale, near Shap, where his father was born in the year 1672. In 1698 his father was appointed head maſter of Haverſham-ſchool, which he conducted with great reputation for nearly forty years. Among other pupils who enjoyed the benefit of his inſtruction, we may mention Ephraim Chambers, the well-known author of the Dictionary of Arts and Sciences (ſee his article), Mr. Preſton, afterwards biſhop of Ferns, in Ireland, and the ſubject of this memoir. To this ſchool belonged two exhibitions, (now of 50*l.* a year each,) one to Trinity college, in Cambridge, and the other to Queen's college, Oxford; the former of which was enjoyed by Mr. Preſton, and afterwards by his ſchool-fellow, Mr. Watſon. In the year 1788, theſe two ſcholars, being then biſhops, teſtified their regard for the place of their education by repairing the ſchool-houſe, and by affixing to it a Latin inſcription, expreſſing their reſpect for the memory of its pious founder, and of Mr. Watſon's father. To his mother alſo Mr. Watſon pays a tribute of grateful and affectionate remembrance, deſcribing her as a charitable and good woman, to whom he was indebted for imbuing his young mind with principles of religion, which never forſook him; and obſerving more generally, that "the care of the mother precedes that of the ſchool-maſter, and may ſtamp upon the *raſa tabula* of the infant mind, characters of virtue and religion which no time can efface." Soon after the death of his father, in November 1753, Mr. Watſon was ſent to the Univerſity, and admitted a ſizer of Trinity college, in Cambridge, on the 3d of November, 1754. Apprized that his patrimony, which was 300*l.*, would be barely ſufficient to defray the charges of his education, and having no expectations from any of his relations, he determined to fabricate his own fortune, and applied with aſſiduity and ardour to his academic ſtudies. Before he had been ſix months at college, a circumſtance occurred which indicated his talents for metaphyſical diſquiſition, and which contributed in no ſmall degree to his reputation in this department of ſcience. As he attended the college-lectures, which were then delivered to the under-graduates in the hall, immediately after morning-prayers, during term-time, he was aſked by Mr. Brocket, the head lecturer, whether Clarke had demonſtrated the abſurdity of an infinite ſucceſſion of changeable and dependent beings? to which queſtion he replied *non;* and being aſked his reaſons for ſo thinking, he ſtammered out, as he ſays, in barbarous Latin, "that Clarke had enquired into the *origin* of a ſeries, which, being from the ſuppoſition *eternal*, could have no origin; and into the *firſt* term of a ſeries, which, being from the ſuppoſition *infinite*, could have no firſt." This circumſtance was recollected four years afterwards, when he took his bachelor's degree, and laid the foundation of his acquaintance with Dr. Law, then maſter of Peterhouſe, and reckoned one of the beſt metaphyſicians of his time; from which he derived, as he acknowledges, much knowledge and liberality of ſentiment in theology. Not ſatisfied with his rank of ſizer, he aſpired to a ſcholarſhip, and ſucceeded in obtaining it, on the 2d of May, 1757, a year before the uſual time. Thus advanced in rank, his expences increaſed, but they were more than counterbalanced by the advantage attending it. Dr. Smith, who was then maſter of the college, took occaſion to nominate him to a particular ſcholarſhip (lady Jermyn's); and at the ſame time recommended Saunderſon's Fluxions, juſt publiſhed, and ſome other mathematical books, to his peruſal; thus, as he ſays, "giving a ſpur to my induſtry, and wings to my ambition." At this time he had reſided in college two years and ſeven months, without leaving it for a ſingle day; and during this period, he had acquired ſome knowledge of Hebrew, improved himſelf greatly in Greek and Latin, made conſiderable proficiency in mathematics and natural philoſophy, and ſtudied with much attention Locke's Works, King's book on the Origin of Evil, Puffendorf's Treatiſe "De Officio Hominis et Civis," and ſome other books on ſimilar ſubjects. Conceiving himſelf entitled to ſome degree of relaxation, he ſet out, in May, 1757, on a viſit to his elder and only brother at Kendal, who was the firſt curate of a new chapel erected there, and to the building of which he had liberally contributed. This brother lived freely, ſpent his fortune, injured his conſtitution, and died when the ſubject of our memoir was about the age of 33. With the affection of a brother and ſingular liberality, he paid his debts, to the amount of almoſt his whole property. In the beginning of September he returned to college, with a purpoſe to make his alma mater the mother of his fortunes. He was then only a "junior ſoph;" but ſuch was his reputation, that he was ſolicited to become private tutor to Mr. Luther and Dr. Strachey. From the

time

time in which he undertook this charge he was employed for thirty years, and as long as his health lafted, in inftructing others, without much inftructing himfelf, as he fuggefts, and in prefiding at difputations in philofophy or theology, from which, after a certain time, he derived little intellectual improvement. Addicted, whilft an under-graduate, to affociate with thofe whom collegians call the beft company, fuch as idle fellow-commoners, and other perfons of fortune: he foon perceived that he was purfuing a miftaken courfe: and this conviction was more fenfibly felt, when he often faw, on his return home at one or two in the morning, from fome of his evening feftivities, a light in the chamber of a fellow-ftudent of the fame ftanding with himfelf. His jealoufy was thus excited, and the fucceeding day was always devoted to hard ftudy; nor would he allow himfelf the leifure for dinner. In his folitary walks he profecuted the ftudy of mathematics and philofophy without book, or pen and paper; and went through tedious and intricate demonftrations by the mere exercife of his mental powers. Thefe walks were fo frequent, that among thofe who did not know how he was employed, he incurred the charge of being a lounger; but the fequel of his hiftory fufficiently proves the injuftice of the charge.

Whilft abftract ftudies occupied his chief attention, he did not neglect other purfuits. Every day he impofed upon himfelf the tafk of compofing a theme in Latin or Englifh. Among the firft of his compofitions of this kind, the fubject of that written in Englifh was "Let tribunes be granted to the Roman people," and that of the Latin was "Sociis Italicis datus Civitas:" the fubjects of both were fuggefted to him by a perufal of Vertot's "Roman Revolutions;" and to his account of this incident he adds, "Were books of fuch kind put into the hands of kings during their boyhood, and Tory-trafh at no age recommended to them, kings in their manhood would fcorn to aim at arbitrary power through corrupted parliaments." He alfo introduces this reflection on the choice of his fubjects: "They fhew that a long commerce in the public world has only tended to confirm that political bent of my mind in favour of civil liberty, which was formed in it before I knew of what felfifh and low-minded materials the public world was made." In the courfe of Mr. W.'s claffical reading, to which he devoted the afternoon, whilft the morning was occupied by mathematics, he informs us, that Demofthenes was the orator, Tacitus the hiftorian, and Perfius the fatirift, whom he moft admired. At an early period of his life, Mr. W. inclined to the opinion which has in later times been more prevalent, that the foul is not a diftinct fubftance from the body; though he profeffes not to have troubled himfelf much with perplexing difquifitions concerning liberty and neceffity, matter and fpirit; fhewing, however, on all occafions, his faith in Chriftianity, as founded on teftimony, and more efpecially on the teftimony concerning the refurrection of its divine founder; and his belief of a future ftate of retribution and immortality. His fpeculations on matter and fpirit are not likely, in our judgment, to illumine the darknefs, and to refolve the difficulties that involve this fubject. As to the ftory, recorded in the French Encyclopædia (art. *Mort*), of a man who came to life after having been fix weeks under water, we cannot help confidering it as fabulous; but whether it be true or falfe, it appears to us to afford little fatiffaction with regard to the queftion in difpute. Nor does his reafoning about the effential properties of extenfion, folidity, mobility, divifibility, and inactivity, as common properties, belonging equally to a table, tree, oyfter, and man, and the addition of life to the matter of the tree, of life and perceptivity to that of the oyfter, and to that of the man, life, perceptivity, and thought, feem to have given very great fatisfaction to himfelf. "Whether life can exift without perceptivity," he fays, "or perceptivity without thought, are fubtle queftions, not admitting perhaps, in our prefent ftate, a pofitive and clear decifion either way. Phyfical and metaphyfical difficulties prefent themfelves on every fubject, and ultimately baffle all our attempts to penetrate the darknefs in which the divine mind envelopes his operations of nature and grace."

In January 1759, Mr. W. took his degree of bachelor of arts. In the firft year of his being moderator, he introduced an alteration in the mode of obtaining this degree, which has been continued ever fince. "At the time of taking it, the young men are examined in claffes, and the claffes are *now* formed according to the abilities fhewn by individuals in the fchools. By this arrangement, perfons of nearly equal merits are examined in the prefence of each other, and flagrant acts of partiality cannot take place. Before this alteration was made, they were examined in claffes, but the claffes confifted of members of the fame college, and the beft and the worft were often examined together." In the firft year of his being moderator, Mr. Paley, afterwards fo well known, and a Mr. Frere of Norfolk, were examined together; and Mr. Paley, being Mr. Frere's fuperior, was made fenior wrangler, though it was reported that the grandfather of Mr. Frere had propofed to give 1000*l.* if he were admitted to this honour. This gentleman afterwards candidly acknowledged that he deferved only the fecond place; and this declaration was obvioufly the refult of their having been examined together. One of the queftions propofed by Mr. Paley for his act was "Æternitas pœnarum contradicit Divinis attributis." This queftion, though accepted by Mr. W., occafioned an alarm; but in order to allay all difquieting apprehenfions, Mr. P. was allowed to put in *non* before *contradicit*, and the alarm fubfided. This, however, fays Mr. W., is a fubject of great difficulty. "It is obferved, on all hands, that the happinefs of the righteous will be, ftrictly fpeaking, everlafting; and I cannot fee the juftnefs of that criticifm which would interpret the fame word in the fame verfe in a different fenfe. (Matt. xxv. 46.) On the other hand, reafon is fhocked at the idea of God being confidered as a relentlefs tyrant, inflicting everlafting punifhment which anfwers no benevolent end. But how is it proved that the everlafting punifhment of the wicked may not anfwer a benevolent end, may not be the means of keeping the righteous in everlafting holinefs and obedience? How is it proved, that it may not anfwer, in fome other way unknown to us, a benevolent end in promoting God's *moral* government of the *Univerfe*?"

In October, 1760, Mr. W. was elected a fellow of Trinity college, although by that appointment he was put over two of his feniors of the fame year; and in the following November became affiftant tutor to Mr. Backhoufe. Soon after this he declined accepting the curacy of Clermont; and he alfo relinquifhed his defign of going out as chaplain to the factory at Bencoolen. "You are far too good," faid the mafter of the college to him, "to die of drinking punch in the torrid zone." Afterwards he reflected with gratitude and felf-complacency on his difappointment of an opportunity of becoming an Afiatic plunderer. "I might not," he fays, "have been able to refift the temptation of wealth and power, to which fo many of my countrymen have yielded in India."

At the commencement of 1762 he took his degree of M.A., and in the following October was made moderator for Trinity college. In his "Memoirs," he recites the queftions which were at that time the fubjects of fcholaftic exercifes,

ercifes, and from their nature and variety he juftly infers the importance of thefe exercifes.

In February 1764 an occafion was afforded him of manifefting his friendly attachment to Mr. Luther, one of the members for Effex, who had been formerly his pupil, and his difinterefted anxiety for his happinefs. Having heard that he had feparated from his wife, and was haftily gone abroad, he immediately prepared to feek him, and to impart to him, if poffible, fome confolation. Although he had no money, and could not fpeak a word of French, he determined on his journey; and having borrowed 50*l.*, and provided a French and Englifh Dictionary, he pofted to Dover, and haftened to Paris, where he found his difconfolate friend. After twelve hours ftay at Paris, he returned to England; and having croffed the channel four times, and travelled 1200 miles in very bad weather within a fortnight, he brought his friend back to his country and his family. Of Mr. Luther, he fays that "he was a thorough honeft man, and one of the friends I ever loved with the greateft affection."

In November 1764, he was unanimoufly elected by the fenate to fucceed Dr. Hadley, as profeffor of chemiftry; and though at this time he knew nothing of chemiftry, he procured an operator from Paris, and immured himfelf in his laboratory, fo that in 14 months from his election he read a courfe of chemical lectures to a very full audience, and another in November 1766. For the fourth time he was made moderator in October 1765, and in 1766 made his laft fpeech in Latin to the fenate. Befides other improvements in the univerfity education, which he had propofed on former occafions, he now recommended the inftitution of public annual examinations, in prefcribed books, of all the orders of ftudents. In 1774 this fubject was revived and enforced by Mr. Jebb. The defign was unequivocally approved by the chancellor of the univerfity, the duke of Grafton. After a long difcuffion of the fubject, the regulations drawn up by the fyndics were propofed to the fenate, and were rejected by the "Non Regent Houfe," 47 againft 43. In 1764 application was made for a ftipend to the profeffor of chemiftry; and after confiderable delay, 100*l.* a year was obtained: and this grant paved the way for fimilar ftipends to the profeffors of anatomy, botany, and common law. In October 1767, Mr. Watfon fucceeded Mr. Backhoufe as head tutor in Trinity college, and, for the fhort period during which he retained the office, difcharged its duties with confcientious diligence. "In this," he fays, "and the two following years, I read chemical lectures to very crowded audiences, in the month of November. I now look back with a kind of terror at the application I ufed in the younger part of my life. For months and years together, I frequently read three public lectures in Trinity college, beginning at 8 o'clock in the morning; fpent four or five hours with private pupils, and five or fix more in my laboratory, every day, befides the incidental bufinefs of prefiding in the fophs fchools."

In 1768 he compofed and printed his "Inftitutiones Metallurgicæ," and about the fame time prefented to the Royal Society a paper on the folution of falts, and was elected a fellow of that fociety. In the following year he publifhed his Affize Sermon, which he dedicated to Mr. Luther. Upon the vacancy in the office of regius profeffor of divinity, occafioned in October 1771 by the death of Dr. Rutherforth, Mr. Watfon propofed to become a candidate; but he was then neither bachelor nor doctor in divinity; and without being one of thefe, he could not be admitted as a candidate. Prompt, however, in the execution of all his meafures, though he had only feven days for the accomplifhment of his object, he obtained the king's mandate for a doctor's degree, and was created a doctor on the day previous to that appointed for an examination of the candidates. The fubjects on which he was to write were, the reconciliation of the genealogies in Matthew and Luke, and the interpretation of the paffage, "What fhall they do that are baptized for the dead?" 1 Cor. xv. 29. He was alfo appointed to read a Latin differtation on Gen. x. 32.

At length he was unanimoufly elected, having, as he fays, by hard and inceffant labour for 17 years, attained, at the age of 34, the firft office for honour in the univerfity, and, exclufive of the mafterfhip of Trinity college, he made it the firft for profit; having advanced it from 330*l.* a year to at leaft 1000*l.* Having been promoted to this honourable and important office, he devoted himfelf, with his accuftomed refolution and perfeverance, to the ftudy of divinity; making the Bible the object of his inveftigation, and feeling no concern about the opinions of councils, fathers, churches, bifhops, or other men, as little infpired as himfelf. Although he was called by the mafter of Peterhoufe, αυτοδιδακτος, the felf-taught divine; and though the profeffor of divinity had been nicknamed "Malleus Hæreticorum," he profeffes that his mind was wholly unbiaffed; without prejudice againft or predilection for the church of England; and actuated only by a fincere regard for the church of Chrift, and an infuperable objection to every degree of dogmatical intolerance. "I never troubled myfelf," thus he proceeds, "with anfwering any arguments which the opponents in the divinity fchools brought againft the articles of the church, nor ever admitted their authority in decifion of a difficulty. But I ufed, on fuch occafions, to fay to them, holding the New Teftament in my hand, '*En facrum codicem!* Here is the fountain of truth; why do you follow the ftreams derived from it by the fophiftry, or polluted by the paffions of men? If you can bring proofs againft any thing delivered in this book, I fhall think it my duty to reply to you: articles of churches are not of divine authority; have done with them; for they may be true, they may be falfe; and appeal to the book itfelf.' This mode of difputing gained me no credit with the hierarchy; but I thought it an honeft one, and it produced a liberal fpirit in the univerfity."

About the clofe of the year 1771 our author printed an Effay on the fubject of chemiftry, which was difperfed among fome few friends; but it was unjuftly charged by the authors of the "Journal Encyclopedique," with favouring the "Syfteme de la Nature." The author remonftrated, and the periodical journalifts made an apology. In the following year Dr. Watfon publifhed two letters to the members of the houfe of commons, under the feigned name of a Chriftian Whig, the fecond of which was infcribed to fir George Savile. In 1773, upon maturely weighing the queftion concerning the abftract right which a national church may claim of requiring fubfcription to human articles of faith from its public minifters, he publifhed "A brief State of the Principles of Church Authority," which he delivered as a charge to the clergy of his diocefe, in June 1813. In this tract it is maintained, that every church has a right of explaining to its minifters what doctrines it holds; and of permitting none to minifter in it, who do not profefs the fame belief with itfelf. With refpect to another queftion, *viz.* whether the majority of the members of any civil community have a right to compel all the members of it to *pay* towards the maintenance of a fet of teachers appointed by the majority to preach a particular fyftem of doctrines, this may admit a ferious difcuffion. Our author once thought the majority had this right in *all* cafes, and he afterwards apprehended that they have it in *many*. But a cafe may happen,

happen, in which the eſtabliſhed religion of a country may be the religion of a minority of the people, that minority at the ſame time poſſeſſing a majority of the property, out of which the miniſters of the eſtabliſhment are paid; and if this ſhould occur, our author ſeems to be undecided in his judgment. His ſentiments as to the *expediency* of requiring from the miniſters of the eſtabliſhed church a ſubſcription to the preſent articles of religion, or to any human confeſſion of faith, further than a declaration of belief in the ſcriptures, as containing a revelation of the will of God, may be collected from his two pamphlets, ſubſcribed " A Chriſtian Whig," and " A Conſiſtent Proteſtant."

In adverting to theſe tracts, our author reflects with ſatisfaction on the coincidence of his ſentiments, on many points civil and religious, with thoſe of biſhop Hoadly, though he has been ſarcaſtically and injuriouſly called " A republican biſhop."

On the 21ſt of December 1773, Dr. Watſon married the eldeſt daughter of Edward Wilſon, eſq. of Dallum Tower, in Weſtmoreland; and the connection was a ſource of uninterrupted ſatisfaction and felicity. Having obtained, by the intereſt of the duke of Grafton with the biſhop of St. Aſaph, a ſinecure in Wales, he exchanged it, by the ſame intereſt, on his return to Cambridge, for a prebend of Ely; and this favour was granted, though the duke and Dr. Watſon held different political opinions. They afterwards differed alſo in their religious ſentiments; the duke having avowed himſelf an Unitarian. Referring to him under this denomination, Dr. Watſon, with laudable liberality, declares, " that he is happy in ſeeing a perſon of his rank profeſſing with intelligence and ſincerity Chriſtian principles. If any one thinks that an Unitarian is not a Chriſtian, I plainly ſay, without being myſelf an Unitarian, that I think otherwiſe."

Dr. Watſon's political principles are well known. From his earlieſt youth to his dying day he was a Whig, in that ſenſe of the term which is well underſtood, and need not here be explained. In 1776 it came to his turn to preach the reſtoration and acceſſion ſermons before the univerſity; and they were both printed. The firſt was entitled " The Principles of the Revolution vindicated." Although it was written with great caution, a report was circulated in London that it was treaſonable; but when Mr. Dunning (afterwards lord Aſhburton) was aſked what he thought of it, he replied, " that it contained ſuch treaſon as ought to be preached once a month at St. James's." However, it gave great offence to the court, and, in Dr. Watſon's opinion, continued to be an obſtacle to his preferment. The author was much abuſed, in conſequence of the publication of this ſermon, by miniſterial writers, as a man of republican principles; but by Mr. Fox, and others of his claſs, it was very highly commended.

In the ſame year, 1776, Dr. Watſon publiſhed his " Apology for Chriſtianity," in reply to Mr. Gibbon's obnoxious chapters in his " Hiſtory of the Decline and Fall of the Roman Empire." His treatment of the hiſtorian was liberal and conciliatory, and was acknowledged with great courteſy and reſpect. In February 1780, Dr. Watſon preached, at the requeſt of the vice-chancellor, the faſt ſermon before the univerſity, which became very popular, and was widely circulated. In May of this year he publiſhed a charge to the clergy of the archdeanery of Ely, at his firſt viſitation; the primary object of which charge was to recommend an eſtabliſhment at Cambridge, for the expreſs purpoſe of tranſlating and publiſhing Oriental MSS., wherever found. Dr. Keene, biſhop of Ely, expreſſed his approbation of this charge; but as he reflected on the author's politics, he retorts it by obſerving in a letter to his lordſhip, " My politics may hurt my intereſt, but they will not hurt my honour. They are the politics of Locke, Somers, and Hooker; and in the reign of George II., they were the politics of this univerſity." In February 1781, our author was preſented by the duke of Rutland with the rectory of Knaploft, in Leiceſterſhire; and as he was juſt then printing the firſt two volumes of Chemical Eſſays, he availed himſelf of this opportunity of dedicating them to his grace. In 1782, Soame Jenyns publiſhed his Diſquiſitions on various ſubjects, the ſeventh of which advanced principles very oppoſite to thoſe which were contained in the " Principles of the Revolution vindicated," with occaſional glances at that ſermon. Although our author was ſcarcely recovered from a dangerous illneſs, he drew up, in the courſe of a few hours, " An Anſwer to the Diſquiſitions, &c." Upon a change of miniſtry, lord Shelburne was induced to confer the biſhopric of Landaff on Dr. Watſon; and on the 26th of July 1782, he kiſſed hands on his promotion. But he was not very much gratified by this advancement; becauſe lord Shelburne had expreſſed to the duke of Grafton his expectation that he would occaſionally write a pamphlet for their adminiſtration. The duke, however, did the new prelate the juſtice to aſſure his lordſhip, that he had totally miſtaken the character of the biſhop; for though he might write as an abſtract queſtion, concerning government, or the principles of legiſlation, it would not be with a view of aſſiſting any adminiſtration. " I had written," ſays the independent and high-ſpirited biſhop, " in ſupport of the principles of the revolution, becauſe I thought thoſe principles uſeful to the ſtate, and I ſaw them vilified and neglected. I had taken part in their petitions againſt the influence of the crown, becauſe I thought that influence would deſtroy the conſtitution, and I ſaw that it was increaſing. I had oppoſed the ſupporters of the American war, becauſe I thought that war not only to be inexpedient, but unjuſt. But all this was done from my own ſenſe of things, and without the leaſt view of pleaſing any party: I did, however, happen to pleaſe a party, and they made me a biſhop. I have hitherto followed, and ſhall continue to follow, my own judgment in all public tranſactions: all parties now underſtand this, and it is probable that I may continue to be biſhop of Landaff as long as I live. Be it ſo. Wealth and power are but ſecondary objects of purſuit to a thinking man, eſpecially to a thinking Chriſtian." Lord Shelburne ſeems to have courted an intimate acquaintance with the biſhop; alleging that he had Dunning to aſſiſt him in law points, and Barry in army concerns, and expreſſing his wiſh to conſult him in church matters. The biſhop availed himſelf of this overture, and propoſed to the miniſter a plan by which ſervice might be done to religion and to the eſtabliſhed church. Being invited to dine with his lordſhip, he put into his hand a paper, containing the following ſcheme of reform, comprehending the doctrine, the juriſdiction, and the revenue of the church of England. The two following hints on the ſubject of the revenue he ſubmitted to the conſideration of his lordſhip:—" Firſt, a bill to render the biſhoprics more equal to each other, both with reſpect to income and patronage; by annexing, as the richer biſhoprics became vacant, a part of their revenues, and a part of their patronage, to the poorer. By a bill of this kind, the biſhops would be freed from the neceſſity of holding eccleſiaſtical preferments *in commendam;* a practice which bears hard on the rights of the inferior clergy. Another probable conſequence of ſuch a bill would be, a longer reſidence of the biſhops in their ſeveral dioceſes; from which the beſt conſequences fequences both to religion, the morality of the people, and to the true credit of the church, might be expected: for the two great inducements to wifh for tranflations, and confequently to refide in London, namely, fuperiority of income, and excellency of patronage, would in a great meafure be removed. Second, a bill for appropriating, as they become vacant, one half, or a third part, of the income of every deanery, prebend, or curacy, of the churches of Weftminfter, Windfor, Canterbury, Chriftchurch, Worcefter, Durham, Ely, Norwich, &c. to the fame purpofes, *mutatis mutandis*, as the firft fruits and tenths were appropriated by queen Anne. By a bill of this kind, a decent provifion would be made for the inferior clergy, in a third or fourth part of the time which queen Anne's bounty alone will require to effect it. A decent provifion being once made for every officiating minifter in the church, *the refidence of the clergy in their cures might more reafonably be required* than it can be at prefent, and the licence of holding more livings than one be reftricted." Lord Shelburne wifhed to be informed if nothing could be gotten from the church to relieve the burdens of the ftate; to which the bifhop replied, that the whole revenue of the church would not yield, if it were equally divided, which could not be thought of, above 150*l*. a year to each clergyman, which could not be thought too ample; and in a political view it would be highly inexpedient, unlefs government would be contented to have a beggarly and illiterate clergy, which no wife minifter would ever wifh to fee. In profecution of the fame plan, the bifhop fent a letter to the archbifhop of Canterbury, and a copy to lord Shelburne, the duke of Grafton, the duke of Rutland, and lord John Cavendifh refpectively. The minifter difcouraged the bufinefs, and earneftly diffuaded the bifhop from any immediate publication of it. Upon the refignation of lord Shelburne, who, by an exercife of prerogative, had been nominated by the king without the recommendation of the cabinet, the coalition miniftry, formed of lord North, and others who had for many years reprobated his political principles, came into power. This circumftance of the coalition roufed our prelate's indignation, and led him to entertain a very unfavourable opinion of the difintereftednefs and integrity of thofe to whom he had been invariably attached. Although the badnefs of the peace, and the fuppofed danger of trufting power in the hands of lord Shelburne, were the oftenfible reafons for this coalition, perfonal diflike of him, and a defire to be in power themfelves, were, in the bifhop's judgment, the real ones. This diffenfion of the Whigs, he fays, did more injury to the conftitution than all the violent attacks on the liberty of the fubject, which were fubfequently made during Mr. Pitt's adminiftration. "This apoftacy from principle in the coalition miniftry ruined," as he conceived, "the confidence of the country, and left it without hope of foon feeing another refpectable oppofition on conftitutional grounds; but it ftamped on the hearts of millions an impreffion which will never be effaced, that *patriotifm is a fcandalous game played by public men for private ends, and frequently little better than a felfifh ftruggle for power*."—"It is," he adds, "a principle with all parties to require from their adherents an implicit approbation of all their meafures: my fpirit was ever too high to fubmit to fuch a difgraceful load of political connection."—"To *forget all benefits*, and to conceal the *remembrance of all injuries*, are maxims by which political men lofe their honour, but make their fortunes."

Our prelate's letter to the archbifhop of Canterbury was publifhed in the interval between lord Shelburne's refignation and the appointment of the duke of Portland to the head of the treafury; but though a copy of it was fent to each bifhop, none thought proper to acknowledge it except Dr. Porteus, then bifhop of Chefter. Soon after the failure of Mr. Fox's Eaft India bill, to which Dr. Watfon was adverfe, Mr. Pitt was appointed firft lord of the treafury; and though he had continued in office for feveral weeks previoufly to the diffolution of parliament, March 25th, 1784, in direct oppofition to the majority of the houfe of commons, which in the judgment of our prelate eftablifhed a dangerous precedent, yet deference to the fenfe of the nation declared by numberlefs addreffes to the king againft the coalition miniftry, induced him to acquiefce. In July of this year he wrote a letter to Mr. Pitt, recommending an union of Britain and Ireland on an equal and liberal footing; but it was not accomplifhed till fixteen years after this period, and not, as the bifhop obferves, "in the liberal way it ought to have been done." Enlarged and liberal as were his fentiments of toleration, he neverthelefs regarded the church of Rome as a *perfecuting* church; and he thought it was more neceffary to guard againft the danger to be apprehended by Proteftants in a country where popery is fimply tolerated than where it is the eftablifhed religion. On another occafion he expreffes fentiments which muft lead the friends of Catholic emancipation to conclude, that he was not favourable to this object. "The perfecuting fpirit of the Roman church remains in the hearts of the generality of its members," he fays, "and whilft it does remain, popery muft be watched, intimidated, and reftrained." In a letter to Mr. Wakefield written in 1784, he avows his belief of the preexiftence of Chrift as the doctrine of the New Teftament; but at the fame time he is far from concurring with thofe who brand the fupporters of it as enemies to the Chriftian fyftem. In the fame year he addreffed a letter to Mr. Wyvill, expreffing his warmeft wifhes for parliamentary reform, which Mr. Pitt feemed at the commencement of his adminiftration inclined to promote. In 1785 he publifhed his "Collection of Theological Tracts," in fix volumes, intended for the benefit of young perfons, who could not afford to purchafe many books in divinity; the defign was laudable, and was generally approved; though, he fays, the bifhops were not pleafed with his having printed fome tracts originally written by Diffenters. In January 1786 he loft his friend Mr. Luther, with whom he had lived on terms of the moft affectionate intercourfe for thirty years; and in mentioning this circumftance he gratefully acknowledges his generous bequeft, which enabled him to preferve his independence, and to provide for his family. To his Suffex eftate, from the fale of which he derived 20,500*l*., this generous teftator added the entail of his eftate in Effex. Having, in the year 1782, publifhed a third volume of his Chemical Effays, he prefented to the public a fourth volume in 1786. About this time application was made to him by government for advice relating to the improvement of gun-powder; and he fuggefted a plan of making charcoal by diftilling the wood in clofe veffels, which was carried into execution at Hythe in 1787, and which produced a confiderable faving in the manufacture of this article.

Dr. Watfon, having been attacked with a diforder in 1781, which continued and rendered the difcharge of his duty, as profeffor of divinity, very irkfome to his feelings, and likely to haften the termination of his life, intimated to Mr. Pitt his wifhes for fome kind of preferment that would enable him to refign his profefforfhip; his church income, exclufive of it, being only about 1200*l*. a year. This application he very reluctantly renewed, but it produced no effect; and the confequence was a kind of remonftrance, in the tone of complaint, on the part of the bifhop to the minifter.

nifter. About this time Mr. Pitt confulted the bifhops about the repeal of the Teft and Corporation Acts; and of all the bifhops who were affembled for the difcuffion of the fubject bifhop Watfon and bifhop Shipley were the only two who voted, that they ought not to be maintained. The queftion was afterwards loft in the commons by a majority of 78; 178 to 100. When it was brought forward again in 1789, it was loft by a majority of 20; 122 to 102. But in 1790, the majority againft it was 194; 299 to 105: the clamour of "the church is in danger" having in the mean while been widely and loudly circulated, under the fanction of fome imprudent or mifunderftood expreffions in the publications of Dr. Hartley and Dr. Prieftley. The bifhop's intereft with the minifter was not promoted by the part which he took on this occafion, and much lefs by his parliamentary fpeech againft Mr. Pitt's commercial treaty with France. Soon after this he was very much enfeebled by a dyfentery; and upon his return from Bath to Cambridge in 1787, the fenate appointed Dr. Kipling to be his deputy as profeffor, with a falary amounting in a courfe of time to two-thirds of the value of the profefforfhip, when Dr. Watfon firft undertook it. At the enfuing commencement he delivered a kind of farewell addrefs to the univerfity, in which he expreffed his warmeft wifhes for its profperity; after having been inceffantly engaged in its bufinefs for more than thirty-three years. After the commencement he took a journey to Weftmoreland, with a view to the re-eftablifhment of his health. He now determined to become an agriculturift; and his purfuits in this department, as an improver of land and planter of trees, were fo favourable to his health, and upon the whole fo profitable, that he fays in the year 1809, "I feel much fatisfaction at this moment in having, by my own exertions, wholly counteracted the effects which might otherwife have followed the neglect I have experienced from the court or from its minifters, or from both, that I fincerely pity, and cordially forgive the littlenefs of mind, which, in fome one or other, has occafioned it." The bifhop relates an incident which occurred on occafion of his attending a levee in November 1787, and which fufficiently evinced the pains that had been taken to inftil wrong notions of his political principles into his majefty's mind. "I was ftanding," he fays, "next to a Venetian nobleman; the king was converfing with him about the republic of Venice, and haftily turning to me faid, 'there now, you hear what he fays of a republic.' My anfwer was, 'Sir, I look upon a republic to be one of the worft forms of government.' The king gave me, as he thought, another blow about a republic. I anfwered that I could not live under a republic. His majefty ftill purfued the fubject: I thought myfelf infulted and firmly faid, 'Sir, I look upon the tyranny of any one man to be an intolerable evil, and upon the tyranny of a hundred to be a hundred times as bad;' thus ended the converfation."

Although Dr. Watfon, as profeffor of divinity, had been for many years a chartered member of the fociety for propagating the gofpel in foreign parts, he had never fubfcribed to it nor attended its meetings; becaufe its miffionaries were more bufily employed in bringing over Diffenters to epifcopacy than in converting heathens to Chriftianity.

In the year 1788 he publifhed a charge which he had delivered at his vifitation, entitled "An Addrefs to Young Perfons after Confirmation." Towards the clofe of this year and the commencement of the next, he took an active part in the bufinefs of the regency, occafioned by the king's mental derangement; and in an elaborate fpeech delivered in the houfe of lords January 22d, 1789, he difcuffed, with fingular ability, the fubject in debate between Mr. Fox, who afferted "that theprince of Wales had a right to affume the regency," and Mr. Pitt, who had faid, "that the prince of Wales had no more right to affume the regency than any other man in the kingdom had." The part he took on this occafion is faid to have offended the queen; who, as he fays, "diftinguifhed by different degrees of courtefy on the one hand, and by meditated affronts on the other, thofe who had voted with, and thofe who had voted againft the minifter." At the drawing-room, held on the king's recovery, the bifhop was received with a degree of coldnefs, "which would have appeared to herfelf ridiculous and ill-placed could fhe have imagined how little fuch a mind as mine regarded, in its honourable proceedings, the difpleafure of a woman, though that woman happened to be a queen." The prince of Wales, who was witnefs to this conduct, paid particular attention to the bifhop, invited him to dine at Carlton-houfe, and entered into a familiar conference with him; the bifhop on the occafion "advifing him to perfevere in dutifully bearing with his mother's ill-humour, till time and her own good fenfe fhould difentangle her from the web which minifterial cunning had thrown around her." When the bifhop, before the clofe of the interview, declared that he was fick of parties, and fhould retire from all public concerns, "No," faid the prince, "and mind who it is that tells you fo, you fhall never retire; a man of your talents fhall never be loft to the public." The bifhop's reflection fubjoined to this anecdote is, "I have now lived many years in retirement, and, in my 75th year, I feel no wifh to live otherwife." About ten years after the publication of the tract which he had given to the young perfons of his diocefe, already mentioned, Mr. Afhdown of Canterbury addreffed two letters to him, in which he contended that the diftinction of ordinary and extraordinary operations of the Holy Spirit is not founded in fcripture, and that if it were, both operations ceafed with the apoftolic age. In reference to this opinion, the bifhop declares, "I am not afhamed to own, that I give a greater degree of affent to the doctrine of the extraordinary operation of the fpirit in the age of the apoftles, than I do to that of his immediate influence, either by illumination or fanctification, in fucceeding ages. Notwithftanding this confeffion, I am not prepared to fay, that the latter is an unfcriptural doctrine: future inveftigation may clear up this point, and God, I truft, will pardon me an indecifion of judgment proceeding from an inability of comprehenfion. If it fhall ever be fhewn, that the doctrine of the *ordinary* operation of the Holy Ghoft is not a fcripture doctrine, Methodifm, Quakerifm, and every degree of enthufiafm, will be radically extinguifhed in the Chriftian church; men, no longer believing that God does that by more means which may be done by fewer, will wholly rely for religious *inftruction*, confequent *converfion*, and fubfequent *falvation*, on his *Word*."

In the fummer of 1789, our bifhop, in purfuit of his plan for retiring from public life, laid the foundation of his houfe on the banks of the Winandermere; where he continued till his death. On occafion of the publication of "Hints to the New Affociation, recommending a Revifal of the Liturgy, &c." in 1789, by the duke of Grafton, two pamphlets were in the following year publifhed in oppofition to thefe "Hints." The bifhop made a reply to thefe attacks; and took a comprehenfive view of the fubject. Although he was diffuaded from publifhing his tract, it foon appeared under the title of "Confiderations on the Expediency of revifing the Liturgy and Articles of the Church of England," by a Confiftent Proteftant. Moreover, it was propofed, in converfation with the duke of Grafton, to commence a reform, by the introduction of a bill into the houfe of lords, for expunging the Athanafian creed from the Liturgy; but on account of the French revolution, the defign was poftponed. In this connection, we cannot forbear mentioning what is called the Windfor anecdote. It is as follows; and given by the bifhop on the authority of Dr. Heberden: "The clergyman there, on a day when the Athanafian creed was to be read, began with *Whofoever will be faved*, &c. the king, who ufually refponded with a loud voice, was filent; the minifter repeated, in a higher tone, his *Whofoever*; the king continued filent; at length the Apoftle's creed was repeated by the minifter, and the king followed him throughout with a diftinct and audible voice." "I certainly diflike," fays the bifhop, "the *impofition* of all creeds formed by human authority; though I do not diflike them, as ufeful fummaries of what *their compilers believe* to be true, either in natural or revealed religion." In a letter to the duke of Grafton, dated October, 1791, he briefly ftates his fentiments on feveral fubjects of importance. Amongft other obfervations that deferve attention, he fays, "In England we want not a fundamental revolution; but we certainly want a reform both in the civil and ecclefiaftical part of our conftitution; men's minds, however, I think, are not yet generally prepared for admitting its neceffity. A reformer of Luther's temper and talents would, in five years, perfuade the people to compel the parliament to abolifh tithes, to extinguifh pluralities, to enforce refidence, to confine epifcopacy to the overfeeing of diocefes, to expunge the Athanafian creed from our liturgy, to free Diffenters from teft acts, and the minifters of the eftablifhment from fubfcription to human articles of faith. Thefe, and other matters refpecting the church, ought to be done: I want not courage to attempt doing what I think ought to be done; and I am not held back by confiderations of perfonal intereft; but my temper is peaceable, I diflike contention, and truft that the ftill voice of reafon will at length be heard.—As to the civil ftate, it cannot long continue as it is, &c. &c." In a charge delivered in 1792, the bifhop touched on feveral fubjects of importance and general intereft; and among other things on the injuftice and impolicy of our Teft and Corporation Acts. "There feem to me," fays our prelate, "but two reafons for excluding any honeft man from eligibility to public office;—want of capacity to ferve the office, and want of attachment to the civil conftitution of the country. That the Diffenters want capacity will not be afferted; that they want attachment to the civil conftitution of the country is afferted by many, but proved by none."—"The Diffenters are neither Tories nor Republicans, but friends to the principles of the revolution;" but their conduct fince the revolution, and at and fince the reftoration, proves that they have no defign to undermine the conftitution of the country.

"But it may be faid, that inafmuch as the Diffenters are enemies to the church eftablifhment, and that the ftate is fo *allied* to the church, that he who is unfriendly to the one muft wifh the fubverfion of both. I think this reafoning is not juft; a man may certainly wifh for a change in an ecclefiaftical eftablifhment, without wifhing for a change in the civil conftitution of a country. An Epifcopalian, *e.g.* may wifh to fee bifhops eftablifhed in all Scotland, without wifhing Scotland to become a republic: and he may wifh that epifcopacy may be eftablifhed in all the American ftates, without wifhing that monarchy may be eftablifhed in any of them. The protection of life, liberty, and property, is not infeparably or exclufively connected with any particular form of church-government. The bleffings of civil fociety depend upon the proper execution of good laws, and upon the good morals of the people; but no one will attempt to prove, that the laws and morals of the people may not be as good in Germany, Switzerland, Scotland, under a Prefbyterian, as in England or France, under an epifcopal form of church-government," with much more to the fame purpofe.

In the year 1795 our bifhop made a fpeech in the houfe of lords in favour of a motion by the duke of Bedford, "that no form of government which may prevail in France fhould preclude a negociation with that country, or prevent a peace whenever it could be made confiftently with the honour, intereft, and fecurity of the nation." In the following fummer he publifhed a charge, and two fermons, one of them entitled "Atheifm and Infidelity refuted from Reafon and Scripture;" and the other "The Chriftian Religion no Impofture." In 1796 he publifhed "An Apology for the Bible," in defence of it againft the fcurrilous abufe of Thomas Paine. Of this tract many thoufands were diftributed at a low price, both in England and Scotland; and we have reafon to believe produced the moft beneficial effects, not only in Great Britain, but in Ireland and America. In 1798 the bifhop publifhed an addrefs to the people of Great Britain, which was of great fervice in raifing the fpirit of the nation. In 1799 he delivered a fpeech, recommending and vindicating againft objections a cordial union with Ireland, as an event which would enrich Ireland without impoverifhing Great Britain: and that would render the empire, as to defence, the ftrongeft in Europe. When Mr. B. Flower was brought to the bar of the houfe of lords for a breach of privilege in publifhing fomething againft the above-mentioned fpeech, the bifhop, when he heard of it, declared, "that he fhould feel much more fatisfaction in forgiving the man's malignity than in avenging it."

In 1805 the petition of the Roman Catholics of Ireland was taken into confideration by both houfes of parliament, and rejected by great majorities in both. Previoufly to the difcuffion on this queftion, bifhop Watfon communicated his fentiments on the fubject in a letter addreffed to the duke of Grafton. As this is a queftion ftill *fub judice*, we fhall here introduce the general heads of argument fuggefted in relation to it by the bifhop. "1. The abfolute juftice of tolerating religious opinions, fince no civil government can juftly poffefs more power over its fubjects than what individuals have *confented* to transfer to it when they entered into fociety; and no individual can give up the right of worfhipping God according to his confcience, and therefore no government can juftly abridge that right. 2. No civil government has any right to take cognizance of opinions either political or religious, but merely of men's actions. This principle, however, is liable to exception with refpect to the public teachers of religion. 3. The eftablifhed religion of every country ought to be the religion of the majority of the people; unlefs an exception be admitted, when the minority of the inhabitants poffeffes a majority of the property by which the eftablifhment is maintained; and even in that cafe, humanity and policy, if not ftrict juftice, require a co-eftablifhment of the religion of the minority. 4. Great credit ought to be given to men of probity and talents, difclaiming, in exprefs terms, the moft obnoxious principles of the church of Rome; the odium of paft tranfactions ought not to be thrown upon thofe who had no concern in them. 5. Conftitutionally fpeaking, the Catholic peers and commons have no more right to fit in parliament than a Catholic king has to fit upon the throne; and if the change of times is not yet fuch that a Proteftant would endure the thought of a Catholic king upon the throne, it may be inquired upon what principle it is that a Proteftant can

endure

endure the thought of a Catholic legiſlator. The principle may be the little comparative influence of a Catholic legiſlator, and his abjuration of temporal tenets formerly profeſſed by Catholics. 6. The progreſs of ſcience has ſubdued the bigotry formerly too apparent not only in the church of Rome, but in all the reformed churches: and it will never be able, till a ſtate of ignorance and barbariſm recurs, to rear up its head again. There is no probability of intolerance and ſuperſtition ever more pervading Europe; and the Catholic religion will continue to derive light from the labour of learning. The learned Catholics are beginning every where to ſoften the aſperities of their religious tenets, and to apologize for what they cannot excuſe. The Iriſh gentry partake of the illumination of the age; and the peaſantry will imitate the example of their ſuperiors. 7. It may be ſaid that the *church* of Rome has not formally renounced any of the doctrines maintained at the council of Trent, and that the *court* of Rome has not abandoned any of its pretenſions to temporal dominion; yet Catholic, as well as Proteſtant, ſtates have every where ſpurned theſe pretenſions; and ſomething very like a formal renunciation of one of the moſt dangerous tenets of that church took place in Ruſſia more than twenty years ago. The empreſs Catharine gave permiſſion to the Roman Catholics in her dominions merely to exerciſe their religion; and to have biſhops of their own perſuaſion for the government of their church. She was preſent at the conſecration of the firſt Catholic archbiſhop. When the ceremony had proceeded to the adminiſtration of the oath uſually taken by the biſhops of that church, the archbiſhop (that was to be) refuſed to repeat the clauſe "Hæreticos ſchiſmaticos et rebelles domino noſtro papæ pro poſſe perſequar et impugnato." On this refuſal, the ceremony was ended, freſh inſtructions were required from Rome, and the then pope ordered the clauſe to be omitted; and it has been ſince omitted, by the authority of the pope, in the oath taken by the Iriſh biſhops."

"My great objection," ſays Watſon, "to the church of Rome is the uncharitable principle of the inſalvability of perſons out of its pale; for this principle produces a perſecuting principle, and I muſt ever deteſt every ſpecies of perſecution. I cannot however believe that Catholic emancipation will tend to the increaſe of the number of Catholics, either in Ireland or in England; on the contrary, I think the number would, by ſuch a meaſure, be leſſened. Nothing unites men ſo much as any degree of perſecution. Individuals, otherwiſe of no conſequence, either from talents or fortune, become conſpicuous, and acquire a degree of weight, when connected with a party. Men claim merit from what they call their ſufferings, who would have no ground for claiming it on any other ſpecies of deſert."

In ſubſequent letters addreſſed to lord Grenville in 1810, and to ſir John Cox Hippeſley in 1812, he gives the following opinion of the *veto:* "the appointment of the Iriſh Catholic biſhops ought to be in the king, if they are to be paid by the ſtate; and if they are to be paid by the Catholics themſelves, it ought to be in them; but excluſive of all foreign influence, recommendation, or confirmation. If they do not accede to this, or to ſomething ſimilar to this, they will act on a *principle which I did not expect, nor can approve.*" In a letter to lord Hardwicke, dated April 2, 1812, he ſays, "I make no ſecret of my opinion; a cordial reception of Catholics and Diſſenters into the boſom of the conſtitution, by the extinction of all diſqualifications, is become neceſſary to ſecure the independence of the empire, and the ſafety of the country."

In conſequence of an imputation of want of orthodoxy, partly occaſioned by a ſermon publiſhed by the biſhop, and entitled "A Second Defence of revealed Religion," he makes the following reflections on the ground of this charge. "What is this thing called orthodoxy, which mars the fortunes of honeſt men, miſleads the judgment of princes, and occaſionally endangers the ſtability of thrones? In the true meaning of the term, it is a ſacred thing, to which every denomination of Chriſtians lays an arrogant and excluſive claim, but to which no man, no aſſembly of men, ſince the apoſtolic age, can prove a title. It is frequently, among individuals of the ſame ſect, nothing better than ſelf-ſufficiency of opinion, and phariſaical pride, by which each man eſteems himſelf more righteous than his neighbours. It may, perhaps, be uſeful in cementing what is called the *alliance* between the church and ſtate; but if ſuch an alliance obſtructs candid diſcuſſions, if it invades the right of private judgment, if it generates bigotry in churchmen, or intolerance in ſtateſmen, it not only becomes inconſiſtent with the general principles of Proteſtantiſm, but it impedes the progreſs of the kingdom of Chriſt, which we all know is not of this world."

The next public occaſion on which our biſhop diſtinguiſhed himſelf was on the debate which took place in the houſe of lords, March 23, 1807, concerning the abolition of the ſlave-trade. For the affirmative of this queſtion he delivered a ſpeech, abounding with hiſtorical information and ſound argument. When the adminiſtration that had been formed on the death of Mr. Pitt was diſmiſſed, he expreſſed in ſtrong terms his diſapprobation of the oſtenſible reaſon alleged for its diſmiſſion, which was the king's diſlike of a meaſure which had been brought forward in parliament reſpecting the Iriſh Catholic officers; and the requiſition on the part of his majeſty of a pledge that this adminiſtration would never more bring forward the queſtion of granting farther indulgence to the Iriſh Catholics. This requiſition was conſidered by many as having a tendency dangerous to the conſtitution; and to Dr. W. it appeared "to be not in words, but in fact, a declaration of a *ſic volo.*" On occaſion of the diſmiſſion of this "half Whig, and half Tory adminiſtration," as he calls it, he communicated to lord Grenville a reſolution, which he conceived to be fit to be introduced in the houſe of lords, whenever the ſubject ſhould be brought forward, and which lord Grenville actually adopted *in toto*, as better in his opinion than any thing which had occurred either to himſelf or to his friends. The reſotion was as follows: "Reſolved, that whoever has adviſed, or ſhall in future adviſe, his majeſty to require from his confidential ſervants a pledge, that they will, on any occaſion, abſtain from ſubmitting to his conſideration any meaſure of government which they, in their conſciences, believe to be conducive to the public weal, is and ought by this houſe to be declared to be an enemy to the conſtitution of this country." Soon afterwards he ſent to the duke of Grafton a leſs firm reſolution, which he thought might be more acceptable to the then houſe of lords. Neither of theſe reſolutions, however, was ultimately adopted; but the reſolution that was actually propoſed was, after a debate which laſted till 7 o'clock in the morning, negatived by a great majority. A violent alarm againſt Popery and of the church's danger prevailed, during which the biſhop declared his opinion, "that it was both juſt, and in the ſtate of Buonaparte's ſtrength and temper towards us, highly expedient, to receive both Catholics and Diſſenters into the boſom of the conſtitution; but that it was improper to preſs any innovation till the people were prepared to receive it; and that" (in his opinion) "the time was not yet come for the general adoption of ſuch a political and equitable principle of government. Toleration was in every man's mouth; but dominion over the faith of other men, exclufion from privileges poffeffed by themfelves, and a difpofition to the exercife of *power without right*, were in the hearts of a great part, probably of a majority of the people of Great Britain."

In reply to a letter, in which the writer expreffes a wifh, that the bifhop would anfwer Mr. Malthus's book, intitled "An Effay on Population," and in which, as he reprefents it, the author endeavours to eftablifh a code of morality in oppofition to the morality of the gofpel, Dr. W. obferves that Mr. Malthus appeared to him to be "endeavouring to fhew the utility of bringing down the population of the earth to the level of the fubfiftence requifite for the fupport of man," (a propofition wanting no proof, fince where there is no food, man muft die,) "and that in his judgment, his time and talents would have been better employed in the inveftigation of the means of increafing the fubfiftence to the level of the population." He fays, however, that after having looked into this book, he was juftified in neglecting to perufe it, as it thwarted the ftrongeft propenfity of human nature, and contradicted the moft exprefs command of God, "Increafe and multiply;" more efpecially as he was perfuaded, "that the earth had not, in the courfe of 6000 years from the creation, ever been replenifhed with any thing like one half the number of inhabitants it would fuftain."

The bifhop might indeed well regret, as he frequently, perhaps *too frequently* does, the inattention to his merits, and claims on higher preferment than a poor Welfh bifhopric, which he had long experienced, after a long courfe of literary labour and public fervice. Mr. Pitt profeffed himfelf well difpofed towards him, but alleged "that a *certain perfon* would not hear of it." "Notwithftanding this anecdote," fays the bifhop, "I cannot bring myfelf to believe that the king was either the firft projector, or the principal actor in the forry farce of neglecting a man whom they could not difhonour, of diftreffing a man whom they could not difpirit, which has been playing at court for near 26 years." Acquitting Mr. Pitt, though he knew that no minifter would be very zealous in promoting a man who profeffed and practifed parliamentary and perfonal independence, from the charge of forgetting either obligations or connections in the purfuit of his ambition, he lays the blame on a more exalted perfonage. "As to the king's diflike of me, unlefs his education had made him more of a Whig, it was natural enough. My declared oppofition to the increafed and increafing influence of the crown had made a great impreffion on his majefty's mind."

Of the bill, introduced into the houfe of commons by the chancellor of the exchequer in 1808, for making more effectual provifion for the maintenance of ftipendiary curates in England and Wales, and for their refidence on their cures, he expreffed his difapprobation, with the reafon of it, in letters addreffed both to the archbifhop of Canterbury and Mr. Percival. He rejoiced, however, in the grant of 100,000*l.* a year by a vote of parliament in 1809, in lieu of queen Anne's bounty; but in his charge of that year, referring to a letter previoufly written to lord Hawkefbury on this occafion, he renews his complaint of the manner in which he had been neglected, alleging that he never had any place of refidence amongft his clergy, nor a church-income fufficient to enable him to attend every year his parliamentary duty. Having, in the year 1809, and during an extenfive vifitation of his diocefe, held a confirmation at Merthyr-Tydvil, he was hofpitably accommodated at the houfe of the late Mr. Crawfhay, a well-known iron-mafter, whofe hofpitality the writer of this article has experienced; and before he left the diocefe, Mr. C. came to Landaff to take leave of him. On this occafion, taking the bifhop by the hand, he faid to him, "If ever you have occafion for 5 or 10,000*l.* it fhall be wholly at your fervice." Of courfe declining to avail himfelf of this generous offer, he neverthelefs declares, "I was more delighted with this fubftantial proof of the difinterefted approbation of an iron-mafter than I fhould have been with the poffeffion of an archbifhopric acquired by a felfifh fubferviency to the defpotic principles of a court."

On the fubject of Lancafterian fchools and bible focieties, he declares his opinion to be, "that certain zealous men in the eftablifhed church have fuffered their apprehenfions for its fafety to outftrip all probability of danger arifing to it, from the inftitution of either Lancafterian fchools or auxiliary bible focieties. The church is in no danger from Proteftant or Catholic Diffenters; but the ftate muft ever be in danger from difcontent breeding difaffection, whilft a large portion of its members is looked upon by government with a jealous and repulfive eye." On another occafion, in a letter to Mr. Wyvill, Oct. 21, 1813, he expreffes fentiments of a fimilar kind: "the ftruggle for the liberty of Europe has been moft nobly fuftained by Great Britain, and might it not at this period be fuccefsfully terminated by our government granting emancipation to the Catholics, and a repeal of the Teft and Corporation acts to the Diffenters? Thefe conceffions would be more powerful means of defence than all the confcriptions of our enemy can ever be to the contrary." We cannot forbear fubjoining a paragraph from Mr. Wyvill's reply: "Mr. Fox proved the fincerity of his attachment to liberty, civil and religious, by the long fervice of 30 years, almoft wholly fpent in parliament, under the frowns of power: your lordfhip, I believe, has given a fimilar proof of your attachment to that beft of caufes. You have endured a fimilar profcription from men who acted on the fame unworthy motives, and the confequence has been almoft the fame: you have at Landaff been fo long fhut out from the road to the higher honours of the church. But how much higher have you rifen by having obtained the undifputed dignity of virtue, benevolence, patriotifm, and the true fpirit of Chriftianity!" Well might the bifhop reply to Mr. Wyvill, "I am proud of *your* honourable teftimony to that political confiftency of principle, which unites my name to that of Mr. Fox."

From this period the health of the bifhop rapidly declined; and though his mental faculties continued unimpaired, yet bodily exercife and literary compofition became irkfome to him. He expired on the 4th of July, 1816, in the 79th year of his age; illuftrating, as the publifher of his Memoirs fays, in death the truth of his favourite rule of conduct through life: "Keep innocency, and take heed unto the thing that is right, for that fhall bring a man peace at the laft."

Having availed ourfelves of the work now before us, we make no apology for extending this article beyond the ufual limits of our biographical fketches. From the honour of an early acquaintance with the fubject of this article, and from a full conviction of his uniform integrity, as well as his pre-eminent talents, we felt a peculiar intereft in the perufal of the memoirs of his life. Diftinguifhed by mental powers of a fuperior order, and by public fervices which have feldom been paralleled, we pay this tribute of refpect to his memory. His character needs no delineation befides the "Anecdotes" which his own pen has furnifhed. In every department which he occupied, firft as a ftudent, and afterwards as a tutor and profeffor in the univerfity of Cambridge, as a prelate and a member of the legiflature, and in the

the latter period of his life as an agriculturift, his affiduity and activity were indefatigable and perfevering. To fay nothing of his folicitude for the beft interefts of his friends and his family, the ardour of his zeal in promoting the honour and profperity of the church and civil community to which he belonged, by thofe means which, according to his comprehenfive and liberal views, he thought to be moft conducive to this purpofe, muft approve itfelf in a high degree to thofe who entertained fentiments fimilar to his own, and it will need little apology in the candid judgment of thofe who moft differ from him in their opinion of public men and public meafures. As he always fpoke and acted from the conviction of a well-informed and upright mind, and counteracted his own fecular intereft by the courfe he purfued, his fentiments claim deference, and his conduct will command refpect. If it fhould occur to any who perufe the anecdotes now before us, that he was too ambitious of preferment, it muft be recollected, that the merit of his fervices, both to the church and ftate, of which he could not be unconfcious, and the elevated connections which his ftation in the univerfity had led him to form, encouraged reafonable expectations of a higher rank in the church than a poor bifhopric in Wales; fo that he could not otherwife than feel himfelf neglected and difappointed. His private fortune, though his patrimony had been expended, was rendered ample by the liberality of his friend Mr. Luther, and therefore he had no juft reafon for complaint on this account; and yet it fhould be confidered that he had a family, for which he wifhed to provide in a manner fuitable to the circumftances in which his aggregate income had placed them. Anecdotes of the Life of Richard Watfon, bifhop of Landaff, written by himfelf at different intervals, and revifed in 1814, 4to., publifhed by his fon, Richard Watfon, LL.B. prebendary of Landaff and Wells. Lond. 1817.

Watson, in *Geography*, a town of Virginia; 35 miles S.W. of Richmond.

Watson's *Ifland*, an ifland in the Mergui Archipelago, of an oval form, and about 12 miles in circumference. N. lat. 9° 36′.

WATSONIA, in *Botany*, was fo called by Miller, after the late fir William Watfon, knight, M.D. F.R.S., well known by his numerous papers in the Philofophical Tranfactions, on many fubjects connected with the hiftory of Botany, and eminently diftinguifhed for his cultivation of feveral branches of philofophical and medical knowledge. Miller's genus being funk by Linnæus in *Antholyza*, the *Büttneria* was called *Watfonia* by Boehmer; but the original one, reftored by Mr. Ker, is now generally, and with great propriety, adopted.—Mill. Ic. 184. Ker in Sims and Kon. Ann. of Bot. v. 1. 229. Dryand. in Ait. Hort. Kew. v. 1. 93.—Clafs and order, *Triandria Monogynia*. Nat. Ord. *Enfatæ*, Linn. *Irides*, Juff.

Gen. Ch. *Cal.* Spatha inferior, fhorter than the corolla, of two oblong, clofe-preffed, permanent valves. *Cor.* of one petal, fuperior: tube cylindrical throughout, fomewhat enlarged, but not fpreading, in the elongated throat, curved: limb nearly regular, in fix deep, flat, fpreading, almoft equal fegments. *Stam.* Filaments three, inferted into the tube at the origin of the throat, thread-fhaped, afcending, fhorter than the corolla; anthers oblong, fomewhat parallel, incumbent. *Pift.* Germen inferior, oblong, furrowed; ftyle thread-fhaped, longer than the ftamens; ftigmas three, flender, deeply cloven, fpreading, recurved. *Peric.* Capfule oblong, bluntly triangular, cartilaginous, of three cells and three valves. *Seeds* numerous, imbricated downwards, angular in their lower part, dilated into more or lefs of a wing at the upper end.

Eff. Ch. Spatha of two valves. Corolla tubular, with a cylindrical throat; its limb in fix deep, nearly equal, fegments. Stigmas three, thread-fhaped, deeply cloven, the fegments recurved. Capfule cartilaginous. Seeds numerous, angular.

This genus differs from Gladiolus in its almoft regular *corolla*, with a cylindrical throat; narrow, divided, not dilated, *ftigmas*; and angular, fcarcely winged, feeds: Antholyza, as now limited, is diftinguifhed from it, by having a ringent *limb*, of unequal and diffimilar fegments; fimple *ftigmas*; and nearly globular *feeds*. See thofe articles.

1. W. *fpicata*. Hollow-leaved Watfonia. Ker in Curt. Mag. at p. 553. Ait. n. 1. (Ixia fpicata; Willd. Sp. Pl. v. 1. 200. I. cepacea; Redout. Liliac. t. 96. I. fiftulofa; Curt. Mag. t. 523. I. alopecuroidea; Linn. Suppl. 92. Gladiolus fpicatus; Linn. Sp. Pl. 53. Thunb. Gladiol. n. 13. G. fiftulofus; Jacq. Hort. Schoenbr. v. 1. 8. t. 16.)—Leaves cylindrical, hollow.—Gathered by Thunberg, on the higheft hills of Hottentot's Holland, at the Cape of Good Hope, flowering in December and January. By fir Jofeph Banks's herbarium, this fpecies appears to have been cultivated by Mr. W. Malcolm, in 1791. It blooms in the European green-houfes in May, but not very readily, often bearing fmall oat-like bulbs in the place of flowers. The *bulb* is fmall, round, with a fibrous coat. *Stem* leafy, from eight to twelve inches high. *Leaves* alternate, very remarkable for their cylindrical inflated form, gradually fwelling upwards, obtufe, with a fmall point; their furface very fmooth; their bafe fheathing. *Flowers* either light blue or pale purple, very numerous, clofely imbricated in a two-ranked tapering fpike, with reddifh crenate *fheaths*. *Corolla* regular, expanding rather more than half an inch. We do not find that the *ftigmas* of this plant are cloven, as the generic character requires, and we fhould rather have left it in *Ixia*, till it could otherwife have been difpofed of. The fame remark applies to the following. The name *fpicata* is not fo exclufively appropriate as *fiftulofa* or *cepacea* would have been, but it is the oldeft name, and liable to no objection. This is certainly, as far as we can make out, the original *Gladiolus fpicatus* of Linnæus, though he, long after its publication, very inadvertently laid into his herbarium, under that name, a Siberian fpecimen of a fmall-flowered variety of *G. communis*.

2. W. *plantaginea*. Plantain-fpiked Watfonia. Ker in Curt. Mag. t. 553. Ait. n. 2. (Ixia plantaginea; Willd. Sp. Pl. v. 1. 200. Gladiolus alopecuroides; Linn. Sp. Pl. 54. Amoen. Acad. v. 4. 301. Thunb. Gladiol. n. 14.)—Upper leaves linear-fwordfhaped, many-ribbed: lowermoft hollow, compreffed. Flowers imbricated in two rows.—Gathered by Thunberg in feveral places near the town, at the Cape of Good Hope, often in the highways. This differs effentially from the fpecies juft defcribed, in having the ufual fword-fhaped *foliage* of its natural order. Their *flowers* nearly refemble each other. Thefe are in the prefent fpecies either blue or white, very numerous, forming a denfe two-ranked *fpike*, with membranous-edged *fheaths*, recalling the idea of fome kind of Plantain. Sometimes each *ftem* bears two or three fuch *fpikes*, which are then very large and luxuriant; but in our cultivated fpecimens they are ufually folitary, as well as much fmaller. The *flowers* are without fcent.

3. W. *punctata*. Dotted-flowered Watfonia. Ker in Ann. of Bot. n. 1. Ait. n. 3. (Ixia punctata; Andr. Repof. t. 177.)—Leaves linear-awlfhaped, compreffed. Spike about three-flowered.—Sent from the Cape of Good Hope, in 1800, by Mr. Niven, to his employer Geo. Hibbert,

minion over the faith of other men, excluſion from privileges poſſeſſed by themſelves, and a diſpoſition to the exerciſe of *power without right*, were in the hearts of a great part, probably of a majority of the people of Great Britain."

In reply to a letter, in which the writer expreſſes a wiſh, that the biſhop would anſwer Mr. Malthus's book, intitled "An Eſſay on Population," and in which, as he repreſents it, the author endeavours to eſtabliſh a code of morality in oppoſition to the morality of the goſpel, Dr. W. obſerves that Mr. Malthus appeared to him to be "endeavouring to ſhew the utility of bringing down the population of the earth to the level of the ſubſiſtence requiſite for the ſupport of man," (a propoſition wanting no proof, ſince where there is no food, man muſt die,) "and that in his judgment, his time and talents would have been better employed in the inveſtigation of the means of increaſing the ſubſiſtence to the level of the population." He ſays, however, that after having looked into this book, he was juſtified in neglecting to peruſe it, as it thwarted the ſtrongeſt propenſity of human nature, and contradicted the moſt expreſs command of God, "Increaſe and multiply;" more eſpecially as he was perſuaded, "that the earth had not, in the courſe of 6000 years from the creation, ever been repleniſhed with any thing like one half the number of inhabitants it would ſuſtain."

The biſhop might indeed well regret, as he frequently, perhaps *too frequently* does, the inattention to his merits, and claims on higher preferment than a poor Welſh biſhopric, which he had long experienced, after a long courſe of literary labour and public ſervice. Mr. Pitt profeſſed himſelf well diſpoſed towards him, but alleged "that a *certain perſon* would not hear of it." "Notwithſtanding this anecdote," ſays the biſhop, "I cannot bring myſelf to believe that the king was either the firſt projector, or the principal actor in the ſorry farce of neglecting a man whom they could not diſhonour, of diſtreſſing a man whom they could not diſpirit, which has been playing at court for near 26 years." Acquitting Mr. Pitt, though he knew that no miniſter would be very zealous in promoting a man who profeſſed and practiſed parliamentary and perſonal independence, from the charge of forgetting either obligations or connections in the purſuit of his ambition, he lays the blame on a more exalted perſonage. "As to the king's diſlike of me, unleſs his education had made him more of a Whig, it was natural enough. My declared oppoſition to the increaſed and increaſing influence of the crown had made a great impreſſion on his majeſty's mind."

Of the bill, introduced into the houſe of commons by the chancellor of the exchequer in 1808, for making more effectual proviſion for the maintenance of ſtipendiary curates in England and Wales, and for their reſidence on their cures, he expreſſed his diſapprobation, with the reaſon of it, in letters addreſſed both to the archbiſhop of Canterbury and Mr. Percival. He rejoiced, however, in the grant of 100,000*l.* a year by a vote of parliament in 1809, in lieu of queen Anne's bounty; but in his charge of that year, referring to a letter previouſly written to lord Hawkeſbury on this occaſion, he renews his complaint of the manner in which he had been neglected, alleging that he never had any place of reſidence amongſt his clergy, nor a church-income ſufficient to enable him to attend every year his parliamentary duty. Having, in the year 1809, and during an extenſive viſitation of his dioceſe, held a confirmation at Merthyr-Tydvil, he was hoſpitably accommodated at the houſe of the late Mr. Crawſhay, a well-known iron-maſter, whoſe hoſpitality the writer of this article has experienced; and before he left the dioceſe, Mr. C. cam take leave of him. On this occaſion, takin the hand, he ſaid to him, "If ever you h 5 or 10,000*l.* it ſhall be wholly at your ſervi declining to avail himſelf of this generous theleſs declares, "I was more delighted wi tial proof of the diſintereſted approbation of than I ſhould have been with the poſſeſſi biſhopric acquired by a ſelfiſh ſubſerviency t principles of a court."

On the ſubject of Lancaſterian ſchools and he declares his opinion to be, "that certain z the eſtabliſhed church have ſuffered their app its ſafety to outſtrip all probability of dange from the inſtitution of either Lancaſterian ſc liary bible ſocieties. The church is in no dan teſtant or Catholic Diſſenters; but the ſtate n danger from diſcontent breeding diſaffection, portion of its members is looked upon by gove jealous and repulſive eye." On another occaſ to Mr. Wyvill, Oct. 21, 1813, he expreſſes ſ ſimilar kind: "the ſtruggle for the liberty o been moſt nobly ſuſtained by Great Britain, not at this period be ſucceſsfully terminated b ment granting emancipation to the Catholics, a the Teſt and Corporation acts to the Diſſent conceſſions would be more powerful means of all the conſcriptions of our enemy can ever b trary." We cannot forbear ſubjoining a pa Mr. Wyvill's reply: "Mr. Fox proved the fin attachment to liberty, civil and religious, by vice of 30 years, almoſt wholly ſpent in parli the frowns of power: your lordſhip, I believe, ſimilar proof of your attachment to that bel You have endured a ſimilar proſcription fro acted on the ſame unworthy motives, and the has been almoſt the ſame: you have at Landaff ſhut out from the road to the higher honours of But how much higher have you riſen by having undiſputed dignity of virtue, benevolence, pa the true ſpirit of Chriſtianity!" Well might t ply to Mr. Wyvill, "I am proud of *your* hon timony to that political conſiſtency of prin unites my name to that of Mr. Fox."

From this period the health of the biſhop clined; and though his mental faculties conti paired, yet bodily exerciſe and literary compoſi irkſome to him. He expired on the 4th of Jul the 79th year of his age; illuſtrating, as the pub Memoirs ſays, in death the truth of his favo conduct through life: "Keep innocency, and unto the thing that is right, for that ſhall bring at the laſt."

Having availed ourſelves of the work now be make no apology for extending this article beyo limits of our biographical ſketches. From the an early acquaintance with the ſubject of this from a full conviction of his uniform integrity a his pre-eminent talents, we felt a peculiar intere i ruſal of the memoirs of his life. Diſtinguiſhe b powers of a ſuperior order, and by public ſer have ſeldom been paralleled, we pay this tribute r his memory. His character needs no delineation "Anecdotes" which his own pen has furniſhed department which he occupied, firſt as a ſtudent a wards as a tutor and profeſſor in the univerſi bridge, as a prelate and a member of the legiſla

WAT-TAUPAUMENE, or St. Peter, in *Geograph* a river of North America, which runs into the Miffiffipp N. lat. 44° 42′. W. long. 93° 38′.

WATTEAU, Anthony, in *Biography*, one of the mo agreeable painters of the French fchool, was born at Valer ciennes in 1684. His parents were in indigent circumftance and he was placed with an obfcure artift in his native city, t cultivate a talent which manifefted itfelf early. When he wa about 16 years old, having already furpaffed his preceptor he connected himfelf with a fcene-painter on his way to Paris and for fome time affifted his affociate in decorating the opera-houfe in that city. When this engagement was com pleted Watteau found it difficult to refcue himfelf from the obfcurity and embarraffment into which he fell, when happily he became acquainted with Claude Gillot, a painter of grotefque and fabulous fubjects, who was pleafed with his works and difpofition. Gillot afforded him an afylum in his own houfe, and then inftructed him in all he knew of the art, and found an apt and agreeable fcholar in his protegée. With the help he thus received from Gillot, and his own admiration and attentive ftudy of the Luxembourg gallery, he formed a tafte for colouring, which if not as grand, is at leaft as agreeable, as ever was employed by any one.

He attempted to prepare himfelf for hiftorical painting, and ftudied at the academy with that view; he even was fo fuccefsful as to obtain the firft prize there for an hiftorical picture; but happily he difcovered a character of fubject quite original and exactly fuited to his tafte, for which he wifely deferted hiftory, and which has fince formed plenty of afpirants, but has never been fo fuccefsfully practifed. The theatre, the opera, fêtes champetres, mafquerades, pantomimes, puppet-fhows, afforded him his figures; the gardens of the Luxembourg and of the Thuilleries, of Verfailles and St. Cloud, furnifhed the fcenes. In thefe nature prevails only in the colouring, and that is exquifite, rich, delicate, clear, and full; bright without gaudinefs, and deep without blacknefs; laid on with a freedom, fulnefs, and delicacy of touch, which no one ever furpaffed; but the airs of his figures are generally affected to the higheft degree; people of rank and fafhion, aping the enjoyments of rural life: and when he attempted to paint domeftic or rural fcenes, he carried the fame tafte into his practice. The true character of Watteau's pictures is French gentility, gay, cheerful, debonnaire, of which felf-fatisfaction is the fureft bafis. "In his halts and marches of cavalry, the carelefs ftrut of his foldiers retains the air of a nation that afpires to be agreeable as well as victorious." Watteau vifited England in the reign of George I., but did not enjoy his health here, and returned to France in about a year, where he died in 1721, at the early age of 37.

WATTEN, in *Geography*, a town in Scotland, in the county of Caithnefs; 7 miles N.W. of Wick.—Alfo, a town of France, in the department of the North, on the Aa; 4 miles N. of St. Omer.

WATTENSCHIED, a town of Germany, in the county of Mark; 5 miles S.W. of Bockum.

WATTER, a river which rifes in the county of Waldeck, and runs into the Erpe, near Volckmarfen.

WATTERPUTTEN, a town of Hindooftan, in Concan; 5 miles S. of Geriah.

WATTINAD, a town of Hindooftan, in the Carnatic; 20 miles S.S.E. of Tanjore.

WATTLE, in *Agriculture* and *Rural Economy*, a kind of hurdle formed by means of fplit wood, or fmall rods, and ufed for making folds for fheep. The term alfo fignifies a flefhy excrefcence growing from under the top of the throats

of

bert, efq. in whofe green-houfe at Clapham it flowered the fpring following. *Bulb* roundifh, depreffed. *Stem* leafy, flender, about a foot high. *Leaves* few, alternate, very narrow, fpreading in two directions. *Flowers* agreeing in fize and difpofition with thofe of *Ixia maculata*, about three in number, of a fine purple, marked with dotted or beaded veins; their fegments regular, elliptical, longer than the tube, three of them rather fmaller than the reft. *Stigmas* three, deeply divided; or rather, we fhould fay, fix, ftrap-fhaped, obtufe, revolute, downy. The character of the *ftigmas* anfwers to *Watfonia*, but the habit is very unlike the other fpecies.

4. W. *marginata*. Broad Bordered-leaved Watfonia. Ker in Curt. Mag. t. 608. Ait. n. 4. (Gladiolus marginatus; Linn. Suppl. 95. Willd. Sp. Pl. v. 1. 217. Thunb. Gladiol. n. 20.)—Leaves fword-fhaped, with thick callous edges. Spike fomewhat compound. Mouth of the corolla with fix teeth.—Abundant on graffy hills at the Cape of Good Hope, as well as on the Table-mountain, and other elevated ground, flowering from October to December often in fuch profufion, as to cover the hills as it were with a beautiful rofe-coloured carpet. *Thunberg*. In our green-houfes it readily bloffoms from June to Auguft, efpecially if planted in deep pots, and as readily increafes, being, as Mr. Ker obferves, become within a few years one of the commoneft of its tribe. The great fize of the plant, its thick-edged *leaves*, not indeed well expreffed in the Botanical Magazine, and the copious, rofe-coloured *flowers*, fmelling like Hawthorn, or Heliotrope, render this one of the moft defirable and ftriking of the Cape bulbs. The *corolla* is regular, with a tube about equal to its limb, having a fhort cylindrical throat. *Stigmas* long, each in two divaricated revolute fegments.

5. W. *rofea*. Pyramidal-fpiked Watfonia. Ker in Ann. of Bot. n. 5. Curt. Mag. t. 1072. Ait. n. 5. (Gladiolus glumaceus; Thunb. Prodr. 186. Vahl Enum. v. 2. 105. G. marginatus δ; Thunb. Gladiol. n. 20. G. iridifolii varietas; Jacq. Ic. Rar. t. 235. G. pyramidatus; Andr. Repof. t. 335.)—Leaves fword-fhaped, thickened at the edges. Spike compound. Mouth of the corolla naked.—Native of the Cape of Good Hope. It appears to have flowered, for the firft time in England, at the Dowager Lady de Clifford's, in Auguft 1803. One of the largeft of its tribe, being fometimes four feet high. We cannot wonder at this having been taken for a variety of the laft, at leaft while the fpecies of this difficult order of plants were but fuperficially examined. The prefent is, however, the larger and more ftately plant of the two, with even more beautiful rofe-coloured *flowers*, whofe *corolla* wants the fix marginal teeth round the mouth, which effentially diftinguifh the preceding.

6. W. *brevifolia*. Short-leaved Watfonia. Ker in Curt. Mag. t. 601. Ait. n. 6. (Antholyza fpicata; Andr. Repof. t. 56. Gladiolus teftaceus; Vahl Enum. v. 2. 105.) — Leaves ovate-fwordfhaped, equitant, very fhort. Tube, throat, and limb, of the corolla equal in length; mouth naked.—Native of the Cape of Good Hope, from whence it was imported by Meffrs. Lee and Kennedy, through the hands of Mr. Pringle of Madeira, in 1794. The *leaves* are about four, almoft perfectly radical, remarkable for their fhortnefs, being but two or three inches long, though near an inch wide; their edges cartilaginous, though very narrow. *Stem* twelve or eighteen inches high. *Spike* long, erect, fimple, or fometimes branched, but not compofed of little fpikelets. *Flowers* of a tawny red, about the fize of *W. marginata*, but the proportion of their *tube*, and efpecially their *throat*, is longer compared with the *limb*. Their *colour* would lead us to expect fome fragrance, in the evening at leaft, but this is faid not to be the cafe. They have, however, the advantage of being much more lafting than fome of their allies. The *ftigmas* are deeply cloven.

7. W. *iridifolia*. Flag-leaved Watfonia. Ker in Ann. of Bot. n. 12. Ait. n. 7. (Gladiolus iridifolius; Jacq. Ic. Rar. t. 234. Willd. Sp. Pl. v. 1. 215, excluding the fynonym of G. cardinalis.)—β. var. fulgens; Curt. Mag. t. 600. (Antholyza fulgens; Andr. Repof. t. 192. Gladiolus marginatus γ; Thunb. Gladiol. n. 20.)—Throat of the corolla curved, longer than the tube, and rather longer than the acute limb. Leaves fword-fhaped, erect, with a prominent midrib.—Native of the Cape of Good Hope, from whence it was fent by Mr. Maffon, in 1795. The variety β is preferred, on account of the fplendid fcarlet colour of its flowers, in which alone it is faid to differ from the pale greyifh-flowered plant, figured by Jacquin. We have not feen the latter, but if the figure be correct, the *tube*, and the cylindrical *throat*, are, each of them, fhorter in proportion to the *fheath*, and to the *limb*, than in the fcarlet kind. The *leaves* in both are long, erect, and fcarcely thickened at the edges, having more of a midrib than the feveral foregoing fpecies. The *fpathas*, in the fcarlet variety, are not much above half the length of the flender *tube*, which is about two-thirds as long as the greatly-extended, cylindrical, curved, and ftrongly deflexed *throat*. The latter exceeds the length of the elliptical, acute, recurved, nearly equal, fegments of the *limb*. *Anthers* violet. *Stigmas* cloven half way down, divaricated.

8. W. *Meriana*. Red Watfonia. Ker in Ann. of Bot. n. 11. Curt. Mag. t. 1194. Ait. n. 8. (Watfonia; Mill. Ic. t. 276. Antholyza Meriana; Linn. Sp. Pl. 54. Curt. Mag. t. 418. Gladiolus Merianus; Willd. Sp. Pl. v. 1. 214. Vahl Enum. v. 1. 94. Jacq. Ic. Rar. t. 230. Redout. Liliac. t. 11. Meriana flore rubello; Trew. Ehret. t. 40.)

β. W. angufta; Ker Ann. of Bot. n. 9. (G. Merianæ var. Jacq. Ic. Rar. t. 231.) — Throat of the corolla curved, rather longer than the tube, and longer than the obtufe limb; tube longer than the fpatha. Leaves fword-fhaped, erect, with a prominent midrib.—Native of the Cape of Good Hope. Raifed from feed, before 1750, in Chelfea garden, by Miller, who firft gave it the name of *Watfonia*. A large and handfome fpecies nearly akin to the laft, but fufficiently diftinct, and characterized by the blunt fegments of its *corolla*. The proper hue of the *flowers* is a peculiar falmon-coloured red, rather than a fcarlet, as may be feen in Miller's and Jacquin's figures, and efpecially Curtis's t. 418. But the *corolla* varies in this refpect, as well as in fize, of which the two extremes are the Botan. Mag. t. 1194, and Jacq. Ic. Rar. t. 231. The latter, which we have never feen in England, was referred to this fpecies by the late Mr. Dryander, from a drawing fent by Jacquin, how juftly can only be a matter of opinion, unlefs living fpecimens were accurately compared. The fpecies before us flowers with other Cape bulbs in May and June, increafing plentifully by offsets.

9. W. *humilis*. Crimfon Watfonia. Mill. Ic. t. 297. f. 2. Ker in Curt. Mag. t. 631. 1195. Ait. n. 9. (Gladiolus laccatus; Jacq. Ic. Rar. t. 232. Willd. Sp. Pl. v. 1. 215.)—Throat of the corolla curved, rather longer than the acute limb; tube the length of the fpatha. Leaves fword-fhaped, erect, with a prominent midrib.—Native of the Cape of Good Hope, from whence the feeds were obtained by Miller, in 1754. Much fmaller than feveral of the laft defcribed, being feldom above a foot high,

high, with linear *leaves*. The *flowers* are of a crimſon, or roſe-coloured, hue, not verging towards a ſcarlet, or tawny red. They vary in ſize, as may be ſeen by the two figures in the Botanical Magazine. The *throat* is correctly cylindrical; tube generally ſhorter than the *ſpatha*, not longer. We are obliged to content ourſelves with the above ſpecific characters, founded on the proportion of theſe parts, for want of better. Mr. Ker and Mr. Dryander have done much towards the correct diſcrimination of genera and ſpecies in this favourite tribe, but the ſubject is far from being exhauſted.

10. W. *roſeo-alba*. Long-tubed Watſonia. Ker in Curt. Mag. t. 537. Ait. Epit. 376. (Gladiolus roſeoalbus; Jacq. Hort. Schoenbr. v. 1. 7. t. 13. Vahl Enum. v. 2. 93.)

β. Variegated with red. Ker in Curt. Mag. t. 1193. Ait. Epit. 376.—Tube about twice the length of the throat, limb, or ſpatha, making nearly a right angle with the throat. Leaves ſword-ſhaped, with a midrib.—Native of the Cape of Good Hope. The *tube* is one and a half or two inches long, erect; throat ſuddenly deflexed, cylindrical, rather ſlender, an inch long; ſegments of the limb lanceolate, acute, the length of the throat. *Anthers* but juſt projecting out of the mouth of the flower, violet-coloured. *Stigmas* in linear ſegments. The *corolla* is either cream-coloured, with roſe-coloured tints about the mouth and throat, or fleſh-coloured blotched with ſcarlet, or all over crimſon. The *flowers* are more numerous and crowded than in *W. Meriana* and its allies. We cannot doubt the diſtinctneſs of this ſpecies.

11. W. *aletroides*. Aletris-flowered Watſonia. Ker in Ann. of Bot. n. 7. Ait. n. 10. Curt. Mag. t. 533. (Gladiolus tubuloſus; Jacq. Ic. Rar. t. 229. Antholyza tubuloſa; Andr. Repoſ. t. 174. A. Merianella; Curt. Mag. t. 441, excluding the reference to Miller.)—Throat deflexed, four times as long as the ſegments of the limb.—Found at the Cape of Good Hope by Mr. Maſſon, who ſent bulbs to Kew garden in 1774. This elegant ſpecies bears numerous drooping *flowers*, of a rich crimſon, ſometimes ſpeckled with a darker tint, or with white, and remarkable for their ſmall ſlightly-ſpreading *limb*, ſo ſhort in proportion to the long tubular deflexed *throat*, that they reſemble the flowers of an *Aletris* or *Aloe*. The *leaves* are ſword-ſhaped, narrow, with a central rib not very ſtrongly marked, and ſeveral ſmall lateral ones.

12. W. *ſtrictiflora*. Straight-flowered Watſonia. Ker in Curt. Mag. t. 1406. Ait. Epit. 376.—Tube thread-ſhaped, twice the length of the ſpatha; throat erect, very ſhort, ſlightly dilated; ſegments of the limb elliptical, obtuſe, half the length of the tube. Leaves ſword-ſhaped, with a prominent midrib.—Native of the Cape of Good Hope, from whence it was imported by the honourable W. Herbert. The *ſtem* is about twelve or eighteen inches high, with ſeveral ſhortiſh taper-pointed *leaves* at the bottom, and bears about two handſome crimſon *flowers*, reſembling ſome of the larger *Ixiæ*, in the ſhape, ſize, and poſture of the *limb*, with a very long ſtraight ſlender *tube*. *Stigmas* divided, as in true *Watſoniæ*, the only character in which this plant anſwers to the genus. On the contrary, *Gladiolus Watſonius*, Jacq. Ic. Rar. t. 233. Willd. Sp. Pl. v. 1. 214. Ait. v. 1. 96. Curt. Mag. t. 450 and 569, (ſee Gladiolus,) has every character and appearance of a *Watſonia*, even a regular *flower*, except the narrow deeply cloven *ſtigmas*. We are obliged, therefore, to confeſs, that theſe genera do not at preſent reſt on any natural diſtinction, however different ſome of their ſpecies may be from each other.

WAT-TAUPAUMENE, or St. Peter, in *Geography*, a river of North America, which runs into the Miſſiſſippi, N. lat. 44° 42′. W. long. 93° 38′.

WATTEAU, Anthony, in *Biography*, one of the moſt agreeable painters of the French ſchool, was born at Valenciennes in 1684. His parents were in indigent circumſtances, and he was placed with an obſcure artiſt in his native city, to cultivate a talent which manifeſted itſelf early. When he was about 16 years old, having already ſurpaſſed his preceptor, he connected himſelf with a ſcene-painter on his way to Paris, and for ſome time aſſiſted his aſſociate in decorating the opera-houſe in that city. When this engagement was completed Watteau found it difficult to reſcue himſelf from the obſcurity and embarraſſment into which he fell, when happily he became acquainted with Claude Gillot, a painter of groteſque and fabulous ſubjects, who was pleaſed with his works and diſpoſition. Gillot afforded him an aſylum in his own houſe, and then inſtructed him in all he knew of the art, and found an apt and agreeable ſcholar in his protegée. With the help he thus received from Gillot, and his own admiration and attentive ſtudy of the Luxembourg gallery, he formed a taſte for colouring, which if not as grand, is at leaſt as agreeable, as ever was employed by any one.

He attempted to prepare himſelf for hiſtorical painting, and ſtudied at the academy with that view; he even was ſo ſucceſsful as to obtain the firſt prize there for an hiſtorical picture; but happily he diſcovered a character of ſubject quite original and exactly ſuited to his taſte, for which he wiſely deſerted hiſtory, and which has ſince formed plenty of aſpirants, but has never been ſo ſucceſsfully practiſed. The theatre, the opera, fêtes champetres, maſquerades, pantomimes, puppet-ſhows, afforded him his figures; the gardens of the Luxembourg and of the Thuilleries, of Verſailles and St. Cloud, furniſhed the ſcenes. In theſe nature prevails only in the colouring, and that is exquiſite, rich, delicate, clear, and full; bright without gaudineſs, and deep without blackneſs; laid on with a freedom, fulneſs, and delicacy of touch, which no one ever ſurpaſſed; but the airs of his figures are generally affected to the higheſt degree; people of rank and faſhion, aping the enjoyments of rural life: and when he attempted to paint domeſtic or rural ſcenes, he carried the ſame taſte into his practice. The true character of Watteau's pictures is French gentility, gay, cheerful, debonnaire, of which ſelf-ſatisfaction is the ſureſt baſis. "In his halts and marches of cavalry, the careleſs ſtrut of his ſoldiers retains the air of a nation that aſpires to be agreeable as well as victorious." Watteau viſited England in the reign of George I., but did not enjoy his health here, and returned to France in about a year, where he died in 1721, at the early age of 37.

WATTEN, in *Geography*, a town in Scotland, in the county of Caithneſs; 7 miles N.W. of Wick.—Alſo, a town of France, in the department of the North, on the Aa; 4 miles N. of St. Omer.

WATTENSCHIED, a town of Germany, in the county of Mark; 5 miles S.W. of Bockum.

WATTER, a river which riſes in the county of Waldeck, and runs into the Erpe, near Volckmarſen.

WATTERPUTTEN, a town of Hindooſtan, in Concan; 5 miles S. of Geriah.

WATTINAD, a town of Hindooſtan, in the Carnatic; 20 miles S.S.E. of Tanjore.

WATTLE, in *Agriculture* and *Rural Economy*, a kind of hurdle formed by means of ſplit wood, or ſmall rods, and uſed for making folds for ſheep. The term alſo ſignifies a fleſhy excreſcence growing from under the top of the throats of of animals, ſuch as the cock, turkey, and ſome others. See HURDLE.

WATTLE-*Bird*. See GLAUCOPIS *Cinerea*.

WATTLES, in *Rural Economy*, a term applied, in ſome places, to the rods that are laid upon a roof to be thatched on. This is found an uſeful and cheap mode for farm buildings in ſome of the ſouthern diſtricts. See THATCHING.

WATTON, in *Geography*, a ſmall market-town in the hundred of Wayland and county of Norfolk, England, is ſituated on the confines of what is called the Filand, or open part of the county, at the diſtance of 21 miles W. by S. from Norwich, and 91 miles N.N.E. from London. Since the making of the turnpike-road through the hundred, Watton has become a place of conſiderable thoroughfare. It has three annual fairs, and a reſpectable weekly market on Wedneſdays. Great quantities of butter are ſent hence for the ſupply of the London markets. In the enumeration of the population for the year 1811, the pariſh was ſtated to contain 177 houſes, with a population of 794 perſons. The church is very ſmall, being only twenty yards long and eleven broad: the tower is round at the bottom, and octangular at the top. Blomefield was induced, from the appearance of the church, to ſuppoſe it was erected ſo early as the reign of Henry I. It ſtands at a diſtance from the town, near the ſcite of the old manorial houſe; and was evidently ſo placed to accommodate the tenants of the ſeveral hamlets belonging to the manor. On the 25th of April 1673, a dreadful fire happened in the town, when above ſixty houſes were burnt down, beſides outhouſes, &c. to the damage of 7450*l*., and goods to the further value of 2660*l*.: for which a brief was granted to collect throughout England for two years.—Blomefield's Eſſay towards a Topographical Hiſtory of Norfolk, vol. 2. 8vo. 1805. Beauties of England and Wales, vol. xi. Norfolk. By Rev. J. Evans, and J. Britton, F.S.A.

WATTS, ISAAC, D.D. in *Biography*, a Nonconformiſt divine, eminently diſtinguiſhed for talents and piety, was born at Southampton in 1674, where, under the tuition of a clergyman of the eſtabliſhed church, he made rapid progreſs in the Latin and Greek languages, and acquired ſome knowledge even of Hebrew. When it was propoſed by ſome gentlemen who were apprized of his proficiency, to bear the charges of his education in one of the Engliſh univerſities, he declared his purpoſe of continuing among the Diſſenters, though his father, who was of that profeſſion, had often ſuffered perſecution; and at the age of ſixteen he was placed under the care of the Rev. Thomas Rowe, who kept an academy in London. Twenty-two Latin diſſertations on metaphyſical and theological ſubjects, found among his papers, afford ample evidence of his zealous application during his connection with this inſtitution. Of his poetical talents at the early age of fifteen years ſeveral ſpecimens have been preſerved, and more particularly a Pindaric ode, addreſſed to his preceptor Mr. Pinhorne. At the age of twenty he finiſhed his academical ſtudies, and reſided with his father for two years with a view to farther improvement. At this time he was invited to become private tutor to the ſon of ſir John Hartopp, bart. at Stoke-Newington near London, and in this ſituation he continued for five years, gaining univerſal eſteem, cultivating a friendſhip with his pupil which laſted through life, and connecting with the diſcharge of his office the ſtudy of the ſcriptures in the original languages. Although he was well qualified for the public exerciſe of his miniſtry, ſuch was his diffidence that he would not venture to aſcend the pulpit till he had completed his twenty-fourth year, at which time he was choſen aſſiſtant to Dr. Iſaac Chauncy, whom he ſucceeded as paſtor in the year 1702. His conſtitution was ſo delicate that he could not undertake the whole ſervice, and the attack of a fever in 1712 diſqualified him for his public duties for four years. In this ſtate of debility he was kindly received in the houſe of ſir Thomas Abney, where the indulgent treatment of this gentleman and his lady contributed to reſtore his health and ſpirits. In this hoſpitable manſion he not only found a temporary aſylum, but a permanent abode for the remaining thirty-ſix years of his life. Here he enjoyed every comfort which friendſhip and liberality could beſtow, and which, by repairing his enfeebled frame, enabled him to reſume his ſervices in public and to proſecute his private ſtudies, no leſs to the improvement and ſatisfaction of thoſe with whom he was immediately connected, than to the benefit of the world; inſomuch that few perſons have acquired a more extenſive and a more permanent popularity, as it reſpects the intereſts both of literature and of religion. His reputation attracted the notice of both the univerſities of Edinburgh and Aberdeen, and they ſeemed to vie with each other which ſhould firſt confer upon him the honour of the degree of doctor in divinity, and he received it from theſe two univerſities in the year 1728. His conſtitution, though in ſome degree renovated by the attention and kindneſs which he experienced, was ſtill ſo delicate and feeble, that he found it neceſſary to remit, and at length to reſign his miniſterial duties; but his congregation teſtified their reſpect for him by declining to accept his offer of the renunciation of his uſual ſalary: However, he gradually declined, and calmly expired at Stoke Newington, November the 25th, 1748, in the 75th year of his age.

Dr. Watts was a man of lively fancy, warm feelings, and a comprehenſive underſtanding, and diſtinguiſhed by that verſatility of talents and purſuits, which enabled him to acquire a conſiderable degree of reputation in various departments of literature, but which prevented his arriving at a ſupereminent rank in any. The characteriſtic quality of his mind, manifeſted in his numerous productions, was a devotional ſpirit. Of his "Horæ Lyricæ," the greateſt number belongs to the devotional claſs, and in theſe his ardent feelings and imagination have ſometimes tranſported him beyond the bounds which a correct taſte and ſound judgment would have preſcribed. The ſame obſervation may be alſo applied to his "Pſalms and Hymns," and more eſpecially to the latter, which were juvenile compoſitions, and in which a ſober reader will be diſguſted with the contraſt that is exhibited between the wrath of the Supreme Being and the benignity of the Son of God; as if the Deity were inclined to puniſh his offending creatures with everlaſting puniſhment, and the Son were diſpoſed to reſcue and ſave them. Many of the pſalms and hymns, however, are admirably adapted to Chriſtian worſhip, and a ſelect collection of them, which has been lately made by ſome miniſters in London, and which they have enriched by extracts from other ſources, is leſs exceptionable in a variety of reſpects than either the pſalms or hymns even of Dr. Watts in their original ſtate; and in theſe devotion and poetry are more happily combined for the worſhip of Diſſenters and even of Churchmen than in the pſalmody of the eſtabliſhment. Many of Watts's lyric productions poſſeſs conſiderable poetical merit, and diſplay a fertility and elegance of fancy. His "Divine Songs for Children" have been widely circulated, and are well calculated to intereſt and impreſs youthful minds; and they are, generally ſpeaking, unexceptionable, though not incapable of caſtigation and improvement.

The doctor's philoſophical publications are numerous, and moſt of them are well known. Among theſe we may reckon his "Logic," and the ſupplement to it, entitled the "Improvement of the Mind;" "A Diſcourſe on Education;" "An Elementary Treatiſe on Aſtronomy and Geography;" "Philoſo-

"Philofophical Effays on various Subjects, with Remarks on Locke's Effay on the Human Underftanding;" and "A brief Scheme of Ontology." His other works are chiefly theological, confifting of Sermons, Difcourfes, Effays, and Controverfial Tracts, &c. His fcheme of theology was undoubtedly that which is ufually called orthodoxy, and, to fay the leaft of it, approaching to Calvinifm. His temper, however, was kind and gentle, and his moderation was increafing as he advanced in years, and the maturity of his judgment reftrained and controlled the fervour of his feelings and paffions. Some have faid that towards the clofe of life his fentiments, with regard to the doctrine of the Trinity, were materially altered. This, however, is a queftion *fub judice.* Whilft it is needlefs in this place to enter into the difpute, and to examine the allegations *pro* and *con*, we incline to think, as far as we have had an opportunity of examining the evidence, that the fuppofition of fome degree of change is not improbable. The printed Works of Dr. Watts, together with thofe which were left in M.S. for the revifion of Dr. Jennings and Dr. Doddridge, were publifhed collectively by Dr. Gibbons, in 6 vols. 4to. 1754. We fhall conclude this article with the words of one of his biographers. "To whatever clafs Dr. Watts belongs," ranked by this biographer among the decided advocates for orthodoxy, "he muft always be regarded as one of thofe whofe whole heart was devoted to the promotion of the beft interefts of mankind, and whofe life would have done honour to any fyftem of opinions." Gibbons's Memoirs of Watts. Johnfon's Lives of the Poets. Gen. Biog.

WATTS, in *Geography*, a town of Virginia; 30 miles N.W. of Alexandria.—Alfo, a town of the ftate of Georgia. N. lat. 34° 22′. W. long. 86° 25′.

WATTS *Ifland*, a fmall ifland in the Chefapeak. N. lat. 37° 54′. W. long. 76° 3′.

WATTUSKIFLET, a channel of the Baltic, between the ifland of Aland and the coaft of Finland, abounding with fmall iflands.

WATWEILER, or WATTERWEILER, a town of France, in the dapartment of the Upper Rhine. Near it is a medicinal fpring; 16 miles S. of Colmar.

WAU, a town of Hindooftan, in the circar of Werrear; 24 miles N. of Radunpour.

WAU-CA-HATCHO, or COW-TAIL *River*, a river of Louifiana, which is the laft ftream of any confequence that enters the Sabine.

WAVE, UNDA, in *Phyfics*, a cavity in the furface of the water, or other fluid, with an elevation on its fides. Or, it is a volume of water elevated by the action of the wind upon its furface, into a ftate of fluctuation.

The origin of waves may be thus conceived. The furface of a ftanding water being naturally plain, and parallel to the horizon, (allowing for that fmall degree of curvature which refults from its gravitation to the centre,) if by any means it be rendered hollow, as at A, (*Plate* XV. *Hydraulics*, *fig.* 11.) its cavity will be furrounded with an elevation B B; for if a certain quantity of water be depreffed below the ufual level, an equal quantity muft rife in fome other place above that level, and the water which ftands clofeft to the place of the original impreffion will of courfe be moved. The raifed water will defcend by its gravity, and, with the celerity acquired in defcending, will form a new cavity; by which motions, the water will afcend at the fides of this cavity, and fill the cavity A, while there is a new elevation towards C; and, when this laft is depreffed, the water rifes anew towards the fame part. Thus arifes a fucceffive motion in the furface of the water; and a cavity, which carries an elevation before it, is moved along from A, towards C. Thus the alternate rifing and falling of the water in ridges will extend all round the original fource of motion; but as they recede from that place, fo the ridges, as well as the adjoining hollows, become fmaller and fmaller, until they vanifh. This diminution of fize is produced by three caufes; *viz.* by the want of perfect freedom of motion amongft the particles of water, by the refiftance of the air, and by the further ridges being larger in diameter than thofe which are nearer. It is likewife on account of the friction, or adhefion, among the particles of water, and of the refiftance of the air, that, in the fame place, the alternate elevations and depreffions diminifh gradually, until the water reaffumes its original tranquillity, unlefs the external impreffion be renewed or continued. This cavity, with the elevation next it, is called a *wave;* and the fpace taken up by the wave on the furface of the water, and meafured according to the direction of the wave's motion, is called the *breadth of the wave;* which is evidently equal to the diftance between the tops of contiguous ridges, or between the loweft parts of two contiguous hollows; and a wave is faid to *have run its breadth*, when its elevated part is arrived at the place where the elevated part of the next wave ftood before, or (the fituations of two contiguous waves being given) when one of them is arrived at the place of the other; and the time which is employed in this tranfition is called *the time of a wave's motion.*

WAVES, *the Motion of*, forms an article in the new philofophy; and its laws being now pretty well determined, we fhall give the reader the fubftance of what is taught on this fubject.

1. The cavity, as A, is encompaffed every way with an elevation; and the motion above-mentioned expands itfelf every way: therefore the waves are moved circularly.

2. Suppofe, now, A B (*fig.* 12.) an obftacle, againft which the wave, whofe beginning is at C, ftrikes; and we are to examine what change the wave fuffers in any point, as E, when it is come to the obftacle in that point. In all places through which the wave paffes in its whole breadth, the wave is raifed; then a cavity is formed, which is again filled up; which change while the furface of the water undergoes, its particles go and return through a fmall fpace: the direction of this motion is along C E, and the celerity may be reprefented by that line. Let this motion be contrived to be refolved into two other motions, along G E and D E, whofe celerities are refpectively reprefented by thofe lines. By the motion along D E, the particles do not act againft the obftacle; but, after the ftroke, continue their motion in that direction with the fame celerity; and this motion is here reprefented by E F, fuppofing E F and E D to be equal to one another; but by the motion along G E, the particles ftrike directly againft the obftacle, and this motion is deftroyed: for though the particles are elaftic, yet, as in the motion of the waves they run through but a fmall fpace, going backward and forward, they proceed fo flowly, that the figure of the particles cannot be changed by the blow; and fo are fubject to the laws of percuffion of bodies perfectly hard. See PERCUSSION.

But there is a reflection of the particles from another caufe: the water which cannot go forward beyond the obftacle, and is pufhed on by that which follows it, gives way where there is the leaft refiftance; that is, it afcends; and this elevation, which is greater in fome than other places, is caufed by the motion along G E; becaufe it is by that motion alone that the particles impinge againft the obftacle. The water, by its defcent, acquires the fame velocity with which it was raifed; and the particles of water are repelled from the obftacle with the fame force in the direction E G,

 as

as that with which they ftruck againft the obftacle. From this motion, and the motion above-mentioned along E F, arifes a motion along E H, whofe celerity is expreffed by the line E H, which is equal to the line C E; and by the reflection, the celerity of the wave is not changed, but it returns along E H, in the fame manner as if, taking away the obftacle, it had moved along E *h*.

If from the point C, C D be drawn perpendicular to the obftacle, and then produced, fo that D *c* fhall be equal to C D, the line H E continued will go through *c*; and as this demonftration holds good in all points of the obftacle, it follows, that the reflected wave has the fame figure on that fide of the obftacle, as it would have had beyond the line A B, if it had not ftruck againft the obftacle. If the obftacle be inclined to the horizon, the water rifes and defcends upon it, and fuffers a friction, by which the reflection of the wave is difturbed, and often wholly deftroyed; and this is the reafon why very often the banks of rivers do not reflect the waves.

If there be a hole, as I, in the obftacle B L, the part of the wave which goes through the hole, continues its motion directly, and expands itfelf towards Q Q; and there is a new wave formed, which moves in a femicircle, whofe centre is the hole. For the raifed part of the wave, which firft goes through the hole, immediately flows down a little at the fides; and, by defcending, makes a cavity which is furrounded with an elevation on every part beyond the hole, which moves every way in the fame manner as was laid down in the generation of the firft wave.

In the fame manner, a wave to which an obftacle, as A O, is oppofed, continues to move between O and N, but expands itfelf towards R, in a part of a circle, whofe centre is not very far from O. Hence, we may eafily deduce what muft be the motion of a wave behind an obftacle, as M N.

Waves are often produced by the motion of a tremulous body, which alfo expand themfelves circularly, though the body goes and returns in a right line; for the water which is raifed by the agitation, defcending, forms a cavity, which is every where furrounded with a rifing.

Different waves do not difturb one another, when they move according to different directions. The reafon is, that whatever figure the furface of the water has acquired by the motion of the waves, there may in that be an elevation and depreffion; as alfo fuch a motion as is required in the motion of a wave.

To determine the celerity of the waves, another motion, analogous to their's, muft be examined. Suppofe a fluid in the bent cylindric tube E H (*fig.* 13.); and let the fluid in the leg E F be higher than in the other leg by the diftance *l* E; which diftance is to be divided into two equal parts at *i*. The fluid, by its gravity, defcends in the leg E F, while it afcends equally in the leg G H; fo that when the furface of the fluid is arrived at *i*, it is at the fame height in both legs; which is the only pofition in which the liquid can be at reft: but by the celerity acquired in defcending, it continues its motion, and afcends higher in the tube G H; and in E F is depreffed quite to *l*, except fo much as it is hindered by the friction againft the fides of the tube. The fluid in the tube G H, which is higher, alfo defcends by its gravity, and fo the fluid in the tube rifes and falls, till it has loft all its motion by the friction.

The quantity of matter to be moved is the whole fluid in the tube; the moving force is the weight of the column *l* E, whofe height is always double the diftance E *i*; which diftance, therefore, increafes and diminifhes in the fame ratio with the moving force. But the diftance E *i* is the fpace to be run through by the fluid, in order to its moving from the pofition E H, to the pofition of reft; which fpace, therefore, is always as the force continually acting upon the fluid: but it is demonftrated, that it is on this account that all the vibrations of a pendulum, ofcillating in a cycloid, are ifochronal; and, therefore, here alfo, whatever be the inequality of the agitations, the fluid always goes and returns in the fame time. The time in which a fluid thus agitated afcends, or defcends, is the time in which a pendulum vibrates, whofe length is equal to half the length of the fluid in the tube, or to half the fum of the lines E F, F G, E H. This length is to be meafured in the axis of the tube. See PENDULUM.

From thefe principles, to determine the celerity of the waves, we muft confider feveral equal waves following one another immediately; as A, B, C, D, E, F, (*fig.* 14.) which move from A towards F: the wave A has run its breadth, when the cavity A is come to C; which cannot be, unlefs the water at C afcends to the height of the top of the wave, and again defcends to the depth C; in which motion, the water is not agitated fenfibly below the line *b i*: therefore, this motion agrees with the motion in the tube above-mentioned; and the water afcends and defcends, that is, the wave goes through its breadth, while a pendulum of the length of half B C performs two ofcillations, or while a pendulum of the length B C D, that is, four times as long as the firft, performs one vibration; fince the times in which pendulums of different lengths perform their vibrations are as the fquares of their lengths. (See VIBRATION.) Therefore, the celerity of the wave depends upon the length of the line B C D; which is greater, as the breadth of the wave is greater, and as the water defcends deeper in the motion of the waves. In the broadeft waves, which do not rife high, fuch a line as B C D does not much differ from the breadth of the wave; and in that cafe a wave moves its breadth, while a pendulum, equal to that wave, ofcillates once. Hence, if the breadth of a wave be 39.1196 inches, (this being the length of a pendulum which vibrates feconds,) then that wave will move on at the rate of 39.1196 inches *per* fecond of time; that is, at the rate of 195 feet *per* minute, nearly.

In every equable motion, the fpace gone through increafes with the time and the celerity; wherefore, multiplying the time by the celerity, you have the fpace gone through; whence it follows, that the celerities of the waves are as the fquare roots of their breadths: for as the times in which they go through their breadths are in that ratio, the fame ratio is required in their celerities, that the products of the times, by their celerities, may be as the breadths of the waves, which are the fpaces gone through.

Dr. Young is of opinion, that fir Ifaac Newton's analogy, refulting from a comparifon of a wave with the ofcillation of a fluid in a bent tube, is too diftant to admit our founding any demonftration upon it. Legrange, he fays, has inveftigated the motions of waves in a new and improved manner; and Dr. Young has alfo demonftrated a theorem fimilar to his, but, as he apprehends, more general and explicit. From thefe premifes it appears, that, fuppofing the fluids concerned to be infinitely elaftic, that is, abfolutely incompreffible, and free from friction of all kinds, any fmall impulfe communicated to a fluid would be tranfmitted every way along its furface, with a velocity equal to that which a heavy body would acquire in falling through half the depth of the fluid; and he concludes, from obfervation and experiment, that where the elevation or depreffion of the furface is confiderably extenfive in proportion to the depth, the velocity approaches nearly to that which is thus deter-

mined,

mined, being frequently deficient one-eighth or one-tenth only of the whole. In other cafes, where a number of fmall waves follow each other at intervals confiderably lefs than the depth, he has endeavoured to calculate the retardation which muft be occafioned by the imperfect elafticity or compreffibility of the fluid; but it feems probable that the motion of fmall waves is ftill much flower than this calculation appears to indicate. Many of the phenomena of waves, fays this ingenious author, may be very conveniently exhibited by means of a wide and fhallow veffel, with a bottom of glafs, terminated by fides inclined to the horizon; in order to avoid the confufion which would arife from the continual reflections produced by perpendicular furfaces. The waves may be excited by the vibrations of an elaftic rod or wire, loaded with a weight, by means of which its motions may be made more or lefs rapid at pleafure; and the form and progrefs of the waves may be eafily obferved, by placing a light under the veffel, fo that their fhadows may fall on a white furface, extended in an inclined pofition. In this manner, the manifeft inflection of the furface of the water may be made perfectly confpicuous.

This motion of the fea-water depends greatly on the winds, and on the fituation of mountains, in regard to the fea; for the winds are driven back from thefe with great impetuofity; and in fome places this occafions a great and very irregular undulation, befide that which is produced by the immediate action of the winds on the furface of the water in their own direct courfe.

Waves are to be confidered as of two kinds, and thefe may be diftinguifhed from one another by the names of *natural* and *accidental* waves.

The *natural* waves are thofe which are regularly proportioned in fize to the ftrength of the wind, whofe blowing gives origin to them. The *accidental* waves are thofe occafioned by the wind's reacting upon itfelf by repercuffion from hills and mountains, or high fhores, and by the wafhing of the waves themfelves, otherwife of the natural kind, againft rocks and fhoals: all thefe caufes give the waves an elevation, which they can never have in their natural ftate.

It feems to be pretty well determined, from a variety of experiments and obfervations, that the moft violent wind never penetrates a great way into the water; and that in great ftorms the water of the fea is flightly agitated at the depth of 20 feet below the ufual level, and probably not moved at all at the depth of 30 feet, or 5 fathoms; confequently the natural difplacing of the waters by the wind cannot be fuppofed to reach nearly fo low: and hence it fhould feem, that the greateft waves could not be fo very high as they are reprefented by accurate and creditable navigators. Mr. Boyle found, upon inquiry, that when the wind was high, fo that the waves were manifeftly fix or feven feet high above the furface of the water, no fign of agitation was perceived at the depth of 15 fathoms; but if the blaft continued long, then the mud at the bottom was ftirred, and the water became thick and dark. Perfons who have remained for fome time at a confiderable depth have been furprifed to find a ftorm, when they have returned to the upper parts of the water. At the depth of 12 or 15 feet, the agitation of the water has been accordingly diminifhed; and at a confiderable diftance from the fhore, and in deeper water, the fea has been found proportionably calm and tranquil. It has alfo been found, that in a part of the fea often tempeftuous, the ftorm did not reach with any efficacy four fathoms beneath the furface of the water. Boyle's Works, vol. iv. p. 354, 4to. Relations about the Bottom of the Sea, § 3.

Count Marfigli meafured carefully the elevations of the waves near Provence, and found that, in a very violent tempeft, they arofe only to feven feet above the natural level of the fea; and this additional foot in height, above the refult of Mr. Boyle's deductions, he eafily refolved into the accidental fhocks of the water againft the bottom, which was, in the place he meafured them in, not fo deep as to be out of the way of affecting the waves; and he allows that the addition of one-fixth of the height of a wave, from fuch a difturbance from the bottom, is a very moderate alteration from what would have been its height in a deep fea; and concludes, that Mr. Boyle's calculation holds perfectly right in deep feas, where the waves are purely natural, and have no accidental caufes to render them larger than their juft proportion.

In deep water, under the high fhores of the fame part of France, this author found the natural elevation of the waves to be only five feet; but he found alfo that their breaking againft rocks, and other accidents to which they were liable in this place, often raifed them to eight feet high.

We are not to fuppofe, from this calculation, that no wave of the fea can rife more than fix feet above its natural level in open and deep water; for waves immenfely higher than thefe are formed in violent tempefts in the great feas. Thefe, however, are not to be accounted waves in their natural ftate, but they are fingle waves formed of many others; for in thefe wide plains of water, when one wave is raifed by the wind, and would elevate itfelf up to the exact height of fix feet, and no more, the motion of the water is fo great, and the fucceffion of waves fo quick, that, during the time this is rifing, it receives into it feveral other waves, each of which would have been at the fame height with itfelf: thefe run into the firft wave one after the another, as it is rifing; and by this means its rife is continued much longer than it naturally would have been, and it becomes accumulated to an enormous fize. A number of thefe complicated waves arifing together, and being continued in a long fucceffion by the continuation of the ftorm, makes the waves fo dangerous to fhips, which the failors in their phrafe call mountains high. Marfigli, Hift. Phyf. de la Mer.

When it blows frefh, the waves not moving with fufficient rapidity, their tops, which are thinner and lighter, are impelled forward, broken, and changed into a white foam, particles of which, called the "fpray," are carried a great way. Waves, with regard to their form, are circular or ftraight, or otherwife bent, according as the original impreffion is made in a narrow fpace nearly circular, or in a ftraight line, or in other configurations. In open feas the waves generally are in the fhape of ftraight furrows, becaufe the wind blows upon the water in a parallel manner, or at leaft for a long apparent tract. The fame caufes which raife water into waves muft evidently produce the like effect on other fluids, but in various degrees, as the fluid is more or lefs heavy, as its particles adhere more or lefs forcibly to each other, and probably likewife as there is a greater or lefs degree of attraction between the fluid and the other body which gives it the impulfe. If it be attempted to raife waves upon oil by the force of wind, it will be found very difficult to fucceed in a fimilar degree. This difficulty is probably owing to the natural attraction of the particles of oil; and befides, there may be lefs attraction between oil and air than between the latter and water, for water always contains a certain quantity of air; and if it be deprived of that air by boiling, or otherwife, a fhort expofure to the atmofphere will enable the water to reimbibe it. It is likewife probable, that the furface of water, even when ftag-

nant,

nant, may not be fo fmooth as the furface of oil, fo that the wind may more eafily catch into the inequalities of the former than the latter. Hence it is that the effect of the wind upon waves may in a great degree be prevented or moderated, by fpreading a thin film of oil on the furface of the water. For an account of this operation and its effects, fee OIL.

WAVE-*Offering*, among the *Jews*, a facrifice offered by agitation or waving towards the four cardinal points.

To WAVE, is ufed, in the *Sea-Language*, for the making figns for a veffel to come near, or keep off.

WAVED, or WAVY, a term in *Heraldry*, when a bordure, or any ordinary or charge in a coat of arms, has its outlines indented, in manner of the rifing and falling of waves. This is alfo called *undy*, *undé*, or *ondé*, and denotes that the firft of the family in whofe arms it ftands, acquired his honours for fea fervices, and has this peculiar commemoration of it ordered in his arms.

WAVED *Hair-Grafs*, in *Agriculture*, a fort of grafs which is found to be pretty productive on mountain heathy lands, and which abounds pretty much in nutritive matter, but which lofes confiderably in its weight in drying, according to the trials which have lately been made on graffes at Woburn. See AIRA *Flexuofa*.

WAVELLITE, in *Mineralogy*, a mineral firft difcovered at Barnftaple, in Devonfhire, by Dr. Wavell, and fince found in various other fituations. From its appearance, it has been claffed by Mr. Jamefon as a member of the zeolite family. See ZEOLITE.

Wavellite occurs in a botryoidal, ftalactical, and globular form; alfo cryftallized in very oblique four-fided prifms, flatly bevelled on the extremities: the bevelling planes are fet on the obtufe lateral edges. The prifms are fometimes deeply truncated on the obtufe lateral edges. Wavellite occurs alfo in fibres, or acicular prifms, diverging from a common centre, and either feparated or adhering laterally to each other, compofing hemifpherical concretions of various fizes, to the magnitude of a bullet. The luftre of wavellite is pearly, more or lefs fhining. The colour is yellowifh-white, greyifh-white, and greenifh-white; it is tranflucent. This mineral is brittle, and, according to profeffor Jamefon, it is fufficiently hard to fcratch quartz: others afcribe to it a lower degree of hardnefs. Before the blow-pipe it becomes foft and opaque, but neither decrepitates nor fufes. It is foluble by the affiftance of heat in the mineral acids, in which it effervefces and leaves very little refidue. The fpecific gravity of wavellite varies from 2.22 to 2.70.

The moft remarkable peculiarity of this mineral is its compofition; wavellite being nearly a pure hydrat of alumine; but fome fpecimens contain a trace of fluoric acid. When fragments of the Englifh or Irifh wavellite are laid upon a glafs plate, and a drop of fulphuric acid is added, the glafs is flightly corroded on the application of heat, indicating the prefence of the above-mentioned acid.

The conftituent parts of wavellite are given as under:

	Wavellite from Barnftaple.	
Alumine -	71.50	70
Oxyd of iron	.50	
Lime - -		1.4
Water -	28.	26.2
	100 Klaproth.	97.6 Davy.

	Cornifh Wavellite.	South American Wavellite.
Alumine -	58.70	68.
Oxyd of iron	0.19	1.
Lime -	0.37	
Silex -	6.12	4.50
Water -	30.75	
Lofs -	3.87	26.50
	100 Gregor.	100 Klaproth.

Wavellite occurs in veins in the granite of Cornwall, with fluor-fpar, quartz, tin-ftone, and copper pyrites. At Barnftaple, in Devonfhire, it occurs in foft flate. Several mineralogifts confider wavellite as a variety of the fame mineral, which Hauy has called diafpore.

WAVENEY, in *Geography*, a river of England, in the county of Suffolk, which joins the Yare, at its mouth.

WAVEREN, a town of France, in the department of the Scheld, on the Dyle. By war and accidental fires much decayed; 12 miles S. of Louvain.

WAVERS, in *Rural Economy*, a term ufed to fignify the young timber-trees, or timberlings as they are moftly called, that are left ftanding for further growth, in felling or cutting over woods of different kinds. See TIMBER.

WAVESON, in the *Admiralty-Law*, a term ufed for fuch goods, as, after fhipwreck, appear fwimming on the waves.

WAVIGNIES, in *Geography*, a town of France, in the department of the Oife; 10 miles N. of Clermont.

WAUKEAGUE, a town of the diftrict of Maine, near the coaft; 5 miles W. of New Briftol.

WAUNGLY, a town of Hindooftan, in Vifiapour; 10 miles S.E. of Currer.

WAVY, in *Botany*, is fynonymous with *repandum* and *undulatum*; in the firft inftance, it expreffes an undulating outline, with an even furface; in the fecond, an undulating furface, caufed by the marginal region of a leaf, or petal, being more ample or luxuriant than the central part, or bafe. The latter is often the cafe with cultivated plants, as *Malva crifpa*, and the different curled varieties of cabbage, brocoli, parfley, mint, &c.

WAVY, in *Heraldry*. See WAVED.

WAWAY, in *Geography*, a fmall ifland in the Eaft Indian fea, near the E. coaft of the ifland of Celebes, about 40 miles in circumference. S. lat. 4° 8′. E. long. 123° 30′.

WAWARSING, a large townfhip of New York, in the fouth-weft angle of Ulfter county, 25 miles S.W. of Kingfton, erected in 1806, from the S.W. part of Rochefter, and lying on the W. of the Shawangunk mountain. Plumbago, of a good quality, is found in this townfhip, and here are many indications of iron-ore. Here are feveral fmall fettlements, as at Warwafing, Napenagh, and Lurenkill; but much of the land is uncultivated. Here are one Dutch reformed church, and eight or ten fchool-houfes. In 1812, the whole population confifted of 1335 perfons, and the number of electors was 117; and here were 74 looms in families, which produced 18,047 yards of cloth.

WAWIACHTANOS, Indians of America, inhabiting chiefly between the rivers Wabafh and Sciota.

WAWRA, a fmall negro town of Africa, properly belonging to Kaarta, but when Park vifited it, tributary to Maafong, king of Bambarra. It is furrounded with walls, and inhabited by a mixture of Mandingoes and Foulahs. The inhabitants are chiefly employed in cultivating corn, which they

they exchange with the Moors for ſalt; 60 miles E.S.E. of Benowm.

WAX, a term which comprehends two or three ſubſtances, differing in their nature and origin, and yet poſſeſſing ſeveral common properties. The common properties of the animal and vegetable productions, of which we ſhall give a brief account in the ſequel of this article, are fuſibility at a moderate heat; when kindled, burning with much flame; inſolubility in water; ſolubility in alkalies, and alſo in alcohol and ether; in which two latter properties all the ſpecies of wax differ from the concrete oils, to which in other reſpects they bear a very ſtrong reſemblance. The moſt important, and moſt generally known and uſed of theſe ſubſtances, is

Bees'-wax, excreted from the body of the bee, and employed by theſe inſects in the conſtruction of their cells, both for the accommodation of their young and the depoſition of their honey. Of this ſubſtance, a young hive will yield at the end of the ſeaſon about a pound of wax; and an old hive about twice as much. The fineſt wax is that which is made in dry, heathy, or hilly countries; but in parts abounding with vineyards it is decidedly inferior. Although the commonly received notion, which aſcribes this ſubſtance to the elaboration of the pollen of flowers, which the bees viſibly collect on their thighs, had received the ſanction of obſervers not leſs diſtinguiſhed than Bonnet and Reaumur (ſee PAIN *D'Abeilles*), yet the Luſatian Society, as long ago as the year 1768, was not unacquainted with the fact, that the wax, inſtead of being diſcharged from the mouth, is ſecreted in the form of thin ſcales among the abdominal rings or ſegments. In 1792, the celebrated Mr. John Hunter detected the genuine reſervoir of the wax under the belly of the bees, and gave an account of his obſervations in the Philoſophical Tranſactions, (vol. lxxxii. part 1.). On elevating the lower ſegments, he obſerved plates of a fuſible ſubſtance, which he aſcertained to be wax; and he was convinced, that an eſſential difference ſubſiſts between the pollen, which theſe little creatures collect with ſo much care and induſtry in the form of pellets on their thighs, and the matter of which the combs are conſtructed. This curious ſubject has been further inveſtigated by Meſſrs. Huber, father and ſon; and they have demonſtrated the organs in which the wax is ſecreted, though they had eluded the perſpicuity of Swammerdam, Hunter, and other acute anatomiſts. Theſe facklets, or ſmall compartments, now minutely explained and illuſtrated by engravings, are peculiar to the working bees, which alone produce wax; and each individual is furniſhed with eight of them. The waxy matter, as it occurs in a tranſuded ſtate in the ſecretory organs, differs from the freſh wax of the combs only in being of a leſs compounded nature, which has been aſcertained by trials with ſpirit of turpentine and ſulphuric ether. Proſecuting theſe reflections, our ingenious authors concluded that the common opinion was probably erroneous; becauſe, like Hunter, they had obſerved ſwarms, newly placed in the empty hives, conſtruct their combs without fetching home any pollen; while the bees of old hives, where no freſh cells were required, nevertheleſs provided an ample ſtock of this powder. In order, however, to determine the point more directly, they confined a recent ſwarm within an empty ſtraw-hive, leaving at their diſpoſal only a ſufficiency of honey and water for their conſumption, and preventing them from going beyond the precincts of a well-cloſed room; when, in the ſhort ſpace of five days, they had conſtructed five cakes of a beautiful white though very fragile wax. This experiment was repeated, and was uniformly accompanied by ſimilar reſults; and therefore they no longer heſitated in admitting the fact, that honey, through the organic intervention of bees, may be converted into wax. In order to determine whether vegetable pollen, alſo, was ſuſceptible of this converſion, the honey was wholly removed, and the confined bees were fed on fruits and pollen, of which laſt a large ſtore was left at their diſpoſal; but, though they continued in this ſituation during eight days, they neither made any wax, nor exhibited any plates under their abdominal rings. Having ſuſpected that the ſecretion of wax originated in the coheſive principle contained in honey, our authors recurred to various experiments, which conſtantly proved that ſugar alone was an excellent ſubſtitute for honey, and, on ſome occaſions, afforded a ſuperior wax. They afterwards found, that bees, when left at perfect liberty to roam abroad, act preciſely on the ſame principle in the conſtruction of their combs; and they alſo diſcovered, that labourers of two deſcriptions exiſt in each hive. The firſt, ſuſceptible of acquiring conſiderable dimenſions, when they have received all the honey which their ſtomachs can contain, are principally deſtined to the elaboration of the wax; while the ſecond, whoſe abdomen undergoes no ſenſible change of bulk, neither gather nor retain more honey than is neceſſary for immediate ſubſiſtence, and readily ſhare that which they collect with their companions; who take no charge of ſtoring the hive with proviſions, their appropriate office being to attend the young. Theſe they call nurſing or ſmall bees, in contradiſtinction to thoſe with dilated bellies, and which, as they ſay, are entitled to the appellation of "wax-workers." The exiſtence and ſeparate offices of theſe two ſorts of bees were ſufficiently aſcertained. When the hives are filled with combs, the wax-working bees diſgorge their honey into the uſual magazines, and produce no more wax; but, if they have no receptacle in which they can depoſit it, and if the queen finds no cells formed ready for the reception of her ova, they retain in their ſtomachs the honey which they had amaſſed; and, at the end of 24 hours, the wax oozes out between the rings, when the fabrication of the combs commences. The nurſing bees alſo produce wax, but in a much ſmaller quantity than the others.

As for the uſe of the pollen, our authors have aſcertained, that it is collected for the purpoſe of feeding the young; and they have alſo found, that bees, fed too long on the ſyrup of ſugar alone, are incapable of rearing their offspring, and at length deſert the hive. The waxy matter, when newly ſecreted and moulded in its appropriate organs, differs from real wax in being tranſparent like ſcales of talc, white, and quite friable, or brittle; whereas that of which the cells are compoſed is of a yellowiſh-white, opaque, and flexible. Our limits will not allow our deſcribing the proceſs obſerved by our authors with the aid of a glaſs apparatus, by which theſe inſects commence and conduct the conſtruction of their combs. The difference of aſpect and conſiſtency between cells juſt formed, and thoſe which are of older ſtanding, cannot fail to attract the attention of every obſervant apiarian. The former are, in fact, of a dull white colour, ſemi-tranſparent, ſoft, and even, without being ſmooth; but, in the courſe of a few days, the whole of their internal ſurface aſſumes a yellow tint of greater or leſs intenſity: their ſharp edges become thicker and leſs regular; and thoſe tubes, which at firſt could not reſiſt the ſlighteſt preſſure, become flexible, ſomewhat more heavy, and more difficult of ſolution in hot water. The contour of the orifice of mature cells is bound with a rim of a reddiſh and odorous reſin, which is alſo employed to cement the angles of other parts of the cell. This ſolder or varniſh is found, on chemical trial, to be identical with the propolis,

and

and quite diftinct from the wax. Meffrs. Huber have not only eftablifhed this important fact, but detected the origin of the propolis itfelf. Having obtained branches of the wild poplar, cut in fpring before the developement of their leaves, with very large buds filled with vifcous, reddifh, and odorous juice, they placed thefe in the way of the bees to the fields, fo that they muft fee them: foon after this arrangement, a bee alighted on one of the branches, and approached one of the largeft buds; fhe then feparated its folds with her teeth, attacked the parts which fhe had half-opened, pulled off filaments of the vifcid matter with which they were filled, and then feized, with one of the legs of the fecond pair, the fubftance held between her jaws, brought forwards one of her hind-legs, and finally placed in the bafket of that leg the little ball of propolis which fhe had juft collected. Having accomplifhed this object, fhe again opened the bud in another place, carried off new threads of the fame matter with her teeth, laid hold of them with the legs of the fecond pair, and placed them nicely on the other bafket. She then took her departure, and rejoined her hive. In a few minutes afterwards, a fecond bee alighted on the fame branches, and loaded herfelf with propolis in the fame manner. This propolis was found to be different from the matter which imparts the yellow colour to the wax, which is probably fecreted in the cavity of the teeth, and depofited on the wax. We obferve, however, that bees are not contented with merely painting and varnifhing their cells, but they alfo impart additional folidity to their aggregate amount by the ufe of a mortar, compofed of wax and propolis; and which the ancients, who had not overlooked this department of their economy, termed *metis*, or *piffocerum*. (See PROPOLIS.) With the neceffary documents before us, we cannot forbear introducing fome further obfervations on the economy of thefe infects, though they are not immediately connected with the fubject of this article. As the clofenefs of a hive, and the multitude of living creatures which inhabit it, (amounting fometimes to twenty-five or thirty thoufand,) are circumftances which feem to preclude a free ventilation and renewal of air, we might be induced to fuppofe that bees are not endowed with any particular fyftem of refpiratory organs, and that they are capable of exifting in any atmofphere, however vitiated. As a teft of this fuppofition, our ingenious and perfevering authors recurred to various experiments; which inconteftibly prove, that thefe infects cannot long exift either in *vacuo*, or in air that is contaminated by noxious gafes; that, in fhort, they breathe like other animals of their clafs; and that they are fpeedily deprived of life if the procefs of refpiration be arrefted. Yet it refults, from eudiometrical trials, that the air of a well-ftocked hive is equally pure with that of the atmofphere. It has been afcertained, too, that neither wax nor pollen favours the production of oxygen gas, and that the bees themfelves have no internal faculty of generating vital air; fince, if that of the atmofphere be entirely excluded, they are obferved to perifh in the courfe of a few hours. Our authors, therefore, took an opportunity of examining, whether the induftry of thefe infects prefented no particular caufe of this phenomenon; and at length they were ftruck by the connection which might fubfift between the circulation of the air and that beating of the wings which they had recently obferved, and which occafioned a continual humming in the interior of their habitation. They fufpected that the play of thefe membranes, which imprefs the air with fufficient force to elicit from it a very diftinct found, might be deftined to replace that which had been vitiated by refpiration. Although this may feem to be a trivial caufe for counteracting the pernicious effect above ftated, yet by putting the hand near to a fanning-bee, we fhall perceive that fhe agitates the air in a manner that is very fenfible, and moves her wings with fuch rapidity as that they are fcarcely diftinguifhable.

United at their edge by means of fmall hooks, the two wings of each fide prefent a larger furface to the air, on which they have to ftrike; they form, befides, a flight concavity, which fhould fomewhat contribute to increafe their energy; and we may be fatisfied that they defcribe an arc of 90°, becaufe we fee them, fimultaneoufly, on the two extremes of their vibrations. When engaged in this exercife, the bees cling faft to the ftand with their legs, the firft pair being projected forwards, the fecond feparated and fixed to the right and left of the body, while the third, clofely approximated, and in a direction perpendicular to the abdomen, contributes to fupport the hinder parts in an elevated pofition. During the fine feafon, we may always obferve a certain number of bees agitating their wings in front of the entrance to their hive; but we may alfo be convinced, by infpection, that ftill more of them are employed in fanning within their dwelling. The ordinary ftation of the ventilating bees is on the lower floor of the hive. All thofe which are occupied in this way, on the outfide, have their heads turned towards the entrance, but thofe within prefent their backs to it. Thefe bees feem to arrange themfelves methodically, fo that they may manage the ventilating procefs with the greateft eafe; being diftributed into files, which terminate at the entrance of the hive, and are fometimes difpofed like fo many diverging rays; but this order is not uniform: and it is probably owing to the neceffity to which the fanning bees are fubjected of leaving room for fuch as go and come, whofe rapid courfe conftrains them to form in file, that they may avoid being joftled and overturned at every inftant. More than 20 bees may fometimes be feen ventilating in the lower part of the hive; but their number at other times is fmaller; and each of them vibrates her wings for a longer or fhorter period. They have been obferved to continue the exertion during 25 minutes, without refting; although they feemed occafionally to take breath by fufpending the vibration of their wings for an almoft imperceptible inftant; but, as foon as they ceafe from fanning, others take their place, fo that the humming noife in a well-filled hive never fuffers interruption.

But to return from this digreffion to the principal fubject of the article.

Bees'-wax makes a very confiderable article in commerce; the confumption of it throughout the feveral parts of Europe being incredible. There are two kinds, *white* and *yellow*; the yellow is the native wax, juft as it comes out of the hive, after expreffing the honey, &c. This colour, fays Thorley, is owing to the age of the combs, and breath of the bees; wax, he fays, both as it is gathered, and wrought into combs, being always white: the white is the fame wax, only purified, wafhed, and expofed to the air. The preparation of each follows.

WAX, *Yellow*. To procure the wax from the combs for ufe; after feparating the honey from them as much as poffible by the prefs, they are either foaked for fome days in clear water, in order to extract all the honey, or they are broken into pieces, and fpread on a fheet near the hives, fo that the bees in time fuck out all the honey that is left, and reduce the wax into fmall fragments like bran. Then the whole of the wax is put into a large kettle, with a fufficient quantity of water; and with a moderate fire, it is melted, and then ftrained through a linen cloth, by a prefs, and thus freed from all remaining impurity. Before it is cold, they fcum it with a tile, or a piece of wet wood, and caft it, while

while yet warm, in wooden, earthen, or metalline moulds; having firft anointed them with honey, oil, or water, to prevent the wax from fticking. Some, to purify it, make ufe of Roman vitriol, or copperas; but the true fecret is to melt, fcum it, &c. properly, without any ingredients at all.

The beft is that of a high colour, an agreeable fmell, fomewhat refembling that of honey, foft, fomewhat unctuous to the touch, but not fticking to the fingers, nor to the teeth when chewed. When new, it is of a lively yellow colour; it is fomewhat tough, yet eafy to break; by age, it lofes its fine colour, and becomes harder and more brittle. In winter it becomes confiderably hard and tough. It is deprived of its yellow colour and fmell by expofing it in thin laminæ to the action of the light and air, in the procefs of bleaching; by which it becomes perfectly white, fcentlefs, fomewhat harder, and lefs greafy to the touch. However, wax is often fophifticated with refin, or pitch, coloured rocou, or turmeric.

The prefence of refin may be fufpected when the fracture appears fmooth and fhining, inftead of being granulated: and it may be faturated by putting fmall pieces of the wax into cold alcohol, which will readily diffolve the refinous part, without affecting the wax in any confiderable degree.

Its adulteration with earth or peas meal may be fufpected when the cake is very brittle, and the colour inclining more to grey than bright pale yellow; and they may be feparated by fmelting and ftraining the wax. White wax is fometimes adulterated with white oxyd of lead, in order to increafe its weight. This may be known by melting the wax in water, when the oxyd falls to the bottom of the veffel.

It is alfo adulterated by tallow, fuet, or any kind of animal fat. It then becomes more fufible, and when rebleached and expofed to a hot fun, it is very apt to cake. It likewife lofes its femi-tranfparency, the diftinguifhing property of pure bleached wax. This adulteration may be detected by boiling alcohol, which will diffolve wax, but not tallow.

Wax, *White*. The whitening, blanching, or bleaching of wax, is performed by reducing the yellow fort, firft, into little bits or grains, and melting it in a copper cauldron, with water juft fufficient to prevent the wax from burning. The cauldron in which the wax is melted is fo difpofed, that it may flow gradually through a pipe at the bottom into a large tub filled with water, and covered with a thick cloth, to preferve the heat till the water and impurities are fettled. From this tub the clear melted wax flows into a veffel, the bottom of which is full of fmall holes, about the fize of a grain of wheat, and hence it falls in fmall ftreams upon a cylinder, conftantly revolving over water, into which it occafionally dips, fo that the wax is cooled, and at the fame time drawn out into thin fhreds or ribbands. The continual rotation of the cylinder carries off thefe ribbands as faft as they are formed, and diftributes them through the tub. The wax, thus granulated or flatted, is expofed to the air on linen cloths, ftretched on large frames, about a foot or two above the ground, in which fituation it remains night and day for feveral days, expofed to the air and fun; and thus the yellow colour nearly difappears. In this half-bleached ftate, it is heaped up in a folid mafs, and allowed to remain for a month or fix weeks; after which, to complete the procefs for whitening it, it is re-melted, and ribbanded, and bleached as before, (in fome cafes feveral times) till it wholly lofes its colour and fmell. Some manufacturers, in re-melting it, add alum or cream of tartar, which are fuppofed to increafe the whitenefs and folidity of the wax. Some alfo, inftead of fpreading the ribbands of wax on cloths, lay evenly a broad courfe of bricks, which are frequently watered, fo that the wax is kept from melting by the fun's heat abforbed by the bricks.

When the fun and air have at length perfectly blanched the wax, fome melt it for the laft time in a large kettle; out of which they caft it, with a ladle, upon a table, covered over with little round dents or cavities, of the form of the cakes of white wax, as fold by the apothecaries, &c. having firft wetted thofe moulds with cold water, that the wax may be the more eafily got out. Laftly, they lay out thefe cakes to the air for two days and two nights, to render it more tranfparent and dry.

As the volatile fulphureous acid has the property of deftroying more quickly almoft all the colours of vegetables, it has been fuggefted by Macquer, the author of the Chemical Dictionary, that this bleaching might perhaps be fhortened, by expofing ribbands of yellow wax to the vapour of fulphur, as is practifed for wool and filk; but this procefs has not been found to fucceed.

However, the operation of bleaching wax above defcribed can be performed well only in fine weather, as it depends chiefly on the action of the fun. This circumftance being attended with much inconvenience to the manufacturers, the difcovery of a method of whitening wax independently of the feafons would be very ufeful, and has been recommended to the attention of chemifts by fome economical focieties.

With a view to difcover fuch a method, Mr. Beckman has made experiments, an account of which is publifhed in the fifth volume of the "Novi Commentarii Societatis Regiæ Scientiarum Gottingenfis." According to thefe experiments, thin pieces of yellow wax were whitened and hardened, by being digefted and boiled in diluted and undiluted nitrous acid, in a few hours. But the wax thus whitened, being melted by means of boiling water, was obferved to acquire a yellow colour, lefs intenfe, however, than it was before it had been treated with the mineral acids. The marine and vitriolic acids were lefs effectual than the nitric or nitro-muriatic. He expofed wax to the flames of burning fulphur, but without fuccefs. Yellow wax being melted in vinegar, was rendered of a grey colour. The oil of tartar whitened wax, but lefs effectually than acids had done; and this wax being wafhed in water, and afterwards digefted in nitrous acid, was rendered ftill more white; but upon melting it in water, a yellowifh tinge returned. He liquefied wax in folutions of nitre and alum, but without any good effect. Spirit of wine, which is recommended by Mr. Boyle for this purpofe, did indeed whiten the wax, but changed it to a butyraceous fubftance, fo frothy, that its bulk was increafed thirty times. Reflecting that tartar is purified from its oily particles by means of a calcareous earth, he tried the effects of a kind of fuller's earth, which he threw upon wax liquefied in water, and he agitated the mixture. This method rendered wax of a greyifh colour, and is, therefore, recommended by him as preparatory to bleaching; the time neceffary for which, he thinks, may be thus greatly fhortened.

M. Sennebier made fome remarks on the effect of light, and other fuppofed difcolouring agents. Some yellow wax was melted, and thinly fpread upon a plate of glafs; and a fimilar plate was laid upon it when hot; and the edges of the plates were clofed with fealing-wax. Thus the bees'-wax was deprived of the accefs of air, and it was placed in the fun, to the light of which it was expofed for four or five hours daily. Another quantity of wax was inclofed between plates in a like manner, but kept in the dark. In two days the wax expofed to the fun began to bleach, and in in a month's time the whole, when it did not exceed one-fixth of an inch in thicknefs, was quite white; whilft no change at all took place in that which was kept in darknefs.

Alcohol has no fenfible action on wax when cold, but if the fluid be boiled, it will diffolve rather lefs than one-twentieth of its weight of wax; and the greater part of it feparates, when cold, in the form of white bulky flocculi, while the fmall quantity that remains is wholly precipitated by water. Such is the refult of Pearfon's and Boftock's experiments; whereas Fourcroy, Chaptal, and Nicholfon affert, that it is infoluble in this fluid. Sulphuric ether diffolves wax when heated, and much more copioufly than alcohol diffolves it, but the greater part, like that of the former, is feparated by cooling, and the remainder by water. Wax boiled in cauftic potafh makes the fluid turbid, and in procefs of time rifes to the furface in a flocculent form. The portion of the wax, held in folution by the clear alkaline liquor, may be feparated by an acid, and the refidue floating on the furface is fo far converted into a faponaceous ftate as to have loft its inflammability, and to be no lefs foluble in pure water than white foap, and again precipitable by acids nearly in its original form, with a reftoration of its inflammability. Pure ammonia nearly refembles the fixed alkalies in its action; but the refulting faponaceous form is lefs foluble in water.

When yellow wax has been long fwimming in a folution of carbonate of potafh, it becomes grey; and this colour is entirely changed into a milk white by fubfequent digeftion in nitric acid, and the wax refumes its whitenefs.

If wax be diftilled with a heat greater than that of boiling water, it may be decompofed. By this diftillation, a fmall quantity of water is firft feparated from the wax, and then fome very volatile and penetrating acid, (probably a modification of the acetous,) accompanied with a fmall quantity of a very fluid and very odoriferous oil. As the diftillation advances, the acid becomes more and more ftrong, and the oil more and more thick, till its confiftence be fuch, that it becomes folid in the receiver, and is then called *butter of wax*. When the diftillation is finifhed, nothing remains but a fmall quantity of coal, which is almoft incombuftible, from the want of fome faline matter. Wax cannot be kindled, unlefs it be previoufly heated, and reduced into vapours; in which refpect it refembles fat oils. The oil and butter of wax may, by repeated diftillations, be attenuated, and rendered more and more fluid, becaufe fome portion of acid is thereby feparated from thefe fubftances; which effect is fimilar to what happens in the diftillation of other oils and oily concretes; but this remarkable effect attends the repeated diftillation of oil and butter of wax, that they become more and more foluble in fpirit of wine; and that they never acquire greater confiftence by the evaporation of their more fluid parts. Boerhaave kept butter of wax in a glafs veffel open, or carelefsly clofed, during twenty years, without acquiring a more folid confiftence. Wax, its butter, and its oil, differ entirely from effential oils and refins, in all the above-mentioned properties; and in all thefe perfectly refemble fweet oils. Hence Macquer concludes, that wax only refembles refins in being an oil rendered concrete by an acid; but that it differs effentially from thefe in the kind of oil, which in refins is of the nature of effential oils; while in wax and other analogous oily concretions, it is of the nature of fweet, unctuous oils, that are not aromatic, and not volatile, and are not obtained from vegetables by expreffion.

Although wax is not diffoluble at all in watery liquors, yet the gelatinous folution obtained by boiling it in fpirit of wine, by mixture with a thick mucilage of gum arabic, becomes foluble in water, fo as to form therewith an emulfion or milky liquor: the wax itfelf is made in like manner foluble, without the intervention of fpirit, by thoroughly mixing it with the gum in fine powder; but when thus diffolved, it proves ftill infipid, and perfectly void of acrimony.

Wax is foluble abundantly in the fixed oils, and melted with them, produces an uniform mafs, the confiftence of which, whatever be the proportion of each, is intermediate between the two. It is diffolved but fparingly in effential oils.

Bleached wax burns with a very pure white light, without any offenfive fmell, and with much lefs fmoke than tallow; and as it is lefs fufible than tallow, it requires a fmaller wick. (See CANDLES.) Bleached wax melts at about 155° of Fahrenheit; and the unbleached at 142°, according to Pearfon and Nicholfon, and alfo Dr. Boftock, but at 117° according to Fourcroy; whilft tallow melts at 92°, fpermaceti at 133°, adipocire at 127°, and the pela of the Chinefe at 145°. (See Nicholfon's Journal, vol. i. p. 70, 4to.) The fpecific gravity is lefs than that of water, being about .96.

The *yellow* wax is brought to market in round cakes about two inches thick; and large quantities of it are imported from the Baltic, the Levant, and the Barbary coaft.

The *white* wax is ufed in the manufacture of candles, torches, tapers, figures, and a variety of other wax-works. See CANDLES, &c.

It is alfo an article of the *Materia Medica*, and ufed as an ingredient, partly for giving the requifite confiftence to other ingredients, and partly on account of its own emollient quality, in plafters, cerates, and divers pomatums and unguents for the complexion.

The yellow fort, diffolved into an emulfion, or mixed with fpermaceti, oil of almonds, conferve of rofes, &c. into the form of an electuary; or divided, by ftirring into it, when melted over a gentle fire, as much as it will take up of powdery matter, as the compound crab's-claw powder, has been given alfo internally, and, as fome have pretended, often with great fuccefs, in diarrhœas and dyfenteries, for obtunding the acrimony of the humours, fupplying the natural mucus of the inteftines, and healing their excoriations or erofions.

The empyreumatic oil, into which wax is refolved by diftillation with a ftrong heat, is greatly recommended by Boerhaave and others, for healing chaps and roughnefs of the fkin, for difcuffing chilblains, and with proper fomentations and exercife, againft ftiffnefs of the joints, and contractions of the tendons. It is, without doubt, fays Dr. Lewis, highly emollient; but does not appear to have any other quality by which it can act in external applications; it has nothing of the acrimony or pungency which prevail in all the other known diftilled vegetable oils; though in fmell it is not a little difagreeable and empyreumatic; a circumftance which occafions it to be at prefent more rarely ufed than formerly. As the wax fwells up greatly in the diftillation, it is convenient to divide it, by melting it with twice its weight of fand; or putting the fand above it in the retort, that it may mingle with the wax when brought into fufion. The oil, which is preceded by a fmall quantity of acid liquor, congeals in the neck of the retort, from whence it may be melted down, by applying a live coal, and made fluid by rediftilling it two or three times without addition. The fæces remaining, after expreffing the wax, have been ufed used both by surgeons and farriers, with success, against strains.

The officinal preparations are as follow: *cera flava purificata* of Dub. Ph.; *oxidum antimonii vitrificatum cera* of Edinb.; *emplastrum ceræ* of Lond. and Edinb.; *emplastrum cumini* of Lond.; *empl. picis compositum* of Lond.; *empl. oxidi ferri rubri* of Edinb.; *empl. assafœtidæ* of Edinb.; *empl. gummosum* of Edinb.; *empl. meloes vesicatorii* of Edinb. and Lond.; *empl. galbani* of Dub.; *empl. aromaticum* of Dub.; *ceratum* of Lond. and Dub.; *ceratum calaminæ* of Lond. and Dub.; *ceratum resinæ* of Lond. Edinb. and Dub.; *ceratum sabinæ* of Lond. and Dub.; *ceratum saponis* of Lond.; *unguentum picis aridæ* of Lond. and Edinb.; *ung. infusi meloes vesicatorii* of Edinb.; and *ung. cantharidis* of Dub. Ph. For the first, see *white-wax* below. The second, or vitrified oxyd of antimony with wax, formerly waxed glass of antimony, is formed by melting one part of yellow wax in an iron vessel, and throwing into it eight parts of oxyd of antimony vitrified with sulphur, reduced to powder, and roasting the mixture with a gentle fire for a quarter of an hour, stirring it assiduously with a spatula; then pouring out the latter, and when cold rubbing it into a powder. This preparation is diaphoretic and cathartic, occasionally exciting nausea and vomiting. It was formerly thought to possess efficacy in diarrhœa and dysentery; but is now scarcely ever prescribed. The dose may be from gr. ij. to gr. xv. given twice or three times a day. For the *empl. ceræ*, see *Wax* PLASTER. For the 4th, see EMPLASTRUM *é Cymino.* For the 5th, see *Compound Pitch* PLASTER. For the 6th, see PLASTER *of red Oxyd of Iron.* For the 7th, see *Assa Fœtida* PLASTER. For the 8th, see *Gum* PLASTER. For the 9th, 10th, and 11th, see PLASTER. For the others, comprehending *cerates* and *ointments.* See UNGUENTUM.

The *bleached* or *white wax* is generally melted and cast, in the manner already stated, into thin discs, about 5 inches in diameter, in which form it is found in the shops. For medical purposes, it is regarded as a demulcent; and has been sometimes administered in obstinate cases of diarrhœa and dysentery, with the view of sheathing the bowels; which effect is better produced by simple mucilages and solutions. It is generally exhibited diffused in mucilaginous fluids by means of soap, in the proportion of ⅓d part of the wax, with which it is first melted, and then rubbed in a mortar, with the fluid gradually added; but a preferable method is said to be that of Poerner, which is first to melt the wax with olive oil, and then mix the oily compound while hot with the mucilaginous fluid, by triturating with the yolk of an egg. The dose is a cupfull of the emulsion, containing about ℈j of wax, given every four or five hours. This wax, as well as the yellow sort, is much used in the composition of plasters and ointments. The officinal preparations are *ceratum cetacei* of Lond. Edinb. and Dub. pharmacopeias; *unguentum cetacei* of Lond. and Dub.; *ung. hydrargyri nitrico-oxydi* of Lond.; *linimentum simplex* of Edinb.; and *ung. simplex* of Edinb. See CERATUM, LINIMENT, and UNGUENT. Lewis's Mat. Med.

Yellow wax is made soft with turpentine, yet retains its natural colour. Red wax is only the white melted with turpentine, and reddened with vermilion or alkanet. Verdigrise makes it green; and burnt paper, or lamp-black, black. Some travellers tell us of a natural black wax; assuring us there are bees, both in the East and West Indies, that make an excellent honey, included in black cells. Of this wax, they say, it is, that the Indians make those little vases, in which they gather their balsam of Tolu.

WAX is also produced by the secretion of many plants, and forms the silvery powder or bloom, which covers their leaves and fruit. It is found very abundantly combined with resin, covering the trunk of the wax-palm (*Ceroxylon*) of South America, found in the Quinoliu mountains, 180 feet high, with leaves 20 feet long, the trunk of which is covered with the waxy secretion about two inches thick, and consisting of two-thirds of resin and one of wax; and very pure, encrusting the seeds of the *Myrica cerifera*, or wax-tree of Louisiana, and other parts of North America. The *Pe-la* of the Chinese is an animal wax, and the white lac of India appears to be a variety of wax; so that wax may be regarded, in the extended meaning of the term, both as an animal and a vegetable product. The croton sebiferum, the tomex sebifera, the poplar, the alder, the pine, as well as the Myrica, afford a concrete inflammable matter by decoction, that more or less resembles tallow or wax, that is, a fixed oil saturated with oxygen. But the Myrica cerifera supplies it in the greatest abundance. The grains of this tree, and the shining wax obtained by boiling them in water, have been long ago, *viz.* in 1722 and 1725, noticed in the History of the Academy of Sciences. The wax, it was observed, is drier and more friable than our's; and it was found, that the liquor in which the grain had been boiled, and from which the wax was procured, afforded, on evaporation, a kind of extract that checked the most obstinate dysenteries; and the inhabitants of Louisiana are said to have made candles of the wax. Several authors have mentioned different species of these trees; but the wax they afford has more lately been the subject of experimental investigation, particularly by M. Cadet and Dr. Bostock. The most fertile of these shrubs afford near seven pounds of berries, the gathering of which employ several families. These berries are thrown into a kettle, and covered with water. Whilst the water is boiling, the grains are stirred about against the sides of the vessel, so that the wax may more easily come off. In a little time it floats on the water like fat, and being collected, is strained through a coarse cloth, to free it from any impurities. This operation is repeated with fresh berries; and when a considerable quantity of wax has been obtained, it is laid upon a cloth to drain off the water; and it is then dried and melted a second time; and when thus purified, formed into masses. Four pounds of berries afford about one of wax: that which is first obtained is generally yellow; but in the latter boilings it assumes a green colour, from the pellicle with which the kernel of the berry is covered. M. Cadet made a variety of experiments on these berries, and found that the powder which was obtained from them afforded an astringent solution by alcohol, and that it contained gallic acid, but no tannin; and to this acid he attributes their effect in dysenteries. The wax, obtained either by the decoction of the grains, or the solution of the powder when precipitated from alcohol by water, when melted, is always of a greenish-yellow; of a firmer consistence than bees'-wax, dry, and sufficiently friable to be pulverized; and evidently more oxygenated than the wax prepared by bees. Candles made of this wax yielded a white flame, a good light, without smoke, and without guttering; and when quite fresh, they emit a balsamic odour, considered in Louisiana as very salubrious to persons in bad health. Distilled in a retort, this wax, for the most part, passes over in the form of butter. This portion is much whiter, and has no more consistence than tallow. Another portion that was decomposed afforded a little water, with some empyreumatic oil and sebacic acid. Much carbonated hydrogen gas and carbonic acid gas were disengaged; and there remained in the retort a black and coaly bitumen. Ether was found to dissolve

 this

this wax better than alcohol. Oxygenated muriatic acid rendered this, as well as bees'-wax, perfectly white; but the vegetable wax was bleached with the greateſt difficulty. The ſolution in ammonia is of a brown colour, and a portion of the wax is rendered ſoapy; and it forms ſoap with fixed alkali. When the ſoap of Myrica is decompoſed, a very white wax is obtained, but in a ſtate unfit for our uſes. Litharge diſſolves very well in this melted wax, and forms a hard plaſter, the conſiſtence of which may be diminiſhed at pleaſure by the addition of a little oil. For bleaching this wax, M. Cadet obſerves, that two re-agents preſent themſelves to manufacturers, the ſulphuric acid and the oxygenated muriatic acid. He propoſes the following method as the moſt ſpeedy in its effect:—Let the wax be reduced to a very divided ſtate, and ſtratified in a caſk with ſuper-oxygenated muriate of lime, and let them remain for ſome time in contact without water. Let the ſalt be afterwards decompoſed with water, acidulated by the ſulphuric acid; taking care to pour the water a little at a time at different intervals, until there ſhall be no longer any perceptible diſengagement of muriatic gas; at which period a large quantity of water is to be added, and the mixture agitated with a ſtaff. The inſoluble ſulphate of lime falls down by repoſe, while the bleached wax riſes and ſwims at the ſurface. This is to be waſhed and melted on the water bath. Our author cloſes his memoir with recommending the culture of the plant that yields this wax, and with a brief detail of methods for effecting this purpoſe. Dr. Boſtock has alſo proſecuted an inquiry into the nature and uſes of myrtle wax. He finds that in its more important properties it reſembles bees'-wax, but that in ſome reſpects they differ from one another. The myrtle wax is moderately hard and conſiſtent, poſſeſſing in part the tenacity of bees'-wax, without its unctuoſity, and alſo, in ſome degree, the brittleneſs of reſin. The prevalent colour is pale green, tending in moſt of the pieces to a dirty grey; in others it is lighter, more tranſparent, and of a yellowiſh tinge. Its ſpecific gravity is about 1.0150, water being 1.000, ſo that it ſinks in it, and the white bees'-wax being .9600. Water has no action upon it, either when cold or at the boiling heat. Alcohol, when cold, does not affect it; but 100 parts, by weight, of this fluid, when boiling, diſſolve about five parts of the wax. Nearly four-fifths are depoſited by the cooling of the alcohol; one-fifth remains ſuſpended, but in the courſe of a few days is ſlowly depoſited, or may be precipitated by the addition of water. Sulphuric ether, when at the common temperature of the atmoſphere, diſſolves only a ſmall quantity of this wax, but acts upon it rapidly when boiling. It takes up ſomewhat more than one-fourth of its own weight. As the ether cools, it is moſtly ſeparated, and the ſmall reſidue may be precipitated by water. After ſolution, the wax is nearly colourleſs, and the fluid aſſumes a beautiful green hue. The depoſit by evaporation ſomewhat reſembles ſpermaceti. Rectified oil of turpentine, at the temperature of the atmoſphere, ſoftens the wax, but does not diſſolve it: aided by a moderate heat, 100 grains of the turpentine diſſolves ſix grains of the wax. The turpentine acquires a light green tinge, part of the wax is ſeparated as the fluid cools, and part remains permanently diſſolved in it. Pure potaſh renders it colourleſs by boiling, and forms a ſoap with a ſmall part, which being decompoſed by acid, affords the wax nearly unchanged. Pure ammonia acts nearly as potaſh, but more feebly. The three principal mineral acids act upon the myrtle wax, but with no great force. The ſulphuric acid, with a moderate heat, diſſolves about one-twelfth of its weight, and converts it into a thick, dark-brown maſs, which on cooling becomes nearly concrete, but without any ſeparation of the wax. The nitric and muriatic acids, even when heated, ſeem to poſſeſs little attraction for the wax. From ſuch experiments, Dr. Boſtock aſſigns to myrtle wax, with a conſiderable degree of probability, the place which it ſhould occupy among chemical ſubſtances. Its inflammability, fuſibility, inſolubility in water, and the action which takes place between it and the alkalies, indicate its affinity to the fixed oils; while its texture and conſiſtence, and more particularly its habitudes with alcohol and ether, manifeſt a reſemblance to the reſins. Upon the whole, we may conſider the myrtle wax as a fixed vegetable oil, rendered concrete by the addition of a quantity of oxygen; and ſeeming to hold the ſame relation to the fixed, which reſins do to the eſſential oils of vegetables. Dr. Boſtock has inſtituted a compariſon between myrtle wax and other ſubſtances which it reſembles, ſuch as bees'-wax, ſpermaceti, adipocire, and the cryſtalline matter of biliary calculi; and, upon the whole, deduces this concluſion, that though theſe five ſubſtances poſſeſs certain properties in common, and have a degree of ſimilarity in their external appearance, yet that they differ materially in their chemical nature. There is indeed, he ſays, reaſon to conjecture, that they are all compoſed of the ſame elements, combined together in different proportions, and with different degrees of attraction. Nicholſon's Journal, vol. iv. 8vo.

Wax, *Chafe*. See Chafe.

Wax, *Crude* or *Rough*, called by the French *cire brute*, in *Natural Hiſtory*, a name given to a ſubſtance called by the ancients *erithace*, *ſandarac*, and *ambroſia*.

We ſeem to have no name for it in Engliſh, but may call it after the name of the French, *rough wax*.

The Dutch call it the food of the bees, and that, perhaps, very properly, there appearing many reaſons to think that the bees eat it.

This is the yellow ſubſtance found on the hinder legs of bees in ſmall lumps, of which, as Reaumur and ſome others erroneouſly thought, wax is made by this inſect. See Pain *d'Abeilles*.

Wax, *Myrtle*. See Myrica, and Wax, *ſupra*.

Wax, *Virgin*, *Propolis*, is a ſort of reddiſh wax, uſed by the bees to ſtop up the clefts or holes of the hive. It is applied juſt as taken out of the hive, without any art, or preparation of boiling, &c. It is the moſt tenacious of any, and is held good for the nerves. See Propolis.

Wax, *Sealing*, or *Spaniſh Wax*, is a compoſition of gum lacca, melted and prepared with reſins, and coloured with ſome ſuitable pigment.

There are two kinds of ſealing-wax in uſe: the one hard, intended for ſealing letters, and other ſuch purpoſes, where only a thin body can be allowed; the other ſoft, deſigned for receiving the impreſſions of ſeals of office to charters, patents, and ſuch written inſtruments.

The beſt hard red ſealing-wax is made by mixing two parts of ſhell-lac, well powdered, and reſin and vermilion, powdered, of each one part, and melting this combined powder over a gentle fire; and when the ingredients ſeem thoroughly incorporated, working the wax into ſticks. Seed-lac may be ſubſtituted for the ſhell-lac; and inſtead of reſin, boiled Venice turpentine may be uſed. A coarſer, hard, red ſealing-wax may be made, by mixing two parts of reſin, and of ſhell-lac, vermilion and red-lead, mixed in the proportion of one part of the vermilion to two of the red-lead, of each one part; and proceeding, as in the former preparation. For a cheaper kind, the vermilion may be omitted, and the ſhell-lac alſo, for very coarſe uſes. The hard black ſealing-wax may be prepared in the ſame manner; uſing ufing for the beft fort, inftead of the vermilion, the beft ivory black; and for the coarfer fort, inftead of the vermilion and red-lead, the common ivory black. For hard green fealing-wax, inftead of vermilion, ufe powdered verdigrife; and for a bright colour, diftilled, or cryftals of verdigrife. For hard blue fealing-wax, inftead of the vermilion, fubftitute well powdered fmalt, or for a light blue, verditer; or a mixture of both. For yellow hard fealing-wax, fubftitute mafticot, or, for a bright colour, turbith mineral, inftead of the vermilion. The hard purple wax is made like the red; changing half the quantity of the vermilion for an equal, or greater proportion of fmalt, as the purple is defired to be more blue or more red.

For uncoloured foft fealing-wax, take of bees'-wax, one pound; of turpentine, three ounces; and of olive oil, one ounce; place them in a proper veffel over the fire, and let them boil for fome time; and the wax will be then fit to be formed into rolls or cakes for ufe. For red, black, green, blue, yellow, and purple foft fealing-wax, add to the preceding compofition, while boiling, an ounce or more of any ingredients directed above for colouring the hard fealing-wax, and ftir the mafs, till the colouring ingredient be incorporated with the wax.

The hard fealing-wax is formed into fticks, by rolling the mafs on a copper-plate, or ftone, with a rolling-board, lined with copper, or block-tin, into rolls of any required fize. In order to give them the fire-polifh, or glofs, a furnace or ftove, like a pail, with bars at the bottom for fupporting the charcoal, and notches at the top of the fides for putting the fticks of wax over the fire, is ufually provided. By means of this ftove the fticks of wax may be conveniently expofed to the fire, and turned about, till the wax is fo melted on the furface as to become fmooth and fhining. Hard fealing-wax may be formed into balls, by putting a proper quantity on the plate or ftone, and having fafhioned it into a round form, rolling it with the board till it be fmooth.

The foft wax is eafily formed into rolls or cakes, by pouring the melted mafs of the ingredients, as foon as they are duly prepared, into cold water, and working it with the hands into any defired figure. Some perfume both thefe kinds of wax, by ufing, for a pound of the wax, half an ounce of benjamin, one fcruple of oil of Rhodium, ten grains of mufk, and of civet and ambergrife, each five grains; rubbing the oil with the other ingredients powdered; and when the wax is ready to be wrought into fticks, fprinkling in and well ftirring the mixture; or by ufing one ounce of benjamin, one fcruple and a half of oil of Rhodium, and five grains of ambergrife, in the fame manner. Lewis's Com. of Arts, p. 370. Handmaid to the Arts, vol. ii. p. 34, &c.

WAX-*Candles*. See CANDLE.

WAX, *To imitate Fruit, &c. in.* Take the fruit, and bury it half-way in clay; oil its edges, and the extant half of the fruit; then nimbly throw on it tempered alabafter, or plafter of Paris, to a confiderable thicknefs. When this is concreted, it makes the half mould, the fecond half of which may be obtained in the fame way. The two parts of the mould being joined together, a little coloured wax, melted, and brought to a due heat, being poured through a hole made in any convenient part of the mould, and prefently fhook every way therein, will reprefent the original fruit. Boyle's Works abr. vol. i. p. 136.

Here we muft not forget that pretty invention of M. Benoift, a man famous at Paris for his figures of wax. Being by profeffion a painter, he found the fecret of forming moulds on the faces of living perfons, even the faireft and moft delicate, without any danger either to their health or complexion: in which moulds he caft mafks of wax; to which, by his colours, and glafs eyes imitated from nature, he gave a fort of life: infomuch as, when clothed in proper habits, they bore fuch a refemblance, that it was difficult diftinguifhing between the copy and the original.

WAX, *Gilding*. See GILDING.

WAX, *Grafting*, is a compofition ferving to bind or fix the bud, or graft, in the cleft of the ftock.

Inftead of grafting wax, the country gardeners, &c. only ufe clay, over which they lay a piece of linen cloth, and fo keep it moift; and to prevent its cracking with the heat of the fun, they tie mofs over it. But the wax ordinarily ufed is a compoft of one pound and a half of pitch, a quarter of a pound of wax, and an ounce of oil of almonds, melted and mixed together: with the addition, in fpring or autumn, of a moderate quantity of turpentine.

For cleft-grafting, whip-grafting, and grafting by approach, Mr. Mortimer recommends tempered clay, or foft wax; but for rind-grafting, clay and horfe-dung.

WAX, *Green*. See GREEN *Wax*.

WAX, *thorough*, in *Botany*. See BUPLEURUM.

WAX, *Painting in*. See ENCAUSTIC *Painting*.

WAX-*Bill*. See LOXIA *Aftrild*.

WAX-*Scot*, or *Wax-fhot*, *Ceragium*, in our *Ancient Cuftoms*, money paid twice a year towards the charge of maintaining lights, or candles, in the church.

WAXENBURG, in *Geography*, a town of Auftria; 10 miles W. of Freyftadt.

WAXHOLM, a fortrefs on the coaft of Sweden, in the Baltic; fituated on a fmall ifland at the entrance of the channel of the Malar Lake, and built in the year 1649. It has fince been greatly improved and enlarged, fo that it has the appearance of a little town. Here all homeward-bound fhips are fearched. On this ifland, which is called *Waxon*, befides this fort, are a church, a fchool, and a cuftom-houfe. The chief occupation of the inhabitants is fifhing; 16 miles E. of Stockholm. N. lat. 59° 21′. E. long. 18° 16′.

WAXING, CERATIO, in *Chemiftry*, the preparation of any matter to render it fit and difpofed to liquefy, or melt, which of itfelf it was not.

This is frequently done, to enable things to penetrate into metals, or other folid bodies.

WAXING, in the *Manufacture of Calico*, &c., a procefs by which the operation of certain colours is refifted by ftopping out with wax; but it is too expenfive to be often adopted among calico-printers, who are anxious to finifh their prints with the leaft poffible charge. Formerly this mode was very generally practifed, and great quantities of wax were confumed in the procefs. In the Eaft Indies wax is ftill ufed for preferving the whites in calico-printing. In printing the filk handkerchiefs called bandanas, a procefs called *waxing* is ftill followed. It confifts in making a preparation of tallow and rofin very liquid by heat, and in printing it in that ftate with a block upon the filk. When fuch goods are paffed through the blue vat, thofe parts which are covered with the tallow and rofin are preferved from the action of the indigo, and remain white, while the whole remainder is dyed a faft blue. The method afterwards taken to difcharge a part of this blue, and produce yellow, orange, &c. is as follows:—The agent employed for this purpofe is the nitrous, and fometimes the nitro-muriatic acid. This was ufed for the purpofe of putting yellow figures upon blue filk handkerchiefs. With this view aqua fortis, or nitro-muriatic acid, of a ftrength fuitable to the kind of blue that is to be difcharged, is mixed either with gum-tragacanth, or with flour pafte, to a proper confiftence, and in this form it is printed on the filk, by means of a common block, on which the

the intended pattern is cut. The confequence of this is, that wherever the acid attaches, there the original colour is difcharged, and a yellow dye is produced in its place. The pieces are then fteamed, by paffing them over a veffel containing boiling water, which gives brilliancy to the colour, and finifhes the operation. Parkes's Eff. vol. ii. p. 149. 170. See *Difcharge* WORK, and DISCHARGING *of Colours*.

WAXWAY, in *Geography*, an ifland in the Eaft Indian fea, near the E. coaft of the ifland of Celebes, about thirty miles in circumference. S. lat. 3° 35′. E. long. 123° 15′.

WAY. See PULO *Way*.

WAY, *Via*. See HIGHWAY, ROAD, TURNPIKE, and VIA.

Roman ways are divided into *confular*, *prætorian*, *military*, and *public*. See VIA.

We have four notable ones of thefe in England; anciently called *chimini quatuor*, and intitled to the privileges of pax regis. The firft is *Watling-ftreet*, or *Watheling-ftreet*, leading from Dover to London, Dunftable, Towcefter, Atterfton, and the Severn, near the Wrekin in Shropfhire, extending as far as Anglefea in Wales. The fecond, called *Hekineld*, or *Ikenild-ftreet*, reaches from Southampton, over the river Ifis at Newbridge, thence by Camden and Litchfield, then paffes the Derwent near Derby, fo to Bolfover-caftle, and ends at Tinmouth. The third, called *Foffe-way*, becaufe in fome places it was never perfected, but lies as a large ditch, leads from Cornwall through Devonfhire, by Tetbury near Stow in the Wolds; and befide Coventry to Leicefter, Newark, and fo to Lincoln. The fourth, called *Erming*, or *Erminage-ftreet*, ftretches from St. David's in Weft Wales, to Southampton.

WAY. See WEIGH.

WAY, *Milky*. The opinion, long maintained among aftronomers, but lately controverted, that the milky way contains a great number of ftars, has been confirmed by the obfervations of the ingenious and indefatigable Dr. Herfchel. On applying his telefcope of the Newtonian form, with an object-fpeculum of twenty feet focal length and an aperture of $18\frac{7}{10}$ inches, to a part of this fpace, he found that it completely refolved the whole whitifh appearance into fmall ftars; which his former telefcopes had not light enough to effect In the tract immediately about the hand and club of Orion, to which his obfervations were particularly directed, the multitude of ftars of all poffible fizes that prefented themfelves to view was aftonifhing: and in order to form fome juft idea of their number, Dr. Herfchel counted many fields, and computed from a mean of them, what a given portion of the milky way might contain. Among many trials of this fort, he found that fix fields, promifcuoufly taken, contained 110, 60, 70, 90, 70, and 74 ftars each. A mean of thefe gives 79 ftars for each field. Hence, by allowing fifteen minutes of a great circle for the diameter of the field of view, it is inferred, that a belt of fifteen degrees in length and two in breadth, which is the quantity often obferved by this excellent aftronomer to pafs through the field of his telefcope in one hour's time, could not well contain lefs than fifty thoufand ftars, that were large enough to be diftinctly numbered. But, befides thefe, Dr. Herfchel fufpected at leaft twice as many more, which, for want of light, he could only fee now and then by faint glittering and interrupted glimpfes. See GALAXY and NEBULA.

WAY *of a Ship* is fometimes ufed for the fame with the rake. But the term is more commonly underftood of the courfe or progrefs which fhe makes on the water under fail: thus, when fhe begins her motion, fhe is faid to be *under way*; when that motion increafes, fhe is faid to have *frefh way* through the water; when fhe goes apace, they fay *fhe has a good way*; and they call the account how faft fhe fails by the log, *keeping an account of her way*.

And becaufe moft fhips are apt to fail a little to the leeward of their true courfe; they always, in cafting up the log-board, allow fomething for her leeward-way. Hence alfo a fhip is faid to have *head-way* and *ftern-way*.

WAY *of the Rounds*, *Chemin des Rondes*, in *Fortification*, is a fpace left for the paffage of the rounds, between the rampart, and the wall of a fortified town.

This is not now much in ufe; becaufe the parapet not being above a foot thick, it is foon overthrown by the enemy's cannon.

WAY, *Covert*, *Fofs*, *Gang*, *Hatch*, *Spur*, and *Water*. See the feveral articles.

WAY-*Bread*, in *Agriculture*, a name given in fome places to the herb plantain, which is very ufeful in fome grafs lands, as increafing the quantity of feed very greatly. See PLANTAGO.

WAY-*Going Crop*, a term applied to that which is taken from the ground the year the tenant or occupant leaves a farm. Such crops are regulated in many different ways, according to the nature of the leafes. See LEASE.

WAY-*Leave*, a provincial term for the ground purchafed or hired to make a waggon-way upon, between coal-pits and the river.

WAY-*Pane*, in *Agriculture*, a term applied to the flips left for cartage in watered lands. It is that part of the ground which lies, in a properly watered meadow, on that fide of a main where no trenches are formed and taken out, but is floated all the length of the main over its banks, having a drain parallel to it. It ferves as a road for conveying the hay upon out of the ground, inftead of the teams having to crofs all the trenches.

WAY-*Thiftle*, a troublefome plant of the perennial weed kind, with ftrong roots that branch out in a horizontal manner. Some think it may be weakened or deftroyed wholly by frequent cutting over, the beft feafon for which is when it is coming into full bloom; as the wet then gets down its hollow ftalk, and aids the rotting of it. In tillage-land it is fometimes got quit of by deep repeated ploughing. See THISTLE and WEEDS.

WAY-*Warden*, in *Rural Economy*, a name fometimes given to the furveyor or overlooker of the roads of a diftrict or county.

WAYA, in *Geography*, a town on the E. coaft of the ifland of Celebes, in Tolo bay. S. lat. 1° 50′. E. long. 121° 52′.

WAYAM, a fmall ifland in the Pacific ocean, near the S.E. coaft of the ifland of Waygoo. S. lat. 0° 24′. E. long. 131° 30′.

WAYBARI, a river of Guiana, which runs into the Atlantic, N. lat. 6° 25′. W. long. 58° 6′.

WAYBORN HOPE, a creek and point of land, on the N. coaft of the county of Norfolk, which takes its name from a village, about five miles from Holt.

WAYED HORSE, in *Rural Economy*, a term applied to an animal of this kind which has been already backed and broken in for work, and which fhews a difpofition to be tractable and ufeful. See HORSE and TEAM.

The term is likewife fometimes applied to team-oxen and other animals.

WAYFARING-TREE. See VIBURNUM.

WAYGAT'S STRAIT, in *Geography*, a ftrait of Ruffia in Europe, feparating a fmall ifland, called *Waygat* ifland, from the continent or country of the Samoiedes. It is alfo called Vaigatfkoi and Vaiatch. N. lat. 68°. E. long. 60°. See VAIGATSKOI.

WAYGOO, an ifland in the Pacific Ocean, about 60 miles

miles in length, from E. to W., and 25 in breadth. N. lat. 0° 2′ to 0° 30′. E. long. 130° 31′ to 131° 40′.

WAYNE, a town of America, in the diftrict of Maine, and county of Kennebeck, containing 819 inhabitants.—Alfo, a townfhip of Pennfylvania, in Greene county, containing 588 inhabitants.—Alfo, a townfhip of Pennfylvania, in Crawford county, containing 502 inhabitants.—Alfo, a townfhip of Pennfylvania, in Mifflin county, containing 1501 inhabitants.—Alfo, a county of Pennfylvania, containing 4125 inhabitants.—Alfo, a townfhip of Ohio, in the county of Adams, containing 901 inhabitants.—Alfo, a townfhip of Ohio, in the county of Butler, containing 1135 inhabitants.—Alfo, a townfhip of Ohio, in the county of Columbiana, containing 377 inhabitants.—Alfo, a townfhip of Ohio, in Jefferfon county, containing 1161 inhabitants.—Alfo, a townfhip of Ohio, in Knox county, containing 478 inhabitants.—Alfo, a townfhip of Ohio, in Montgomery county, containing 431 inhabitants.—Alfo, a townfhip of Ohio, in Pickaway county, containing 742 inhabitants.—Alfo, a townfhip of Ohio, in Scioto county, containing 398 inhabitants.—Alfo, a townfhip of Ohio, in Tufcarawa county, containing 191 inhabitants.—Alfo, a townfhip of Ohio, in Warren county, containing 1862 inhabitants.—Alfo, a county of Kentucky, containing 5393 inhabitants, of whom 226 are flaves; the town Monticilio contains 37 perfons, including 4 flaves.—Alfo, a county of North Carolina, containing 8687 inhabitants, 2756 being flaves.—Alfo, a county of Georgia, containing 254 inhabitants.—Alfo, a county of the Miffiffippi territory, containing 1253 inhabitants, 262 being flaves.—Alfo, a large townfhip of New York, in the N.E. part of Steuben county, 15 miles E. of Bath, called Frederick's town till the year 1808: it has a poft-office called Rofcommon. The S. part is hilly, but the central and other parts are arable and productive. The timber is chiefly oak and walnut, and fome pine on the hills. Here are a congregation of Baptifts, and a competent number of fchool-houfes. The fettlement commenced about 1794, and the population is rapidly increafing. In 1810, the number of people was 1025, and that of fenatorial electors 57.

WAYNESBOROUGH, a town of Georgia, containing 111 inhabitants.

WAYS *and* MEANS, *Committee of*. See SUPPLIES.

WAYTE, in *Geography*, a rocky iflet in the ftraits of Macaffar, near the weft coaft of Celebes. S. lat. 0° 40′. E. long. 119° 18′.

WAYTO, a town on the S.E. coaft of the ifle of Timor. S. lat. 8° 39′. E. long. 126° 9′.

WAY-WISER, an inftrument for meafuring the road, or diftance gone; called alfo perambulator, and podometer, or pedometer.

Mr. Lovell Edgworth communicated to the Society of Arts, &c. an account of a way-wifer of his invention; for which he obtained a filver medal. This machine confifts of a nave, formed of two round flat pieces of wood, one inch thick and eight inches in diameter. In each of thefe pieces there are cut eleven grooves, five-eighths of an inch wide and three-eighths deep; and when the two pieces are fcrewed together, they enclofe eleven fpokes, forming a wheel of fpokes, without a rim: the circumference of the wheel is exactly one pole; and the inftrument may be eafily taken to pieces, and put up in a fmall compafs. On each of the fpokes there is driven a ferril, to prevent them from wearing out; and in the centre of the nave, there is a fquare hole to receive an axle. Into this hole there is inferted an iron or brafs rod, which has the thread of a very fine fcrew worked upon it from one end to the other; upon this fcrew hangs a nut which, as the rod turns round with the wheel, advances or recedes towards or from the nave of the wheel. The nut does this becaufe it is prevented from turning round with the axle, by having its centre of gravity placed at fome diftance below the rod, fo as always to hang perpendicularly like a plummet. Two fides of this fcrew are filed away flat, and have figures engraved upon them to fhew by the progreffive motion of the nut, how many circumvolutions the wheel and its axle have made: on one fide the divifions of miles, furlongs, and poles, are in a direct, and on the other fide the fame divifions are placed in a retrograde order.

If the perfon who ufes this machine places it at his right fide, holding the axle loofely in his hands, and walks forward, the wheel will revolve, and the nut advance from the extremity of the rod towards the nave of the wheel. When two miles have been meafured, the nut will have come clofe to the wheel. But to continue this meafurement, nothing more is neceffary than to place the wheel at the left hand of the operator; and the nut will, as he continues his courfe, recede from the axle-tree, till another fpace of two miles is meafured.

It appears from the conftruction of this machine, that it operates like circular compaffes; and does not, like the common-wheel way-wifer, meafure the furface of every ftone and mole-hill, &c. but paffes over moft of the obftacles it meets with, and meafures the chords only, inftead of the arcs of any curved furfaces upon which it rolls.

WAYWODE. See WAIWODE.

WEACHIN, in *Botany*, the name given by the Indians of America to the maize, or Indian corn, which they cultivated for bread before we knew them.

WEADINGSTEDE, in *Geography*, a town of the duchy of Holftein; 7 miles E. of Weflingburen.

WEAK, or EASY BRANCH, in the *Manege*. See BANQUET, and BANQUET-*Line*.

WEAK-*Land*, in *Agriculture*, that which is of a light, thin, open nature, and which is deficient in ftaple, or the quantity of proper mouldy material. It is directly contrary to that of the cold watery kind, which often changes the nature and quality of the produce, and retards vegetation in the early fpring, or during wet feafons, as it forwards the growth of the crops that are put upon it, but is frequently defective in the amount of produce which is afforded. It is to be improved by the ufe of proper earthy fubftances and manures, according as the quality of it may be, and by keeping the furface of it as much covered as poffible by fuitable green crops, to prevent the too great expofure of it to the action of the fun and winds. Such other means, of the fame kind, as the nature, circumftances, and fituation of the land will permit, may likewife be purfued. See SOIL.

WEAK-*Pulfe*. See PULSE.

WEAKY, in *Agriculture*, a term ufed to fignify juicy, in contradiftinction to that of dry or hufky, as applied to different kinds of food.

WEALD, or WEALD-*Land*, a name applied to a kind of wild woody tract of ground of a ftiff heavy quality in fome fouthern diftricts, as thofe of Kent, Suffex, &c.

It is moftly of a deep tenacious clayey, marly, and loamy nature, but occafionally intermixed with earths of a lighter and more open fort. The writer of the account of the agriculture of the former of the above counties, ftates, that the weald part of that diftrict was in ancient times an immenfe wood or foreft, inhabited only by herds of deer and hogs, and belonged wholly to the king. That by degrees it became peopled, and interfperfed with villages and towns; and by piece-meal, was, for the moft part, cleared of its wood, and converted into tillage and pafture. There are, however, ſome woodlands ſtill in their original ſtate; and by the author of that of the latter, it is remarked, that ſo predominant is the timber and wood of one ſort or another in the weald of that county, that when viewed from any eminence in the neighbourhood, it preſents to the eye hardly any other proſpect but a maſs of wood, which is, it is thought, to be aſcribed to the great extent and quantity of wood, preſerved by a cuſtom of a nature ſo extraordinary, that it is not a little ſurpriſing no ſteps have been taken to put an end to it.

When this county was firſt improved by clearing, as in the other diſtrict, it was, it is ſaid, a common practice to leave a *ſhaw* of wood ſeveral yards in width, to encompaſs each diſtinct incloſure, as a nurſery for the timber and other plants. The ſizes of theſe incloſures being ſmall, they muſt of neceſſity contribute to render the general appearance of the tract woody.

Anterior to the Conqueſt, the weald of this county was, it is ſaid, a continued foreſt, extending from the borders of the firſt diſtrict to the confines of Hampſhire, acroſs the whole of it; and the names of a variety of pariſhes ſituated in this line, and evidently derived from Saxon original, atteſt this fact to the preſent day. In ſhort, the foreſt now remaining occupies, it is ſaid, a conſiderable portion of the county.

The weald parts of both theſe counties were probably once one great foreſt.

It is noticed, that there is, perhaps, no object in the weald of the latter county, ſo worthy of attention and obſervation as the growth of timber; that there is no region of the earth where trees of all kinds thrive better, but eſpecially thoſe of the oak and aſh ſorts. The tract there diſtinguiſhed by the title of the Weald has formerly, it is ſtated, been covered with trees, and it was called the foreſt of Anderida; and that now, even if a field be neglected, it will become a wood, principally of oak and birch, intermixed with hazel, ſome kinds of willow, and dog wood.

This diſpoſition for the growth and raiſing of wood and timber ſhould, in all caſes of weald land where it cannot be converted to a better or more profitable purpoſe, be taken advantage of and promoted, by proper planting and encouraging the natural growth of the wood thrown up, as it may form one great feature in the improvement of ſuch land, and be productive of vaſt benefit in bringing every portion and ſort of it to the greateſt profit.

WEALREAF, in our *Old Writers*, ſignifies the robbing of a dead man in his grave.

The word comes from the Saxon *weal*, *ſtrages*, and *reaf*, *ſpoliatio*.

WEANEL, a country term for a young beaſt newly weaned, or taken from ſucking its dam.

WEANING, Ablactation. See Ablactation.

Weaning *Young Live-Stock*, in *Rural Economy*, the ſeparating them from the mothers in the different kinds, for different purpoſes, and in different intentions.

Foals, where they are deſigned for the ſaddle, ſhould, on being taken from the mothers, be put into ſome ſafe ſheds or other proper places at a diſtance, where they can be quiet and out of the hearing of the mares, being well ſupplied with the neceſſary ſorts of food and good water for a day or two; the buildings ſhould be connected with graſs-fields, into which they can be turned in the day-time, but be always brought up for the night, for ſome time, having proper kinds of dry food then given them in full quantities, ſo as to get them on well at firſt. Some intelligent breeders have their young horſe-ſtock fed, after weaning, with coarſely ground oats and one-third flour, divided into proper feeds, and given on the nights in the houſes. This, it is ſaid, puſhes them on early to a full growth, and that they never become ſtunted afterwards. In ſome inſtances, it may be uſeful and proper to put the colt and filly foals into ſeparate paſtures. Where a number are to be weaned at a time, it is of advantage to have the paſture-lands pretty large. See Breeding, Foal, and Horse.

In the weaning of the young of neat cattle, the buſineſs is accompliſhed at different times or ages of the animals, as the nature of the purpoſe for which they are deſigned may be; when for rearing as ſtock, it is often done immediately, or in a few days or weeks, and when for fattening, not at all. If for ſale, the time is uncertain, depending on the demand. Where good neat cattle-ſtock is the object, as ſoon as the natural food milk is laid aſide, a ſubſtitute of ſome good ſort of diet ſhould be had recourſe to, ſuch as oat or barley-meal, ſtirred in with the jelly of linſeed, that has been produced by being ſteeped in hot water, and mixed with flet milk; which ſhould be continued until they become capable of eating more firm and ſolid kinds of food, ſuch as either oats, ſplit beans, and chopped hay, or bran, and barley-flour mixed: in the early ſpring they ſhould be turned out into good graſs paſtures in warm ſituations. By theſe means they will be brought on well, and become good ſtrong ſtock. For the purpoſe of rearing, as well as that of the butcher, thoſe that are dropped early are to be preferred, as after the early ſpring months, they are not found capable of gaining ſufficient ſtrength and hardneſs before the ſucceeding winter comes on, or a proper ſize and growth by the enſuing ſpring.

In the buying of the young of neat cattle for weaning there are many ſyſtems of management among farmers: ſome prefer bull calves for caſtration, and which they keep, in ſome caſes, until they become reared, and are fat bullocks fit for the market; others buy cow-calves of the true ſhort-horned, or ſome other good milking-breed, which they ſell at two years, or two years and a half old, and upwards, to the cow-keepers as milking-ſtock. In this method, they are collected from the latter end of the ſummer through the autumn of the above true breed, as others will not do from Yorkſhire, and other places where they are to be met with of the right kind, as ſuch ſell better, and more readily to the cow-keepers for affording milk. In weaning, they are then firſt put to ſkim-milk, and tempted as ſoon as poſſible to eat ſome other good food, as bran, oats, oil-cake, the ſweeteſt hay, common turnips, and cole or rape; but nothing is found to do better for them than the Swediſh turnip cut ſmall. In keeping them, they ſhould have great attention to cleanlineſs, and the proper and regular feeding of them. In this way they are continued, being kept in ſheds in the night-time, and turned out by day, until the ſpring, when the ray-graſs becomes ready, and then they may go out gradually altogether, according as the weather may be: after ray-graſs to the beſt marſhes or paſtures; in the autumn to cole or rape that is feeding off for wheat, and after that to turnips: it is a rule with ſome to feed them through the whole period of keeping them as well as poſſible. This is expenſive, but it is conceived, that if they will not pay for good keeping, they will not for bad. Some, however, when they are turned out, make them the followers of the fattening ſtock.

In this ſyſtem there are thoſe, too, who buy both cow and bull-calves, diſpoſing of the former in the above manner, and keeping the latter raiſing a ſucceſſion of ſteers for the grazing or fattening farmers.

All theſe modes, though hazardous in ſome inſtances, are often

often very beneficial. A man is required for the purpofe, in autumn, winter, and fpring, when the bufinefs is carried on upon a large fcale. See CALF, BREEDING, and CATTLE. Alfo COW-KEEPING.

The weaning of lambs is a matter of fome trouble and difficulty in many cafes; it fhould be done towards the latter end of the fummer, according to circumftances, but never be delayed too long, as the ewes may thereby be greatly hurt in different ways. After the lambs are taken, or lifted as it is fometimes called, from the mothers, they fhould be allowed to pafs the night about the fold or place. In the following morning fome of them will begin to eat, and teach the others to do the fame. They fhould then be removed to fome convenient foft graffy pafture, difturbing them as little as poffible, care being taken that they do not wafte or exhauft themfelves by running. If there be any danger of their not refting quietly the firft night after they are removed, it is faid that it may be effectually prevented by pafturing them with their mothers the night immediately preceding their weaning, on their future pafture, and driving them to the fold or other place directly in that road or way by which the lambs are to be removed from it. In the courfe of ten or twelve days both the lambs and the ewes may be paftured together again without inconvenience. See LAMB and SHEEP.

Store fwine fhould conftantly be weaned at the end of a few weeks, as about fix or eight, otherwife they do much injury to the fow. The young pigs fhould be well fed for fome time afterwards, in order to pufh them on to their proper growth, and prevent their becoming dwarfifh. The want of attention to this often produces a poor ftunted fort of pigs, worth little or nothing. See SWINE.

WEANLING, a term applied in fome diftricts to the newly-weaned calf. See WEANING.

WEAPONS. See ARM and ARMOUR.

WEAPON-*Salve*, a kind of unguent, fuppofed to cure wounds fympathetically, by being applied, not to the wound, but to the weapon that made it. See SYMPATHETIC *Powder*, and TRANSPLANTATION.

WEAR, or WEER, a great ftank, or dam in a river; fitted for the taking of fifh, or for conveying the ftream to the mill. See FISHING, and WEIR.

WEAR, in *Geography*. See WERE.

WEARE, a townfhip of America, in New Hampfhire, in the county of Kellfborough, containing 2634 inhabitants; 18 miles S.W. of Concord.

WEARING, in *Sea Language*. See VEERING.

WEARY BAY, in *Geography*, a bay on the N.E. coaft of New Holland, S. of Endeavour river.

WEASEL, WEESEL, *Common*, in *Zoology*, a fpecies of the muftela. See MUSTELA *Vulgaris*.

The common weafel ufually refides in cavities under the roots of trees, as well as of banks near rivulets, &c. from which it occafionally fallies out in fearch of birds, and more efpecially of field-mice, great multitudes of which it deftroys.

In Norway, Sweden, Ruffia, and Siberia, the weafel always changes to white at the approach of winter. In Siberia it is called *lafmitfka;* and the fkins are fold to the Chinefe for three or four rubles *per* hundred.

We have authentic accounts of this animal's being fo completely tamed, as to exhibit every mark of attachment to its benefactors, and to be as familiar as a cat or lap-dog. A lady took one of thefe animals under her protection; and fed it from her hand with warm milk, and alfo with veal, beef, or mutton. When it is fatisfied it generally goes to fleep, and when it wakes, it amufes itfelf with various frolics, and beftows the moft affectionate careffes on its guardian. It diftinguifhes the voice of its benefactrefs amidft twenty people, and gives her a decided preference to all the reft. Among other curious particulars which this lady has recited, we cannot forbear mentioning the curiofity of this animal; it being impoffible, as fhe fays, to open a drawer or a box, or even to look at a paper, which this little creature will not alfo examine. Aldrovandus indeed confirms the account given by Buffon; exprefsly afferting, that weafels are eafily tamed, and that, when tame, they are remarkably playful; adding, at the fame time from Curdan, that if their teeth are rubbed with garlick, they will not afterwards prefume to bite. This writer alfo affirms, that the weafel fometimes carries her young in her mouth from place to place feveral times in a day, when fhe fufpects that they will be ftolen from her; refembling fome other animals in this refpect. For other fpecies of weafel we refer to MUSTELA and VIVERRA; and we fhall here add fome few fpecies, mentioned by Dr. Shaw, which have not been noticed under either of thofe articles. Such are the *Viverra Touan*, or ferruginous weafel, white beneath, with the tail naked towards the tip, the "Touan" of Buffon; a native of Cayenne, that lives in hollow trees, and feeds on worms and infects. The *V. Cuja*, or black weafel, with turned up fnout, the "Cuja" of Molina, refembling the ferret in fhape, manners, and teeth; a native of Chili, and preying upon mice. The *V. Maculata*, or dufky weafel, fpotted with white; the "Spotted Martin" of governor Phillips, in its form fomewhat refembling the foffane. There are alfo fome other fpecies, not yet fufficiently defcribed, as the grey-headed weafel, or "La Grande Marte de Guiane," of Buffon; the South American weafel, or "La Fouine de la Guiane," of Buffon; the woolly weafel, or "La petite Fouine de la Guiane," of Buffon; the mufky weafel of Pennant, a native of Bengal; and the flender-toed weafel with a bufhy tail, defcribed, as well as the other, by Mr. Pennant from a drawing; this latter being a native of Cochinchina.

WEASEL-*Coot*, in *Ornithology*, the red-headed fmew, or mergus minutus of Linnæus.

WEATHER, in *Agriculture*, as denoting the ftate or difpofition of the atmofphere, in regard to heat and cold, drought and moifture, fog, fair, or foul, wind, rain, hail, froft, fnow, and other changes, is a fort of knowledge which is of vaft utility and importance to the farmer, as the fecuring of his different produce in a perfect manner greatly depends upon it; and it is in and by means of the atmofphere, that plants are in fome meafure nourifhed, and that animals live and breathe: any alterations or changes in its heat, denfity, purity, or any other refpect, muft, of courfe, neceffarily be attended with proportionable changes in the ftate of thefe.

The great but regular alterations which a little change of weather makes in many parts and forts of inanimate matter, is fully and ftrikingly fhewn in the common inftances and cafes of barometers, thermometers, hygrometers, and other fuch inftruments; and it is owing partly to our inattention, and partly to other caufes and circumftances, that we, like other animals, do not feel as great and as regular ones in the weight, preffure, and affections, in the tubes, chords, and fibres of our own bodies.

In order, however, fully to form and eftablifh a proper and confiftent theory or doctrine of the weather, it would be neceffary to have accounts and regifters of it regularly and carefully kept, in divers parts of the globe, for a long ſeries of years, whence, it is poſſible, we might be enabled to aſcertain and determine the directions, breadths, and bounds of the winds, as well as other matters, and the nature of the weather they bring along with them; with the correſpondence there may be between the weather of different places, in divers parts of the earth, and the difference between one ſort and another at the ſame place; and thus, in time, learn to judge of, and foretell many great changes and emergencies; ſuch as extraordinary heats, droughts, rains, froſts, ſnows, and ſome others. But hitherto very few, and only partial accounts in relation to the weather, have been, for the moſt part, kept. The general concluſions that have been drawn from the experiments that have been made, and the experience had upon this ſubject, are, that barometers generally riſe and fall together, even at very diſtant places, and a conſequent conformity and ſimilarity of weather; and that this is the more uniformly ſo, as might be expected, as the places are the nearer together. That the variations of theſe inſtruments, too, are the greater, as the places are nearer to the pole; thus, for inſtance, the quickſilver in them at London, has a greater range by two or three lines than at Paris, and at that place a greater than at Zurich; and that at ſome places near the equator, there is ſcarcely any variation at all; that the rain in Switzerland and Italy is much greater in quantity, taking it for the whole year, than in the county of Eſſex, though the rains are yet more frequent, or there are more rainy days in that county, than in either of the other places; that cold contributes greatly to rain, and this apparently by condenſing the ſuſpended vapours, and thereby making them deſcend; thus, very cold months, or ſeaſons, are very commonly followed immediately by very rainy ones, and cold ſummers are always wet ones; that high ridges of country, or mountains, ſuch as the Alps and others, and the ſnows with which they are covered, not only affect the neighbouring places, but even diſtant countries, as theſe often partake of their effects; and the weather is moſtly rainy in the vicinities of them, both in this and other countries.

The prognoſtics of the weather that are formed from other circumſtances and obſervations are, that a thick dark ſky laſting for ſome time, without either ſun or rain, always becomes fair firſt and then foul; that is, it changes to a fair clear ſky before it turns to rain. The reaſon is thought to be obviouſly this: the atmoſphere is replete with vapours, which though ſufficient to reflect and intercept the ſun's rays from us, yet want denſity to deſcend, and while theſe vapours continue in the ſame ſtate, the weather will do ſo too: accordingly ſuch weather is commonly attended with moderate warmth, and with little or no wind to diſturb the vapours, but having a heavy atmoſphere to ſuſtain them; the barometer being commonly high: but when the cold approaches, and by condenſing the vapours, drives them into clouds, or drops, the way is made for the ſun-beams to diſplay themſelves; until the ſame vapour, by farther condenſation, be formed into rain, and fall down in drops. And that a change in the warmth of the weather is often followed by a change in the wind. Thus, the northerly and ſoutherly winds, though commonly accounted the *cauſes* of cold and warm weather, are in reality the *effects* of the cold or warmth of the atmoſphere; of which Dr. Derham aſſures us he has had ſo many confirmations, that he makes no doubt of the fact. Thus, it is common to obſerve a warm ſoutherly wind, ſuddenly changed to the north, by the fall of ſnow or hail; or to ſee the wind in a cold froſty morning north, when the ſun has well warmed the air, wheel towards the ſouth, and again turn northerly or eaſterly in the cold of the evening.

From the rules laid down by the ſhepherd of Banbury, many intereſting and uſeful deductions may be made in regard to the weather: it may be concluded, that when the ſun riſes red and fiery, there will be wind and rain; but that when it riſes cloudy, and the clouds ſoon diſappear or leſſen, there will certainly be fair weather; and that when the evening is red and the morning grey, a fine day may moſtly be predicted.

That when there are ſmall and round clouds, of a dapple grey colour, with a north wind, it may be determined, that there will be fair weather for two or three days; but that large clouds like rocks are a ſign of great ſhowers. And that when ſmall clouds increaſe, it is an indication that there will be much rain; but that if the large clouds are ſeen to leſſen, there will be fair weather. In ſummer or harveſt, it may alſo be conſidered, when the wind has been ſouth two or three days and it grows very hot, and clouds are ſeen to riſe with great white tops like towers, as if one were on the top of another, being joined together with black on the lower ſide, a ſign that there will be thunder and rain ſuddenly. And that when two ſuch clouds riſe, one on each hand, it is high time to make haſte to ſhelter.

That when a cloud is ſeen to riſe againſt the wind, or the ſide wind, it is a ſure ſign that when the cloud comes up near you, the wind will blow the way in which the cloud came. It is the ſame, too, with the motion of a clear place in the ſky, when all the parts of it are thick except one edge. That, at all times, when the clouds look black in the weſt, it is ſure to rain; or if raining, it is ſure to continue, whatever quarter the wind may be in: and that, on the contrary, if it ſhould break in the weſt, it is ſure to be fair. That fair weather for a week, with a ſouth wind, is likely to produce a great drought.

That the wind uſually turns from north to ſouth quietly, but comes back to north ſtrong and with rain. That ſudden rains never laſt long; but that when the air grows thick by degrees, and the ſun, or moon and ſtars, ſhine dimmer and dimmer, it is likely to rain for ſome time.

That when it begins to rain from the ſouth with a high wind for two or three hours, and then the wind falls but the rain continues, it is likely to rain twelve hours or more; and that it generally rains until a ſtrong north wind clears the air. But that when it begins to rain an hour or two before ſun riſing, it is likely to be fair before noon, and to continue ſo that day; but that if the rain begin an hour or two after ſun riſing, it is likely to rain all that day, unleſs the rainbow be ſeen before it rains.

That when miſts riſe in low ground and ſoon diſappear, it is a ſign that there will be fair weather; but that when they riſe to the hill tops, there will be rain in a day or two. That a general miſt before the ſun riſes, when near the time of full moon, is a ſign of fair weather. That when there are miſts in the new moon, there will be rain in the old; and if there are miſts in the old moon, there will be rain in the new. That in regard to the ſeaſons, as ſpring and ſummer, when the laſt eighteen days of the month of February and the firſt ten days of the following month are for the moſt part rainy, the ſpring and ſummer may be concluded likely to be ſo too. It is ſaid alſo, that a great drought has never been known by the writer, but which began at that time. In reſpect to the winter, when the end of October and the beginning of the following month are, for the moſt part, warm and rainy, the two beginning months of the new year are likely to be froſty and cold, except after a very

dry

dry ſummer. But that when October and the following month are ſnowy and froſty, the two beginning months of the new year may be likely to be open and mild.

Something may be drawn from the habits, cries, and courſe of animals, in reſpect to the weather. It is remarked, that in ſummer, when ſheep riſe early in the morning, it is a ſure ſign of either rain, or a very hot day; and that, in all ſeaſons, when they jump and play much about, it is an indication of rain or wind, but generally of both, in the ſummer, and of very ſtormy weather in the winter. That in winter, when the ſheep lie under a hedge, and ſeem loath to go off to paſture, and bleat much, it is conſidered a ſign of a ſtorm. And that, when ſheep are fed with hay in the winter, and in froſty and ſnowy weather they leave the hay, it is a certain ſign of the froſts breaking up.

That when rabbits get out to feed early in the morning, it is a ſign of rain in the night in ſummer, and of either rain or ſnow in winter; and that when it is likely to be a bad night, they will be apt to get home before it is dark.

That pigs appear very uneaſy before high winds, and run about ſqueaking as if they were in great pain.

That when owls ſcreech, it is a certain ſign of rain, and moſtly in a very ſhort time. Alſo, that when wood-peckers cry, it is a ſign of rain. For this reaſon, they are called, in ſome places, rain-fowl. That likewiſe, when peacocks cry much, it is a ſign of rain. That when the cocks begin to crow while it rains, it is a ſign of fair weather.

That before a wet ſummer, the ſwans build their neſts very high; but that before a dry ſummer they build very low. That the bittern or bitter bump does the ſame. But that when the raven is obſerved early in the morning ſoaring round and round at a great height in the air, it is a ſure ſign the day will be fine, and that the weather is likely to ſet in for fair. And that in ſummer when the bat is ſeen flying and flitting about very late in the evening, the next day is likely to be fair. That likewiſe when the ſwallow is obſerved to fly high, the weather will moſt likely be warm and fair. But that when it is noticed to fly low, and dip the tips of its wings in the water as it ſkims over the ſurface, the weather is likely to be rainy. And that the continued ſqualling of the guinea-fowl, and the quacking of ducks and geeſe, are certain ſigns of rain.

That before great ſtorms the miſſel thruſh ſings particularly loud, and continues to do ſo until the rain begins. On this account, in ſome places, it is called the ſtorm-fowl. Alſo, that in autumn, when flocks of wild geeſe are ſeen flying over in a weſterly direction, it is a ſign there ſoon will be hard weather. That the early appearance of the wood-cock and field-fare likewiſe indicate cold hard winters.

That when in the time of hay-making the black ſnails are to be ſeen ſtretched along on the ſwath of graſs, it is a ſign of rain. That when frogs look black inſtead of a golden yellow colour, it is a ſign of rain. And the loud hoarſe croakings of frogs are ſure ſigns of rain.

That in autumn, when the dor beetle is ſeen flying about in the evening, the next day is likely to be fine. Alſo, that when bees do not go out as uſual, but keep in their hives, it is a ſign of rain. Much information of this nature may be found in Marſhall's "Minutes of the Southern Counties," which may be conſulted by the cautious farmer with great utility and advantage, in regard to the weather he may have for ſecuring his produce in different caſes.

There are other concluſions, too, in reſpect to the weather, that may be drawn from plants of different kinds, as moſt vegetables expand their flowers and down in ſun-ſhiny weather; and towards the evening and againſt rain cloſe them up, eſpecially at the beginning of their flowering, when the ſeeds are ſenſible and tender. This is viſible and evident enough in the down of dandelion, and many other downs, and eminently ſo in the flowers of pimpernel; the opening and ſhutting of which make what is termed the countryman's *weather-wiſer*, by which he foretels the weather of the following day. The rule is, when the flowers are cloſe ſhut up, it betokens rain and foul weather; but when they are open and abroad fair weather. And lord Bacon obſerves, that the ſtalks of trefoil ſwell againſt rain, and grow more upright; and that the like may be noticed, though leſs ſenſibly, in the ſtalks of moſt other plants. It is added, too, that in the ſtubble fields there is found a ſmall red flower, called by the country people pimpernel, which opening in a morning is a ſure indication of a fine day.

"Eſt & alia (arbor in Tylis) ſimilis, folioſior tamen, roſeique floris; quem noctu comprimens, aperire incipit ſolis exortu, meridie expandit. Incolæ dormire eum dicunt. Plin. Nat. Hiſt. lib. xii. c. 11. See *Sleep of* PLANTS, and VIGILIÆ *Florum*.

It is readily conceivable that vegetables ſhould be affected by the ſame cauſes as the weather, as they may be conſidered as ſo many hygrometers and thermometers, conſiſting of an infinite number of *tracheæ* or air-veſſels, by which they have an immediate communication with the air or atmoſphere, and partake of its moiſture, heat, and other changes. And hence, too, it is, that all wood, even the hardeſt and moſt ſolid, ſwells in moiſt weather, the humid vapours eaſily inſinuating themſelves into the pores of it, eſpecially of the lighter and drier kinds, from which they become applicable to many purpoſes of art, and may tend to ſhew the change of the weather in ſome inſtances.

Hence we derive a very extraordinary uſe of wood, *viz.* for breaking rocks for mill-ſtones.

The method at the quarries is this:—Having cut a rock into a cylinder, they divide that into ſeveral leſs cylinders, by making holes at proper diſtances round the great one; the holes they fill with ſo many pieces of ſallow wood, dried in an oven, which, in moiſt weather, becoming impregnated with the humid corpuſcules of the air, ſwell; and, like wedges, break or cleave the rock into ſeveral ſtones.

The attentive farmer ſhould ſtore up in his mind as many of the uſeful rules relating to the weather as poſſible, as they may ſerve him very effectually, on many occaſions, in the performance of his various buſineſs. See ATMOSPHERE, METEOROLOGY, HEAT, RAIN, WIND, &c.

The members of our Royal Society, the French Academy of Sciences, and many authors of note, have made conſiderable eſſays this way; and the practice of keeping meteorological journals has, of late years, become very general. For inſtructions and examples pertaining to this ſubject, ſee Phil. Tranſ. vol. lxv. part ii. art. 16.

Eraſ. Bartholin has obſervations of the weather for every day throughout the year 1671. Mr. W. Merle made the like at Oxford, for ſeven years, with a very remarkable care and accuracy. Dr. Plott did the ſame at the ſame place, for the year 1684. Mr. Hillier, at Cape Corſe, for the years 1686, 1687. Mr. Hunt, &c. at Greſham college, for the years 1695, 1696. Dr. Derham, at Upminſter in Eſſex, for the years 1691, 1692, 1697, 1698, 1699, 1703, 1704, 1705. Mr. Townley, in Lancaſhire, in 1697, 1698. Mr. Cunningham, at Emin in China, for the years 1698, 1699, 1700, 1701. Mr. Locke, at Oats in Eſſex, 1692. Dr. Scheuchzer, at Zurich, in 1708; and Dr. Tilly, at Piſa, the ſame year. See the Phil. Tranſactions.

The form of Dr. Derham's obſervations we give as a ſpecimen of a journal of this kind; obſerving that he notes

 the

the ftrength of the winds, by 0, 1, 2, 3, &c. and the quantity of rain, as it fell through a tunnel, in pounds and centefimals.

Phenomena of the Weather, October 1697.

	12	Rain.	S.W. by W.	5	29	34	
	9	Stormy.		0	29	88	0 29

We have feveral fchemes for keeping meteorological journals or diaries of the weather, extant in the Philofophical Tranfactions, the Medical Effays of Edinburgh, and in other books. The Ephemerides Ultrajectinæ may alfo be confulted. The inftruments requifite for fuch journal are, a *Barometer*, *Thermometer*, *Anemofcope*, and *Ombrometer*, which fee in their proper places. See a Collection of ingenious obfervations, and meteorological conjectures, by Dr. Franklin, in his Experiments, &c. p. 182, &c. See EVAPORATION, RAIN, and WIND.

We fhall here fpecify fome of the common indications of changes of weather that may be obferved at fea. Under the article TIDES we have already ftated, that they are raifed by the joint actions of the fun and moon; the fpring-tides being raifed by the fum, and the neap-tides by the difference of the actions of thefe bodies; and, alfo, that the fpring-tides, near the time of an equinox, are higher than at other times of the year. Now, fince the atmofphere is a fluid much lighter than water, it muft, therefore, be more affected about the times of new and full moon, and in the months of March and September, than at other times. This is confirmed by obfervation; for, about the times of new and full moon, an alteration in the ftate of the weather ufually happens; and the violent gales about the time of the equinoxes, called *equinoxial gales*, are well known, and expected by every feaman.

According as the ftate of the atmofphere is more or lefs difturbed, it is evident the appearance of the heavenly bodies will be more or lefs altered. Thus, if the moon appears paler than ufual, or if there is a halo about the moon, rain will probably follow foon after. Several circles about the moon portend wind. Thefe obfervations are alfo applicable to the fun. If the moon appears of a red colour, or if the moon's horns are blunt, they are figns of wind, which may be expected from that quarter to which the blunteft horn is directed. In viewing the moon with a telefcope in a quiet evening, if one part of the moon's limb be obferved to be tremulous, while the oppofite part of the limb is without the leaft apparent tremor, the wind may be expected from that point to which the limb free of tremors is directed. A red circle about the moon towards the time of full moon indicates wind.

One of the beft known figns in the heavens is the *Rainbow;* which fee. When the blue and yellow parts of the rainbow are very bright, or if all of it vanifh at the fame time, it will be fair weather: if the bow appears to be broken in feveral places, tempeftuous weather may be expected.

From the various appearances of the clouds, (fee CLOUD,) which are vapours floating in the atmofphere, producing rain, hail, fnow, thunder, and lightning, the approaching weather may, in fome meafure, be predicted. The height of the clouds feldom exceeds a mile; and the fummits of high mountains are free of clouds.

When the fky is of a fine blue colour, without any clouds, it will continue to be fair weather; but if it is of a very dark blue, clouds will be formed, and rain, wind, or fog, will foon follow.

When the fky appears very much clouded for fome time, without rain, it generally firft clears up, and then changes to rain. This is accounted for as follows:—The atmofphere at that time being replete with vapours, which, though fufficient to intercept the rays of the fun, yet want denfity to defcend; and while the vapours continue in the fame ftate, the weather will do fo too; and fuch weather is commonly attended with moderate warmth, and with little or no wind to difturb the vapours, and an heavy atmofphere to fupport them, the barometer being commonly high. But when the cold approacheth, and, by condenfing the vapours, drives them into clouds or drops, then way is made for the fun-beams, till the fame vapours, by farther condenfation, be formed into rain, and fall down in drops.

If the clouds, in a fummer evening, gradually diminifh, and at laft vanifh, it will be fine weather; but, if they increafe, and fmall clouds be obferved to move very fwiftly underneath, it will be rain foon after; or, if the clouds change to a dark colour, thunder may be expected.

If the clouds in the weftern hemifphere, at the time of fun-fet, are tinged with a light red and yellow; or, if there are no clouds, and the fky, towards that part of the horizon where the fun fets, be of a beautiful red and yellow, it will be fine weather: but if the fun be of a pale colour, or if the clouds change to a dark red, and continue, it will be rain. The clouds tinged with a dark red in the oppofite hemifphere to the fun, whether at rifing or fetting, prefage wind.

In winter, when large clouds are obferved with white edges, and a ftrong blue fky above them, it will be hail or fnow; or probably thefe may be diffolved into rain before they reach the earth.

When there are two or more ftrata of clouds moving in different directions, rain generally follows. Many fmall clouds pretty high, and other appearing at the fame time in form of fleeces of wool, denote wind.

A cloud of an oblong form, fometimes called *Noah's Ark*, feen in a clear fky, and changing from a fine light to a dark colour, is a fign of rain; but, if it changes from dark to light, it is a fign of fair weather.

A fmall black cloud feen in a clear fky, or feveral fmall clouds collecting near each other, are an indication of wind from the quarter from whence they are obferved to move: alfo, if the clouds are obferved to diverge from a point in the horizon, wind may be expected from that, or from the oppofite point.

When ftars of the fecond and third magnitudes are fuddenly obfcured, wind or rain will foon follow. Thofe meteors, commonly called *falling* or *fhooting* ftars, are ufually the forerunners of wind.

That appearance in the heavens refembling a portion of the rainbow, but apparently broader than any part of the arch when complete, and generally known by the name of a *Wind-gall*, is an indication of an approaching gale.

The *Aurora Borealis*, (which fee,) or northern light, is a fign of wind from between the S. and S.W. points, attended with hazy weather, and fmall rain, the gale generally commencing between twenty-four and thirty hours after the firft appearance of the aurora. The violence of the gale, and the time of its commencement after the aurora borealis is feen, and duration, depend, in a great meafure, upon the brightnefs and motion of the aurora; for the more brilliant the aurora, and the quicker its motions, the gale will happen fooner, be more violent, and of fhorter duration.

A change

A change in the wind commonly produces a change in the weather. Thus, in fair weather, if the wind changes to the oppofite point, rain may be expected: but, in rainy or foggy weather, it will clear up foon after the change of the wind.

In a ftorm at fea, a fiery meteor, in form of a ball, affording an obfcure flame like a candle burning faintly, is fometimes feen adhering to the mafts, yards, &c. or leaping from one part to another. When only one is feen, it is called *Helena*, and is a fign that the fevereft part of the ftorm is yet to come. When two are obferved, they are called *Caftor* and *Pollux*, and fometimes *Tyndaridæ*, and denote the ftorm to be near an end. If five of thefe balls are feen together, which the Portuguefe call the *Virgin Mary's Crown*, it is confidered to be a fure fign that the ftorm will be foon over. When the meteor adheres to the mafts, yards, &c. it is concluded, from the air not having fufficient motion to diffipate the flame, that a calm will foon enfue; but if it leaps from one place to another, that it denotes a ftorm.

At the Cape of Good Hope, an approaching ftorm, or gale of wind, is eafily known by the following obfervations:—When a fmall black cloud, called the *Ox-eye*, is obferved to rife from the top of Table Mountain, which continues to increafe until the heavens be almoft entirely overclouded, the ftorm then commences. A fimilar phenomenon ufually precedes a ftorm at the Arabian gulf: this ftorm comes from the north, and is accompanied with a great quantity of red fand.

When a hurricane happens in the Weft Indies, it is generally either at new or full moon, or at the quarters, and the figns are as follow:—The fun and moon appear redder than ufual, and are fometimes furrounded with a halo; the ftars at night appear larger and fainter; the fky in the N.W. quarter is dark; the hills are clear of thofe clouds and mifts which ufually hover about them; the fea emits a ftrong fmell, and is violently agitated, often when there is no wind; the wind alfo veers about to the weft, from whence it fometimes blows with intermiffions violently and irregularly for about two hours at a time.

The tumbling of porpoifes indicates a gale of wind. When a fwell fets from any particular point, there being no wind, a gale may be foon expected from that point.

From a very great number of meteorological obfervations, made in England between the years 1677 and 1789, Mr. Kirwan has deduced the following probable conjectures of the weather:

1. That when there has been no ftorm before or after the vernal equinox, the enfuing fummer is generally *dry*, at leaft five times in fix.

2. That when a ftorm happens from any eafterly point, either on the 19th, 20th, or 21ft of March, the fucceeding fummer is generally *dry*, four times in five.

3. That when a ftorm arifes on the 25th, 26th, or 27th of March, and not before, in any point, the fucceeding fummer is generally *dry*, four times in five.

4. If there be a ftorm at S.W. or W.S.W. on the 19th, 20th, 21ft, or 22d of March, the fucceeding fummer is generally *wet*, four times in five.

We fhall further fubjoin the following obfervations:

1. A moift autumn, with a mild winter, is generally followed by a cold and dry fpring, which greatly retards vegetation.

2. If the fummer be remarkably rainy, it is probable that the enfuing winter will be fevere; for the unufual evaporation will have carried off the heat of the earth. Wet fummers are generally attended with an unufual quantity of feed on the white thorn and dog-rofe bufhes. Hence, the unufual fruitfulnefs of thefe fhrubs is a fign of a fevere winter.

3. The appearance of cranes, and birds of paffage, early in autumn, announces a very fevere winter; for it is a fign that it has already begun in the northern countries.

4. When it rains plentifully in May, it will rain but little in September, and *vice verfa*.

5. When the wind is S.W. during fummer or autumn, and the temperature of the air unufually cold for the feafon, both to the feeling and the thermometer, with a low barometer, much rain is to be expected.

6. Violent temperatures, as ftorms or great rains, produce a fort of crifis in the atmofphere, which produces a conftant temperature, good or bad, for fome months.

7. A rainy winter predicts a fteril year; a fevere autumn announces a windy winter.

For indications of the weather by the barometer, fee Barometer. By the *Thermometer*, (which fee,) Mr. Dalton deduces the following conclufions:

The mean altitude of the mercury in the thermometer in Britain is about 55°: if higher, the weather is warm; but if lower, it is cold.

A quick and confiderable alteration in the altitude of the mercury in the thermometer indicates rain.

If it begins to fnow when the thermometer is below 32°, the mercury generally rifes to that altitude, and continues while the fnow falls. If the weather clears up foon after, a fevere cold may be expected. See alfo Hygrometer, from which it is inferred, that, when the index of the hygrometer points to *dry*, and continues proceeding towards extreme drynefs, fair weather, and probably wind, may be expected; but if the index returns to the mean ftate, it will be rain. If the index points to *moift and increafing*, rain will foon follow; if it returns towards the mean, it will be fair weather.

As to the fuppofed influence of the moon upon the weather, fee *Influence of the* Moon.

Weather, in *Sea Language*, is ufed as an adjective, and applied by mariners to every thing lying to windward of a particular fituation: thus, a fhip is faid to have the weather-gage of another, when fhe is farther to windward. Thus alfo, when a fhip under fail prefents either of her fides to the wind, it is then called the weather-fide, or weather-board; and all the rigging and furniture fituated on it are diftinguifhed by the fame epithet; as the weather-fhrouds, the weather-lifts, the weather-braces, &c.

To Weather, is to fail to windward of fome fhip, bank, or head-land.

Weather-*Beaten*. Scattered by a ftorm.

Weather-*Bit*, denotes a turn of the cable of a fhip about the end of the windlafs, without the knight-heads. It is ufed to check the cable, in order to flacken it gradually out of the fhip, in tempeftuous weather, or when the fhip rides in a ftrong current. See Ring-*Ropes*.

Weather-*Boarding*, among *Carpenters*, &c. denotes the nailing up of boards againft a wall, and fometimes the boards themfelves when thus nailed up.

Weather-*Cock*, or *Weather-Vane*, a moveable vane, in form of a cock, or of other fhape, placed on high, to be turned round according to the direction of the wind, and point out what quarter the wind blows from. See Vane.

Weather-*Cord*. See Hygrometer.

Weather, *Hard-a*. See Hard.

Weather-*Houfe*. See Hygrometer.

WEATHER-*Gage*, in *Sea Language*. When a ſhip or fleet is to windward of another, ſhe is ſaid to have the weather-gage of her.

WEATHER-*Glaſſes* are inſtruments contrived to indicate the ſtate or diſpoſition of the atmoſphere, as to heat, cold, gravity, moiſture, &c. to meaſure the changes befalling it in thoſe reſpects; and by thoſe means to predict the alteration of weather, as rains, winds, ſnow, &c.

Under the claſs of weather-glaſſes, are comprehended *barometers*, *thermometers*, *hygrometers*, *manometers*, and *anemometers*, of each of which there are divers kinds. See their theories, conſtructions, uſes, kinds, &c. under BAROMETER, THERMOMETER, HYGROMETER, &c.

WEATHER-*Quarter*, in *Sea Language*, that quarter of the ſhip which is on the windward ſide.

WEATHER-*Quoil* or *Coile*, is the turning of the ſhip's head about, ſo as to lie that way which her ſtern did before without looſing any ſail, but only by bearing up the helm.

WEATHER-*Side*, the ſide of a ſhip upon which the wind blows.

WEATHER-*Shore*, a name given to the ſhore lying to windward.

WEATHER-*Tiling*, in *Building*, the covering of the upright ſide of a houſe with tiles.

WEATHERER, in *Geography*, one of the ſmaller Shetland iſlands. N. lat. 60° 35′. W. long. 1° 13′.

WEATHERING, a doubling, or ſailing by a point, or place.

WEATHERING, among *Mill-wrights*. See WIND-*Mill*.

The WEATHERING *of a Hawk*, among *Falconers*, is the ſetting of her abroad to take the air.

WEATHERSFIELD, in *Geography*, a town of the ſtate of Connecticut, in the county of Hartford, founded about the year 1639, containing 2868 inhabitants; 5 miles S. of Hartford.—Alſo, a townſhip of Vermont, in the county of Windſor, containing 2115 inhabitants; 3 miles S. of Windſor.—Alſo, a town of Ohio, in the county of Trumbull, containing 232 inhabitants.

WEAVER, in *Manufactures*, one who practiſes the art of weaving.

Perſons uſing the trade of a weaver, ſhall not keep a tucking or fulling-mill, or uſe dyeing, &c. or have above two looms in a houſe in any corporation or market-town, on pain of forfeiting 20*s*. a week: and ſhall ſerve an apprenticeſhip for ſeven years to a weaver or clothier, or ſhall ſhall forfeit 20*l*. &c. 2 & 3 Ph. & M.

WEAVER'*s Alarm*. This contrivance is only a weight faſtened to a packthread, which is placed horizontally, ſo that in a certain time a candle may burn down to it. Then the flame of the candle ſetting fire to the thread, the weight falls, and awakens the ſleeping perſon. See Phil. Tranſ. No. 477. ſect. 14, where we have a figure to explain the invention, which has got its name from being in frequent uſe among the weavers.

WEAVER'*s Lake*, in *Geography*, a lake of New York; 3 miles N.W. of Otſego lake.

WEAVING, in *Manufactures*, is the art of combining and uniting threads together, to form cloth. Stocking-knitting or weaving is a diſtinct art from cloth-weaving, the manner of combining the thread, being eſſentially different in the two. In the ſtocking fabric, the whole piece conſiſts of one continuous thread, which is formed into a ſeries of loops in ſucceſſive rows; and the loops of each row are drawn through the loops of a former row. See STOCKING-*Frame*.

Woven cloth is always compoſed of two diſtinct ſyſtems of threads, called the warp and the weft: theſe traverſe the piece of cloth in oppoſite directions, and are uſually at right angles to each other. Thoſe threads, (or, as the weavers call them, yarns,) which run in the direction of the length of the web or piece of cloth, are called the warp, and they extend entirely from one end of the piece to the other. The croſs thread, or yarn, runs acroſs the cloth, and is called the woof or weft. This is in fact one continued thread through the whole piece of cloth, being woven alternately over and under each yarn of the warp, which it croſſes, until it arrives at the outſide one. It then paſſes round that yarn, and returns back over and under each thread, as before; but in ſuch a manner, that it now goes over thoſe yarns which it paſſed under before, and *vice verſâ;* thus firmly knitting or weaving the warp together. The outſide yarn of the warp, round which the woof is doubled, is called the ſelvage, and cannot be unravelled without breaking the weft. The ſtrength of the cloth, in the direction of the length, muſt depend on the threads of the warp; but its ſtrength in the oppoſite direction will depend upon the weft; and the ſtrength of theſe two threads ſhould be always properly proportioned to each other.

The combined arts of ſpinning and weaving are among the firſt eſſentials of civilized ſociety, and we find both to be of very ancient origin. The fabulous ſtory of Penelope's web, and, ſtill more, the frequent alluſions to this art in the ſacred writings, tend to ſhew, that the fabrication of cloth from threads, hair, &c. is a very ancient invention. It has, however, like other uſeful arts, undergone a vaſt ſucceſſion of improvements, both as to the preparation of the materials of which cloth is made, and the apparatus neceſſary in its conſtruction, as well as in the particular modes of operation by the artiſt. Weaving, when reduced to its original principle, is nothing more than the interlacing of the weft or croſs threads into the parallel threads of the warp, ſo as to tie them together, and form a web or piece of cloth. This art is doubtleſs more ancient than that of ſpinning, and the firſt cloth was what we now call matting, *i.e.* made by weaving together the ſhreds of the bark, or fibrous parts of plants, or the ſtalks, ſuch as ruſhes and ſtraws.

This is ſtill the ſubſtitute for cloth amongſt moſt rude and ſavage nations. When they have advanced a ſtep farther in civilization than the ſtate of hunters, the ſkins of animals become ſcarce, and they require ſome more artificial ſubſtance for clothing, and which they can procure in greater quantities. Neverthelеſs, ſome people are ſtill ignorant of the art of weaving; for the cloth made in the iſlands of the South ſea appears to be made by cementing or glueing the ſhreds together, rather than by weaving. From the deſcription given by captain Cook, and other circumnavigators, and from the ſpecimens which have been brought to Europe, their cloth, or rather matting, is in general produced by coheſion of the parts, rather than texture. This aſſimilates it more to the ideas which we attach to paper, or paſteboard, than to thoſe which we form of cloth.

When it was diſcovered that the delicate and ſhort fibres, which animals and vegetables afford, could be ſo firmly united together by twiſting, as to form threads of any required length and ſtrength, the weaving art was placed on a permanent foundation. By the proceſs of ſpinning, which was very ſimple in the origin, the weaver is furniſhed with threads far ſuperior to any natural vegetable fibres in lightneſs, ſtrength, and flexibility; and he has only to combine them together in the moſt advantageous manner.

The art of weaving cloth has been ſo extenſively applied in in almoft every civilized country, and the knowledge of its various branches has been derived from fuch a variety of fources, that no one perfon can ever be practically employed in all its branches; and though every part bears a ftrong analogy to the reft, yet a minute knowledge of each of thefe parts can only be acquired by experience and reflection. We will endeavour to give the reader as comprehenfive an idea of the hiftory and progrefs of this ancient and invaluable art as the nature of the thing, and the limits to which we are neceffarily confined, will permit.

The hiftory of this art is very little known, and its great antiquity neceffarily involves the earlier eras of it in the moft perfect obfcurity.

The art of making linen, which was probably the firft fpecies of cloth invented, was communicated by the Egyptians, the inhabitants of Paleftine, and other eaftern nations, to the Europeans. By flow degrees it found its way into Italy; and it afterwards prevailed in Spain, Gaul, Germany, and Britain. The Belgæ manufactured linen on the continent; and when they afterwards fettled in this ifland, it is probable they continued the practice, and taught it to the people among whom they refided.

When it is confidered that the wants of mankind are nearly the fame in all countries, it is not improbable that the fame arts, however varied in their operations, may have been feparately invented in different countries. It is not, however, certain that the art of making cloth is one which the Britons invented for themfelves.

It is moft probable that the Gauls learned it from the Greeks, and communicated the knowledge of it to the people of Britain. It is very certain that the inhabitants of the fouthern parts of Britain were well acquainted with the arts of dreffing, fpinning, and weaving, both flax and wool, when they were invaded by the Romans. Neverthelefs, we have the authority of Julius Cæfar, that when he invaded Britain, the art of weaving was totally unknown to the Britons.

Whatever knowledge the Britons might poffefs of the clothing arts, prior to the invafion, it is very certain that thefe arts were much improved amongft them after that event. It appears from the Notitia Imperii, that there was an imperial manufactory of woollen and linen cloth, for the ufe of the Roman army then in Britain, eftablifhed at Venta Belgarum, now called Winchefter.

Many public acts relative to the woollen manufacture, in the earlier period of Englifh hiftory, evidently prove that the greater part of our wool was, for a very long feries of years, exported in a raw ftate, and manufactured upon the continent.

In bifhop Aldhelm's book concerning "Virginity," written about A.D. 680, it is remarked, "that chaftity alone forms not a perfect character, but requires to be accompanied and beautified by other virtues." This obfervation is illuftrated by the following fimile, borrowed from the art of figure-weaving: "It is not a web of one uniform colour and texture, without any variety of figures, that pleafeth the eye, and appeareth beautiful; but one that is woven by fhuttles, filled with threads of purple, and many other colours, flying from fide to fide, and forming a variety of figures and images, in different compartments, with admirable art."

Perhaps the moft curious fpecimen of this ancient figure-weaving and embroidery, now to be found, is that preferved in the cathedral of Bayeaux. It is a piece of linen, about 19 inches in breadth, and 67 yards in length, and contains the hiftory of the Conqueft of England by William of Normandy; beginning with Harold's embaffy, A.D. 1065, and ending with his death at the battle of Haftings, A.D. 1066. This curious work is fuppofed to have been executed by Matilda, wife to William, duke of Normandy, afterwards king of England, and the ladies of her court. Although it is certain that the art of figure-weaving was then known in Britain, it muft be owned, that the piece of tapeftry juft mentioned owes moft of its beauty to the exquifite needle-work with which it is adorned.

The filk manufacture was firft practifed in China, and the cotton in India. Both the woollen and linen were borrowed by the Englifh from the continent of Europe; and for many ages, all the improvements in them in this country were firft introduced into this country by foreign artificers, who fettled amongft us.

About the clofe of the eleventh century, the clothing arts had acquired a confiderable degree of improvement in this ifland. About that time, the weavers in all the great towns were formed into guilds or corporations, and had various privileges beftowed upon them by royal charters.

In the reign of Richard I., the woollen manufacture became the fubject of legiflation; and a law was made, A.D. 1197, for regulating the fabrication and fale of cloth.

The number of weavers, however, was comparatively fmall, until the policy of the wife and liberal Edward III. encouraged the art, by the moft advantageous offers of reward and encouragement to foreign cloth-workers and weavers, who would come and fettle in England. In the year 1331, two weavers came from Brabant, and fettled at York.

The fuperior fkill and dexterity of thefe men, who communicated their knowledge to others, foon manifefted itfelf in the improvement and fpread of the art of weaving in this ifland.

Many Flemifh weavers were driven from their native country, by the cruel perfecutions of the duke d'Alva, in the year 1567. They fettled in different parts of England, and introduced or promoted the manufacture of baizes, ferges, crapes, and other woollen ftuffs.

About the year 1686, nearly 50,000 manufacturers, of various defcriptions, took refuge in Britain, in confequence of the revocation of the edict of Nantz, and other acts of religious perfecution committed by Louis XIV. Thefe improvements chiefly related to filk-weaving.

The arts of fpinning, throwing, and weaving filk, were brought into England about the middle of the 15th century, and were practifed by a company of women in London, called filk-women. About A. D. 1480, men began to engage in the filk manufacture, and the art of filk-weaving in England foon arrived at very great perfection. See Silk.

The civil diffentions which followed this period, retarded the progrefs of thefe arts; but afterwards, when the nation was at reft, the arts of peace, and among others that of weaving, made rapid advances in almoft every part of the kingdom.

In the latter part of the laft century, the invaluable inventions of fir Richard Arkwright, introduced the very extenfive manufacture of cotton, and added a lucrative and elegant branch of traffic to the commerce of Britain. The light and fanciful department of the cotton manufacture has become, in fome meafure, the ftaple manufacture of Scotland, whilft the more fubftantial and durable cotton fabrics have given to England a manufacture inferior, in importance and extent, only to the woollen trade.

At the prefent day, our fuperiority in point of quality is is univerfally acknowledged in the cotton manufacture ; but in thofe of filk, linen, and woollen, it is ftill difputed by other countries.

Loom.—Weaving is performed by the aid of a machine called a loom. The common loom for plain cloth is a very fimple machine ; but fome of the varieties which are ufed for weaving ornamental and figured cloth are very curious : ftill there are parts common to all. The principal of thefe are as follows.

1. The yarn-beam, which is a round wooden roller, on which is wound or rolled the warp, or yarns that are to form the length of the piece of cloth. 2. The cloth-beam is a fimilar roller, on which the cloth is rolled up when woven. The yarns of the warp are extended in parallel lines, between the yarn-roll and the cloth-roll, fo as to form a horizontal plane, or fheet, and are combined together by the crofs-threads, or weft. 3. The fhuttle, which has a hollow to contain a bobbin or pirn of the weft. 4. The heddles, which are threads with loops or eyes, through which the yarns of the warp pafs : the heddles are connected with the treadles, upon which the weaver places his feet, to draw down one fet of heddles and raife up another, fo as to open and feparate the warp into two divifions, and allow a paffage, called the fhed, for the fhuttle between them. 5. The reed, which is a frame containing a row of parallel fhreds of reeds or cane, and the yarns of the warp pafs between them, as it were between the teeth of a comb. 6. The reed is fixed in a frame, called the lay or lathe, which fwings upon centres of motion. The ufe of the reed and lay is to comb or pufh the threads of the weft clofe to each other, and make the cloth clofe and denfe.

The operation of weaving or working the loom for plain cloth confifts of three very fimple movements, *viz.* 1. Opening the fhed in the warp alternately, by preffing the two treadles with his feet in oppofite directions. 2. Driving or throwing the fhuttle through the fhed when opened. This is performed by the right-hand, when the fly-fhuttle is ufed, and by the right and left alternately, in the common operation, wherein the fhuttle is thrown from one hand and caught in the other. 3. Pulling forward the lay or batten to ftrike home the woof, and again pufhing it back nearly to the heddles. This is done by the left-hand with the fly-fhuttle, or by each hand fucceffively in the old way.

There are feveral different ways of fetting up a loom for weaving plain cloth ; but the principal parts are always made the fame. We fhall firft defcribe that which is ufed for weaving plain filks : it is fhewn in perfpective in *Plate* II. *Weaving.* In this A is the yarn-roll or beam, on which the thread to form the warp is regularly wound ; B, the cloth-beam, or breaft-roll, on which the finifhed cloth is wound up ; D E, the treadles, on which the weaver preffes his feet ; *d d*, *e e*, are the heddles, or harnefs. Thefe are each compofed of two fmall rods *d d* and *e e*, connected together by feveral threads, forming a fyftem of threads, which is called a heddle ; *e e* is another heddle, behind the former. In the middle of each thread of the heddle is a loop, through which a yarn of the warp is paffed, every other yarn going through the loops of the heddle *e e*, and the intermediate yarns paffing between the threads of that heddle, and afterwards through the eyes or loops of the other heddle *d d*.

The two heddles, *d d* and *e e*, are connected together by two fmall cords going over pulleys, fufpended from the top of the loom, fo that when one heddle is drawn down, the other will be raifed up. The heddles receive their motion from the levers or treadles D E, moved by the weaver's feet. The yarns of the warp being paffed alternately through the loops of the two heddles, by preffing down one treadle, as E, all the yarns belonging to the heddle *e e* are drawn down ; and by means of the cords and pulleys, the other heddle *d d*, with all the yarns belonging to it, are raifed up ; leaving a fpace, called the fhed, of about two inches between the yarns, for the paffage of the fhuttle.

F, G G, H, (*fig.* 2.) is a frame, called the batten or lay, fufpended by the bar F, from the upper rails of the loom, fo that it can fwing backwards and forwards, as on a centre of motion ; the bottom bar H is much broader than the rails G G, and projects before the plane about an inch and a half, forming a fhelf, called the fhuttle-race. The ends of the fhuttle-race H have boards nailed on each fide, to form two fhort troughs or boxes I I, in which pieces of wood or thick leather *k k*, called peckers or drivers, traverfe. The peckers are guided by two fmall wires, fixed at one end to the uprights G G, and at the other to the end-pieces of the troughs I I. Each pecker has a ftring faftened to it, tied to the handle *y*, which the weaver holds in his right-hand when at work, and with which he pulls, or rather fnatches, each pecker either to the right or left alternately.

R is the reed : it is a fmall frame, fixed upon a fhuttle-race H, containing a number of fmall pieces of fplit reeds or canes ; or elfe of pieces of flat wire, of fteel or brafs ; but the cane is moft common, although the frame is called the reed. When *fig.* 2. is in its place in the loom, the yarns of the warp pafs between the canes or dents of the reed. In *fig.* 2. the reed is reprefented without the top or piece which covers it, and which is called the lay-cap. It is a rail of wood with a longitudinal groove along its lowermoft fide, for the purpofe of fuftaining the upper edge of the reed. The lay-cap is that part of the machine on the middle of which the weaver lays hold with his left-hand when in the act of weaving.

The fhuttle (fee *Plate* I.) is a fmall piece of wood pointed at each end, from three to fix inches long. It has an oblong mortife in it, containing a fmall bobbin or pirn, on which is wound the yarn which is to form the weft ; and the end of this yarn runs through a fmall hole in the fhuttle, called the eye. The fhuttle has two little wheels on the under fide, by which it runs eafily upon the fhuttle-race H.

Operation.—The weaver fits on the feat M, (*fig.* 1.) which hangs by pivots at its ends, that it may adapt itfelf to the eafe of the weaver when he fits upon it. It is lifted out when the weaver gets into the loom, and he puts it in again after him. He leans lightly againft the cloth-roll B, and places his feet upon the treadles D E. In his right-hand he holds the handle *y* (*fig.* 2.), and by his left he lays hold of the rail, called the lay-cap, which croffes the batten or lay G G, and ferves to fupport the upper edge of the reed R. He commences the operations by preffing down one of the treadles with his foot : this depreffes one-half of the yarns of the warp, and raifes the other, as before-defcribed. The fhuttle is previoufly placed in one of the troughs I, againft the pecker K, belonging to that trough. By the handle of the pecker, with a fudden jerk, he drives the pecker againft the fhuttle, fo as to throw it acrofs the warp upon the fhuttle-race, into the other trough I, leaving the yarn of the weft, which was wound on the bobbin after it, in the fpace between the divided yarns. With his left-hand he pulls the lay towards him ; and, by means of the reed, the yarn of the weft, which before was lying loofe between the warp, is driven up towards the

the cloth-roll: the weaver now preffes down his other foot, which reverfes the operation, pulling down the heddle which was up before, and raifing that which before was depreffed. By the other pecker he then throws the fhuttle back again, leaving the woof after it between the yarns of the warp; and, by drawing up the batten, beats it clofe up to the thread before thrown.

In this manner the operation is continued until a few inches are woven; it is then wound upon the cloth-roll, by putting a fhort lever into a hole made in the roll, and turning it round, a click acting in the teeth of a ferrated wheel, prevents the return of the roll. At each end of the yarn-roll A, (*fig.* 1.) a cord is tied to the frame of the loom; the other ends of the cords have weights hanging to them. The rope caufes a friction, which prevents the roll from turning (unlefs the yarn is drawn by the cloth-beam), and always preferves a proper degree of tenfion in the yarn.

T T (*fig.* 1.) are two fmooth fticks (cotton-weavers have ufually three) put between the yarns, to preferve the leafe, and keep the threads or yarns from entangling.

In cotton-weaving thefe fticks or rods are kept at an uniform diftance from the heddles, either by tying them together, or by a fmall cord with a hook at one end, which lays hold of the front rod, and a weight at the other, which hang over the yarn-beam.

The cloth is kept extended during the operation of weaving, by means of two hard pieces of wood, called a templet, with fmall fharp points in their ends, which lay hold of the edges, or felvages, of the cloth.

Thefe pieces are connected by a cord paffing obliquely through holes, or notches, in each piece. By this cord they can be lengthened or fhortened, according to the breadth of the web.

They are kept flat after the cloth is ftretched by a fmall bar turning on a centre fixed in one of the pieces of wood. This ftretcher is called the templet. Silk-weavers ufually ftretch their cloth by means of two fmall fharp-pointed hooks faftened to the ends of two ftrings, with little weights at the other ends; and the ftrings are made to pafs over little pulleys in each fide of the loom, at a fuitable diftance from the felvages of the cloth.

The perfection of the work depends very much upon the previous operations which the yarn muft undergo. It is obvious that the yarns of the warp muft be ftretched with great parallelifm and equality of tenfion, fo that when the cloth is finifhed, every individual yarn may bear an equal fhare of any ftrain which tends to tear the cloth; hence great care muft be taken to ftretch the yarns of the warp to an equal length, and roll them with great regularity upon the yarn-roll. Thefe operations are called warping and beaming. Previous to warping, the yarn muft be prepared by fizing or ftarching, in order to cement all the loofe fibres, and render the yarn fmooth.

The fpinners of yarn, whether they employ machinery or not, ufually reel the yarn into fkeins and hanks of a determinate length; and the weight of thefe hanks, or the number which will weigh one pound, is the denomination for the finenefs of the yarn. (See *Manufacture of* COTTON.) In this ftate the yarn is bought by the weaver. The hanks of yarn are firft boiled in water; if it is linen-yarn a little foap and potafh are put into the water, and for cotton-yarn a fmall portion of flour is added, to render the thread firm. When the hanks are perfectly dry they are wound off upon bobbins, each thread having a feparate bobbin, and a certain length is wound upon each. This winding is performed by a very fimple hand-wheel to turn the bobbin rapidly round, the hanks of yarn being extended upon a reel, or over two fmall reels placed at a diftance afunder, which are called wifks.

Warping.—The object of this operation is to ftretch the whole number of parallel threads which are to form the warp of the cloth to an equal length. For this purpofe as many of the above bobbins are taken as will furnifh the quantity of threads which is required in the warp of the piece of cloth. The bobbins are ufually one-fourth or one-fixth of the number of threads required, and are mounted on fpindles in a frame, fo that the thread can draw off freely from them. All thefe threads are drawn off at once, fo as to combine them all into one clue, which will be ready for the warp. The ancient method was to draw out the warp at full length, and ftretch it in a field; and this is ftill practifed in India and China, but is fo very uncertain in our climate that it is feldom ufed. The prefent mode of warping is either by the warping-frame or warping-mill.

The warping-frame is a large wooden frame, which is fixed up againft a wall in a vertical pofition. The upright fides of the frame are pierced with holes to receive wooden pins, which project fufficiently to wind the clue of yarns for the warp round them.

The operator having the threads which are to compofe the warp wound on the bobbins before-mentioned, places thofe bobbins in a frame; then tying the ends of all the threads together, and attaching them to one of the pins at one end of the frame, he gathered all the threads in his hand into one clue; and permitting them to flip through his fingers, he walked to the other end, where he paffed the yarns over the pin fixed there, and then returned to the former end of the frame and paffed the warp over another pin, then went back again, and fo on till he formed the required length of the warp. This being done, he fecured the end of the warp by croffing it round the pin, and then he worked back and returned over all the fame fpace again, laying the threads over the fame pins, fo as to double the clue; and he repeated the doubling until the number of threads neceffary for the breadth was made up. The number of doublings would be according to the number of bobbins and threads which he took in his hand at once.

This method is ufed very much in France, particularly at Lyons: it is alfo ufed in Devonfhire. It is adapted to the weaving carried on in cottages, becaufe the frame is fixed clofe to the wall, and takes little or no room; but the warping-mill or reel is very fuperior, and is adopted in all improved manufactures where the warping is a feparate bufinefs, and is ufually done at the mill where the yarn is fpun.

The warping-mill is a large reel of a cylindrical form, or rather of a prifmatic form, being made with twelve, eighteen, or more fides. The reel is ufually about fix feet diameter and feven feet high: it is turned round on a vertical axis by a band, paffing from a grooved wheel which is turned by a winch, and is placed beneath the feat on which the warper fits. (See a figure of the warping-machine for filk *Plate Silk*, *fig.* 6.) The bobbins which contain the yarn are placed on a vertical rack fufpended from the ceiling, and the threads from them are all collected together and paffed between two fmall upright rollers in a clue, which is wound up by the reel when it is turned round. To guide the clue and diftribute it equally on the length of the reel, the above rollers are fixed on a piece of wood, which flides perpendicularly on an upright bar fixed at one fide of the reel. The fliding-piece is fufpended by a fmall cord, wrapped round a part of the perpendicular axis that rifes above the reel. The cord paffes over a pulley at the top of the upright bar, and goes down to the fliding-piece which carries the two rollers. When the reel turns round, the guide-rollers are flowly drawn up by the coiling of this cord round the axis; and the yarn is wound in a regular fpiral about the reel, until the length which the warp requires is wound upon it. When the full length of the yarn is wound on the reel, the clue of thread is croffed over pins projecting from the frame of the reel, and the mill is then turned the reverfe way, fo that the flider and guide-rollers defcend, and the yarn is laid downwards along the fame fpiral which it before afcended, fo as to double the clue of thread; and this doubling is repeated until the required number of threads is collected together in one clue upon the reel.

When the warp is thus completed, it is taken off the reel and wound upon a ftick into a ball; the croffings which diftinguifh the different returns or doublings of the fimple clue being firft properly fecured, as a means of dividing the warp into as many equal portions as is neceffary for the convenience of the weaver, in counting the threads in the fucceeding operation of beaming.

There is likewife another kind of divifion of the threads of the warp; this is called the leafe, and ferves to feparate all the threads which are to go through one of the heddles of the loom, from thofe which are to go through the other heddle. To effect this feparation, the bobbins from which the threads are drawn are arranged in two rows, and a thread is alternately drawn from the upper row and from the lower row. Then at the beginning and end of every doubling of the warp, the threads of one row of bobbins are croffed over the threads of the other row, and two pins are put into the croffings to retain them. Thefe pins are put into holes made in pieces of board fixed to the warping-reel. One of thefe boards at the top of the reel is fixed faft, but the other is moveable, and can be fixed at any part of the reel, according to the length of the warp.

In the moft improved warping-machines, the feparation is made by an apparatus called in Scotland the heck. It confifts of a row of fteel pins with eyes through one end of each for the threads to pafs through like large needles. Thefe are ftuck into two pieces of wood, by which they are fupported in a row near to the warping-reel. Every alternate pin in the row is faftened in one piece of wood, and the intermediate pins are faftened in the other piece, fo that by lifting up one piece of wood the pins and threads belonging to it will be raifed up, whilft the intermediate pins and threads are held down. This occafions the divifion of the threads, and a pin is put in to keep them fo divided. The other piece of wood is then lifted up, which occafions all the threads to be croffed; that is, every thread forms a crofs over that which is adjacent to it. A fecond pin is then put in, and before the warp is taken off from the reel, this croffing is fecured by a ftring.

Beaming.—When the weaver receives his warp in a large ball or bundle, he proceeds to roll it up regularly upon the yarn-roller of his loom: this is called beaming. For this purpofe he employs an inftrument called a feparator, or ravel, which confifts of a number of fhreds of cane, faftened together, and fixed to a rail of wood, like the teeth of a long comb; the threads are intended to be put into the fpaces between thefe teeth, fo as to ftretch the warp to its proper breadth.

Ravels are fomewhat like reeds, but much coarfer, and are alfo of different dimenfions. One proper for the purpofe being found, one of the fmall divifions of the warp is placed in every interval between two of the teeth. The upper part of the ravel, called the cape, is then put on, to fecure the threads from getting out between the teeth, and the operation of winding the warp upon the beam commences. In broad works, two perfons are employed to hold the ravel, which ferves to guide the threads of the warp, and to fpread them regularly upon the beam; one or two other perfons keep the threads at a proper degree of tenfion, and one more turns the beam upon its centre.

The knottings which fecure the croffings or doublings made in warping, are very ufeful to the weaver in beaming, to afcertain the number of threads, and to diftribute them with regularity. He cuts the knotting before he can put the warp in the ravel, but he ftill keeps them diftinct by a fmall cord.

The French weavers ufe a fmall reel, upon which they wind the warp from the ball, and then from this reel they draw off the warp through the ravel, by winding up the beam. The reel is loaded with a weight, to make a regular friction, and draw the warp with a regular tenfion.

Drawing.—The warp being regularly wound upon the beam, the weaver muft pafs every yarn through its appropriate eye or loop in the heddles: this operation is called drawing. Two rods are firft inferted into the leafe formed by the pins in the warping-mill, and the ends of thefe rods are tied together; the twine by which the leafe was fecured is then cut away, and the warp ftretched to its proper breadth. The yarn-beam is fufpended by cords behind the heddles, fomewhat higher, fo that the warp hangs down perpendicularly. The weaver places himfelf in front of the heddles, and opens the eye of each heddle in fucceffion; and it is the bufinefs of another perfon, placed behind, to felect every thread in its order, and deliver it to be drawn through the open eyes of the heddles. The fucceffion in which the threads are to be delivered is eafily afcertained by the leafe-rods, as every thread croffes that next to it. The warp, after paffing through the heddles, is drawn through the reed by an inftrument called a fley, or reed-hook, and two threads are taken through every interval in the reed.

The leafe-rods being paffed through the intervals which form the leafe, every thread will be found to pafs over the firft rod, and under the fecond; the next thread paffes under the firft, and over the fecond, and fo on alternately. By this contrivance every thread is kept diftinct from that on either fide of it, and if broken, its true fituation in the warp may be eafily and quickly found. This is of fuch importance, that too much care cannot be taken to preferve the accuracy of the leafe. There is likewife a third rod, which divides the warp into what is ufually called *fplitfuls*, for two threads alternately pafs over and under it; and thefe two threads alfo pafs through the fame interval betwixt the fplits of the reed.

Thefe operations being finifhed, the cords or mounting which move the heddles are applied; the reed is placed in the lay, or batten, and the warp is knotted together into fmall portions, which are tied to a fhaft, and connected by cords to the cloth-beam, and the yarns are ftretched ready to begin the weaving.

Manner of Weaving.—The operations of weaving are fimple, and foon learned, but require much practice to perform them with dexterity.

In preffing down the treadles of a loom, moft beginners are apt to apply the weight or force of the foot much too fuddenly. The bad confequences of this are particularly felt in weaving fine or weak cotton-yarn; for the body of the warp muft fuftain a ftrefs nearly equal to the force with which the weaver's foot is applied to the treadle. The art of fpinning has not yet been brought to fuch perfection as to make every thread capable of bearing its fair proportion of this ftrefs. Befides this, every individual thread is fubjected to all the friction occafioned by the heddles and fplits of the reed, between which the threads pafs, and with which

which they are generally in contraft when rifing and finking. A fudden preffure of the foot on the treadle muft caufe a proportional increafe of the ftrefs upon the warp, and alfo of the friction. As it is impoffible to make every thread equally ftrong and equally tight, thofe which are the weakeft, or the tighteft, muft bear much more than their equal proportion of the ftrefs, and are broken very frequently. Even with the greateft attention, more time is loft in tying and replacing them, than would have been fufficient for weaving a very confiderable quantity into cloth.

If the weaver, from inattention, continues the operation after one or more warp-threads are broken, the confequence is ftill worfe. The broken thread cannot retain its parallel fituation to the reft, but croffing over or between thofe neareft to it, either breaks them alfo, or interrupts the paffage of the fhuttle: it frequently does both.

In every kind of weaving, and efpecially in thin wiry fabrics, much of the beauty of the cloths depends upon the weft being well ftretched. If the motion given to the fhuttle be too rapid, it is very apt to recoil, and thus to flacken the thread. It has alfo a greater tendency, either to break the woof altogether, or to unwind it from the pirn or bobbin of the fhuttle in doubles, which, if not picked out, would deftroy the regularity of the fabric. The weft of muflins and thin cotton goods is generally woven into the cloth in a wet ftate.

This tends to lay the ends of the fibres of cotton fmooth and parallel, and its effect is fimilar to that of dreffing of the warp.

The perfon who winds the weft upon the pirn ought to be very careful that it be well formed, fo as to unwind freely. The beft fhape for thofe ufed in the fly-fhuttle is that of a cone; and the thread ought to traverfe freely round the cone, in the form of a fpiral, or fcrew, during the operation of winding.

The fame wheel which is ufed for winding the warp upon the bobbins preparatory to warping, is alfo fit for winding the weft on the pirn. It only requires a fpindle of a different fhape, with a fcrew at one end, upon which the pirn, or bobbin of the fhuttle, can be fixed. The wheel is fo conftructed, that the fpindles may be eafily fhifted, to adapt it for either purpofe.

The reeds are formed of a number of fhort pieces of reed or cane, or of brafs wire, faftened parallel to each other between two fticks, and cemented with pitch. This frame is enclofed between two pieces of the frame of the lay, one of which is made wide, to form the fhuttle-race; the other piece, which is the lay-cap, extends acrofs the frame, but is fitted fo that it can be eafily removed to take away the reeds, and fubftitute a finer or coarfer fort, as the nature of the goods to be woven require. The manufacture of reeds, both of cane and of fteel, is a feparate trade. Thefe are fully defcribed in Les Arts et Metiers, vols. 9 and 15.

To render the fabric of the cloth uniform in thicknefs, the lay or batten muft be brought forward with the fame force every time.

In weaving fome kinds of foft or light goods, the reed is not fixed faft to the lay-cap, but is held in its place by a long thin piece of wood, which is elaftic, and yields or fprings when the weft is beaten up. In fome cafes the reed is fuftained by a double woollen cord, ftretched acrofs the lay, juft beneath the lay-cap, and twifted; this bears the reed, and is very elaftic, but can be rendered more ftiff by twifting the two cords tighter.

In the common operation of weaving, a regular force of the ftroke for beating up the weft muft be acquired by practice. It is, however, of confequence to the weaver to mount or prepare his loom in fuch a manner, that the range or fwing of the lay may be in proportion to the thicknefs of his cloth. As the lay fwings backwards and forwards, upon centres placed above, its motion is fimilar to that of a pendulum. Now the greater the arc, or range through which the lay paffes, the greater will be its effect in driving home the weft ftrongly, and the thicker the fabric of cloth will be, as far as that depends upon the clofenefs of the weft. For this reafon, in weaving coarfe and heavy goods, the heddles ought to be hung at a greater diftance from the place where the weft is ftruck up, and confequently where the cloth begins to be formed, than would be proper in light work. The line of the laft wrought fhot of weft is called by the weavers the fell. The pivots upon which the lay vibrates ought, in general, to be fo placed, that the reed will be exactly in the middle, between the fell and the heddles, when the lay hangs perpendicularly. As the fell is conftantly varying in its fituation during the operation, it will be proper to take its medium; that is, the place where the fell will be when half as much is woven as can be done without taking it up on the cloth-roll, and drawing frefh yarn from the yarn-roll.

The periods for taking up the cloth ought always to be fhort in weaving light goods; for the lefs that the extremes of the fell vary from the medium, the more regular will be the arc or fwing of the lay. Mr. James Hall had a patent, in 1803, for a method of perpetually winding up the cloth-beam, fo as to take away the cloth as faft as it was woven, or fhoot by fhoot. This was effected in a fimple manner by a ratchet-wheel fixed on the end of the cloth-beam, and a proper catch to move it round one tooth at a time: the catch was actuated by the motion of the lay. A fimilar method is ufed in ribband-weaving.

The variations in the ftructure of looms from that which we have defcribed, are not material. The framing is varied in almoft every different kind of loom, and ought always to be fuitable in ftrength to the kind of cloth which is to be woven. The loom ufed for filk is very flight in all its parts; but for carpet and fail-cloth it muft be very ftrong.

In looms for heavy goods, the cloth-beam is not placed at the breaft of the weaver, as it is fo large that it would impede his working; the cloth is therefore paffed over a fixed bar in the place of the cloth-beam reprefented, and the beam is placed lower down, and near the weaver's feet, out of the way of his knees. The heddles are connected by levers, in fome looms, inftead of pulleys; but the effect is always the fame; *viz.* to make one heddle afcend when the other defcends. For weaving fine goods, the heddles would be inconveniently clofe together, if all the yarns went through two heddles; hence they ufe four heddles inftead of two; but their action is juft the fame, becaufe they are connected together in pairs, and when one pair rifes the other pair finks. Many looms are ftill made without the fly-fhuttle; and in that cafe the fhuttle is merely thrown from one hand to the other, and then thrown back again: this obliges the weaver to change his hands continually, and the operation is more complicated. For wide cloths, which are more than a man can reach acrofs, two perfons were always employed before the fly-fhuttle was introduced, which is only within a few years; but by its affiftance one perfon can weave the greateft breadths. The fly-fhuttle is the beft for all kinds of work, and its conftruction is fo fimple that no other ought to be ufed.

Treatment of different Kinds of Yarns. — The manner of weaving all kinds of plain cloth is much the fame, whether it is wool, filk, flax, or cotton; except that the two latter

 require

require what is called dreffing. Silk and woollen warps require little preparation after being put into the loom, except to clear the yarn occafionally with a comb, to remove knots or lumps which might catch in paffing through the reed ; the comb detects fuch lumps, and they are removed with the affiftance of a pair of fciffors. Flax and cotton, but particularly the latter, require the warp to be dreffed with fome glutinous matter, to cement the fibres, and lay them clofe. This is applied in a fluid ftate, and as the weaving does not proceed well after it is fuffered to dry, the warp is dreffed with a brufh when in the loom, a fmall quantity at a time, immediately before it is woven.

Dreffing.—The ufe of dreffing is to give to yarn fufficient ftrength or tenacity, to enable it to bear the operation of weaving into cloth. By laying fmooth all the ends of the fibres of the raw materials, from which the yarn is fpun, it tends both to diminifh the friction during the procefs, and to render the cloth fmooth and gloffy when finifhed. The dreffing in common ufe is fimply a mucilage of vegetable matter boiled to a confiftency in water. Wheat-flour, boiled to a pafte like that ufed by book-binders, or fometimes potatoes, are commonly employed. Thefe anfwer fufficiently well in giving to the yarn both the fmoothnefs and tenacity required ; but the great objection to them is, that they are too eafily affected by the action of the atmofphere. When dreffed yarn is allowed to ftand expofed to the air for any confiderable time, before being woven into cloth, it becomes hard, brittle, and comparatively inflexible. It is then tedious and troublefome to weave, and the cloth is rough, wiry, and uneven. This is chiefly remarked in dry weather, when the weavers of fine cloth find it neceffary to work up their yarn as fpeedily as poffible, after it is dreffed. To counteract this inconveniency, herring or beef brine, and other faline fubftances which attract moifture, are fometimes mixed in fmall quantities with the dreffing : but this has not been completely and generally fuccefsful ; probably, becaufe the proportions have not been fufficiently attended to ; for a fuperabundance of moifture is equally prejudicial with a deficiency. The variations of the moifture of the air are fo great and frequent, that it is impoffible to fix any univerfal rule for the quantity of falt to be mixed. Some weavers put butter-milk in the pafte.

To apply the dreffing, the weaver muft fufpend the operation of weaving, whenever he has worked up that quantity of warp which he has dreffed, or within two or three inches ; he then quits his feat, and applies the comb to clear away knots and burs ; next pufhes back the leafe-rods towards the yarn-roll, one at a time, and if they flide freely between the yarns, it fhews they are clear from knots ; he then brufhes the yarn with the pafte by two brufhes, holding one in each hand. The fuperfluous humidity is afterwards dried by fanning the yarns with a large fan, and then a fmall quantity of greafe is brufhed over the yarn ; the leafe-rods are returned to their proper pofition, and the weaving is refumed.

Dreffing is of the firft importance in weaving warps fpun from flax or cotton ; for it is impoffible to produce work of a good quality, unlefs care be ufed in dreffing the warp.

The fame practice, when ufed upon filk, has a very deftructive tendency : it injures the colours of the filk when ufed, as it is fometimes very improperly, by the weavers of white fatin. The injury done to the work is irreparable. In cotton, the operation of dreffing is indifpenfable ; but in filk, this is by no means the cafe.

The preparation of pafte or fize for warp, has been the fubject of feveral patents. Mr. Foden, in 1799, recommends a quantity of calcined gypfum, or plafter of Paris, to be reduced to a very fine powder, and then mixed with alum, fugar, and the farina or ftarch of potatoes, or any other vegetable farina. This powder, when mixed well with cold water, forms a foft pafte, to which boiling water is to be added, and the mixture thoroughly ftirred till it becomes fufficiently gelatinous for ufe.

Another fize, for which Mr. Wilks had a patent in 1801, is prepared as follows :—The ftarch or flour is to be extracted from any kind of potatoes which are mealy when boiled, by grating them while raw (but wafhed clean) into a tub of water. The water, thus impregnated with the grated potatoes, is run through a fieve or ftrainer, which will retain the coarfer and fibrous parts of the potatoes, but admit the finer particles, conftituting the ftarch or flour, to pafs with the water into a veffel beneath the fieve or ftrainer. This water muft remain in the veffel feveral hours undifturbed, to permit the ftarch to fubfide to the bottom ; then the water is poured off, and the ftarch fo obtained is put into frefh water, and paffed through a finer fieve into another tub, where the ftarch is left to fubfide to the bottom as before, and the water is again poured off.

About two-thirds the quantity of potatoes, which furnifhed the ftarch, are alfo to be boiled without peeling, fo as to make them mealy when boiled ; they are then mafhed, and diluted with water, fo that they will pafs through a fieve into a boiler. In this the mafhed potatoes are heated till they almoft boil; and the ftarch from the grated potatoes is then to be added, and the whole boiled and ftirred for 20 minutes, when it will become pafte proper for ufe. It fhould be fpread in a flat open veffel to cool.

Improved Syftem of Weaving by Machinery.—In our article Cotton we mentioned that weaving-looms, worked by mechanical power, were then coming into ufe : fince the time that article was printed thefe have made great advances ; but to ufe them with advantage, the preparatory proceffes of warping and dreffing muft be conducted in a particular manner. Many attempts have been made to diminifh the number of operations through which the yarn muft pafs by combining feveral together. Mr. Stuart had a patent in 1800 for fizing or ftarching cotton-yarn whilft in the cop, fo that it would be ready to warp at once. Mr. Marfland had a patent in 1805 for the fame object : his plan was to expofe the cops of cotton to the action of the hot ftarch in an exhaufted receiver ; the preffure of the atmofphere being thus removed, the fize penetrated readily to the centre. It was found difficult to dry the cop perfectly, and the threads were fometimes fo glued together as to render the winding off difficult.

Another plan has therefore been introduced both for flax and cotton : this is to wind off the yarn from the cop or bobbin in which it is fpun, and gather it upon the bobbins ready for the warping ; by this manner the reeling is faved. A fmall quantity of ftarch is applied to the yarn during the operation, by caufing it to pafs over a horizontal wooden cylinder, which revolves on its axis in a trough filled with fluid ftarch. The threads, in paffing from the cop to the bobbin, are drawn over the upper furface of the cylinder, and receive the ftarch with which it is covered. The winding machine for this actuated a great number of bobbins at once ; the warping is then conducted, as we have before defcribed, and the dreffing is performed in the loom whilft weaving, that is, if woven by hand ; but for the power-loom it is dreffed previoufly to placing it in the loom.

Dreffing Machines.—Mr. Johnfon, of Stockport, had a patent, in 1804, for a method of dreffing whole webs of warp at once,

once, by a machine. The yarns were wound off from the bobbins or cops of the ſpinning machines upon beams or rollers. Several of theſe rollers were placed parallel to each other, in an horizontal direction, at the oppoſite ends of the machine, from three to ſix at each end; and the yarns from them were all combined together in one web, which was received and rolled up on the yarn-beam of the loom placed in the middle of the machine, and raiſed up conſiderably above the other rollers, ſo that the yarns proceeded from both ends of the machine towards the middle. In their paſſage they paſſed through ſeveral reeds to keep them ſeparate, and were ſupplied with the paſte by paſſing over two cylinders revolving in a trough of fluid paſte. This paſte was dreſſed or worked into the yarn by means of two bruſhes, of a length equal to the breadth of the web; one of the bruſhes acted upon the upper ſide of the yarns, and the other on the lower ſide. A ſimilar pair of bruſhes were applied at both ends; each bruſh had a motion given to it by means of cranks, exactly ſimilar to the movement with which the weaver bruſhes the yarn in the loom. Near the yarn-rolls a fan was placed, like that uſed in a winnowing machine, which blew a current of air through the yarns of the warp to dry them before they were rolled up by the beam. To preſerve the leaſe, the yarns were conducted through a pair of heddles, ſimilar to thoſe of the loom, but they remained ſlack to avoid friction. The machine was moved by the mill with a conſtant and regular movement.

When a warp is thus warped, beamed, and dreſſed, the yarn-beam is carried to a loom, on which the yarn is juſt exhauſted, and is made to replace the empty yarn-roll. The ends of the yarn are joined to the old yarns by twiſting, and are thus drawn through the heddles and reed, ſo that the weaving can be reſumed with very little loſs of time, and the weaver can proceed with his work without any interruption for dreſſing. The principal objection to the above machine is the friction which the yarns muſt undergo in bruſhing, and in paſſing through ſo many reeds: it was, however, practiſed in a large work at Stockport; but the weaving was performed by hand.

Another dreſſing machine was invented by Mr. M'Adam, and he obtained a patent in 1806: it is practiſed by Mr. Monteith, at Pollockſhaws near Glaſgow. This machine is very much like the former in its manner of action. Inſtead of uſing three, four, or ſix beams at each end of the machine, there are only two beams, each containing one half the number of yarns for the intended warp. The ſtarch is ſupplied in the ſame manner as the former, or ſometimes by making the two yarn-beams themſelves turn in a trough of ſtarch without employing a ſeparate cylinder. The bruſhing is performed in a more ſimple and effectual manner by uſing cylindrical bruſhes, which revolve with a regular motion, two of them are applied on the upper ſide of the warp, and two on the lower ſide; alſo four fanners are applied to dry the warp inſtead of one. The yarns were conducted between reeds and through heddles, like the firſt machine; and hence the ſame objection of friction applies to both.

Mr. Duncan, in his Eſſays on Weaving, deſcribes another method of dreſſing warps, which is practiſed by Mr. Dunlop at Barrowfield. In this the yarn is warped and beamed in the uſual manner, upon a yarn-roll: from this the yarn is unwound, and taken up upon another beam; and in its paſſage from one to the other it is extended, ſo that the picking and clearing can be performed in the uſual way by hand with a comb and ſciſſors, and the dreſſing is applied with bruſhes in the uſual way: beneath the warp a fan is placed, to blow a current of air up through the yarns and dry them. In this machine all the operations, except the fanning, are performed by hand; the advantage, therefore, conſiſts only in the diviſion of labour, by making the dreſſing and weaving diſtinct operations.

Power-Looms.—In the article COTTON we have mentioned Mr. Dolignon's claim to the invention of weaving by mechanical power.

The original project, we believe, was by M. De Gennes, and is publiſhed in the Philoſophical Tranſactions for 1768, N° 140. See alſo Lowthorp's Abridgment, vol. i. p. 499. This is a very ingenious invention. The fly-ſhuttle was not then invented, and he ſupplied the want of it by a contrivance which held the ſhuttle as it were in a hand by fingers; this carried it half way through the cloth, and then it was transferred to another ſimilar hand, which drew it through the remainder. By this means there was a greater certainty than in throwing the ſhuttle from one ſide to the other, becauſe the ſhuttle always continued engaged with the mechaniſm: the whole machine is ingenious and worthy of notice.

M. Vaucanſon, the celebrated French mechaniſt, made a machine for weaving ten ribbands at a time, which was worked by a circular motion given by the workman; and it might, therefore, have been worked by mechanical power. This is deſcribed in the Encyclopede Methodique in great detail, with ten folding plates, and is an ingenious machine.

We believe both theſe inventions were prior to that of Mr. Dolignon; and alſo that the merit of inventing the machine, and firſt reducing it to practice, is due to Mr. Auſtin, of Glaſgow. In this gentleman's memoir to the Society of Arts, he ſtates, that his firſt attempt was made in the year 1789, when he entered a caveat for a patent, but did not apply for it further; ſince that time he made many improvements upon the original plan. In 1796 a report in its favour was made by the Chamber of Commerce and Manufactures at Glaſgow; and in 1798, a loom was ſet at work at Mr. J. Monteith's ſpinning works, at Pollockſhaws near Glaſgow, which anſwered the purpoſe ſo well, that a building was erected by Mr. Monteith for containing thirty looms, and afterwards another to hold about two hundred.

Mr. Auſtin's Power-Loom.—The model from which our drawing (*Plate* I. *Weaving*) was made, is depoſited in the Society of Arts: it is an improvement upon the looms conſtructed for Mr. Monteith.

The drawing *Plate* I. is a perſpective view, exhibiting the whole loom at one glance: it is viewed from the back rather than from the front.

A is a ſquare iron axis extending through the whole length of the machine; to this the power of the firſt mover is applied by a cog-wheel B, of thirty-ſix teeth, turned by a pinion of twelve leaves fixed to the axis of the fly-wheel D. A handle is fixed to one of the arms of the wheel to give motion to the model; but in the large machine a live and dead pulley are adapted to the axis of the fly-wheel; and by means of an endleſs ſtrap, the power is communicated from any convenient part of the mill in which a great number of looms are placed together.

The axis A has ſeveral eccentric wheels or camms fixed upon it; as theſe revolve they give motion to a number of levers or treadles, by which all the uſual operations of the loom are performed at the proper intervals: theſe are,

Firſt, To ſeparate the two parts of the yarns of the warp, as ſhewn at G, and admit of the paſſage of the ſhuttle.

Secondly, To throw the ſhuttle, in order to lay the weft or croſs-threads of the cloth.

Thirdly, To move the lay 7.8, and return it; ſo that the reed *g* will beat up the weft cloſe to the fell, or preceding

ceding ſhoot of the weft: this renders the cloth of uniform texture.

Fourthly, To wind up the cloth upon the cloth-roll, as faſt as it is formed by the preceding operations.

The yarns, which are to form the warp of the cloth, are warped in the manner before deſcribed upon the yarn-roll F; and from thence they are extended horizontally to the cloth-roll E, of which only a ſmall part can be ſeen at the oppoſite ſide of the loom: in their way the yarns paſs through the eyes of the heddles G H, which effect the firſt operation above-mentioned. Each heddle is compoſed of a number of perpendicular threads equal to half the number of yarns in the warp; theſe are ſtretched between two ſmall rods *a a* and *b b*, and in the middle of each thread is a ſmall eye, through which a yarn of the warp is paſſed; thus, the firſt yarn of the warp is paſſed through the eye of the heddle G, but has no connection with the heddle H, becauſe it paſſes between its threads. The ſecond yarn is put through the eye of the heddle H, but has no connection with G; the third yarn is attached to H; the fourth to G, and ſo on alternately throughout the whole number. By this means if one heddle is raiſed up, and the other at the ſame time depreſſed, a ſeparation of the yarns will take place as ſhewn at G, every other yarn being raiſed up, whilſt the intermediate ones are drawn down, ſo as to admit the paſſage of the ſhuttle and weft between them.

The two heddles are moved by camms upon the main axis A; and they are ſo connected by ſhort levers I I, which are ſuſpended from the upper part of the loom, that when one heddle is pulled down, the other will be drawn up at the ſame time, becauſe they are ſuſpended from the oppoſite ends of the levers I.

The camms on the main axis for the heddles are marked L; the two are exactly ſimilar, but are reverſed upon the axis; that is, the ſhorteſt radius of one is placed on the ſame ſide with the longeſt of the other. They act upon two levers, which are the ſame as the treadles in a common loom; only one of theſe treadles or levers (*viz.* that which belongs to the camm L) can be ſeen at M, the other lever being concealed from the view; both levers move on centres at *n* between the ſmall uprights *d d*; the other ends ſlide freely up and down between ſimilar uprights at the oppoſite ſide of the frame, which cannot be ſeen in the figure; the levers are connected with the heddles, which being ſuſpended from the levers I as before mentioned, the levers will therefore move in contrary directions, the one riſing when the other is preſſed down by the action of the camm on the axis A.

The connection between the levers or treadles M and the heddles G H, is made by cords communicating with two counter-levers O P, which are centered in uprights ſupported by the frame at the ends of the machine. The counter-levers O P are connected with rods *h* and *k*, and theſe by a double cord are attached to the heddle-rods *a a* and *b b*.

This machinery which we have now deſcribed effects the ſeparation of the warp thus: when the axis A turns round, every revolution of its camms L will cauſe two ſeparations of the warp, and each one in a different manner, for thoſe yarns which are raiſed up at one time are drawn down the next.

The ſecond operation, *viz.* throwing the ſhuttle, is performed by two camms R S, which are reverſed to each other upon the axis A. They act upon two levers, only one of which can be ſeen at T; they are placed beneath the camms. The ſhuttle requires to be projected with a ſudden jerk; theſe levers are therefore centered at *d* on the ſame pin as the levers M and N, but the other ends preſs down ſmaller levers W, which are centered at the oppoſite end of the frame, and lie beneath the long levers. The extreme ends of theſe ſmaller levers are connected by a ſtrap *f* with a ſegment of a wheel, which has a long ſtem of whalebone Y faſtened to it; and by means of two ſtrings, one of which is ſhewn at *q* 4, it moves the peckers or drivers *z* upon the wires 3, 3, and throws the ſhuttle. The ſhuttle, which is ſhewn in a ſeparate figure, is pointed at each end, and ſhod with iron: it contains two ſmall rollers 31 31 upon which it runs; and as they project through both ſurfaces, it will run either way upwards, or either end firſt. In the centre of the ſhuttle is an oblong mortiſe, containing the pirn or bobbin 33, on which the thread for the weft of the cloth is wound; and the end of the weft marked 34, is brought through a ſmall glaſs tube, called the eye of the ſhuttle.

The action of the mechaniſm for throwing the ſhuttle is as follows:—By the revolution of the camm R, the long lever beneath it is depreſſed, and at the ſame time the extremity of the ſhorter lever W deſcends, but with an increaſed velocity; this by means of the ſtrap *f* turns the ſegment of a wheel on its centre, and its tail Y ſnatches the ſtring *q* 4 of the pecker *z*, and makes it ſtrike againſt the ſhuttle with ſuch a velocity, as to drive the ſhuttle out of the trough Q, acroſs the ſhuttle-race, into the oppoſite trough, where it will puſh back the pecker, and remain at reſt in the trough ready for the next ſtroke: by this ſtroke it will be returned back again with an action ſimilar to the laſt, but occaſioned by the other camm S, and its correſponding levers.

The threads of the warp, which are loweſt when the ſeparation takes place, are drawn down by their heddle G or H, ſo as to lie cloſe upon the ſhuttle-race, and cauſe no obſtruction to the paſſage of the ſhuttle. To facilitate this, the ſhuttle muſt be very ſmooth on the ſurface, that it may not catch the threads and be ſtopped. The ſhuttle-race is inclined towards the reed, both that the yarn may lie flat upon it, and that the ſhuttle may not be liable to run off its race; for as it leaves the weft, which is drawn off from its bobbin, in the ſpace between the divided yarns of the warp, it might be drawn off its race ſideways, without this precaution. In this manner the ſecond operation is performed.

The third motion is that of the reed *g*: this is fixed cloſe behind the ſhuttle-race, and is a frame containing a great number of parallel ſlips of reed or cane; between theſe the yarns of the warp paſs, and when the whole frame of reeds is moved towards the cloth-roll E, they will act in the manner of a comb, to beat up the thread of the weft, which is left by the ſhuttle lying looſely between the yarns of the warp.

For this purpoſe, the ſhuttle-race, reeds, peckers, &c. and their ſtem Y, with its ſegment of a wheel, are all placed on a frame which moves on hinges at the lower ends, 8, of the two upright ſides 7 8. This frame, which is termed the lay, is drawn backwards by means of ſtraps 10, 10, rolled upon pulleys 11, faſtened upon the axis 12; upon this ſame axis are two other ſmaller pulleys, upon which two ſtraps, 13, are rolled, to connect with the long levers 14, which are moved by the camms 15, upon the axis A.

The long levers, 14, are centered at one end of the frame, and the pulleys on the axis, 12, being of different diameters, the motion of the reeds will be performed very quickly. To move the lay in a contrary direction, and give the ſtroke to beat up the weft, two large weights, like *m*, are ſuſpended by ſtraps from pulleys on an horizontal axis, which carries two larger wheels *x*; on theſe, ſtraps are wound, to communicate

nicate with the upright fides, 7 8, of the lay, and draw it forwards.

When the loom is acting very quickly, thefe weights would not act with fufficient fharpnefs to throw the reeds againft the threads of the weft with the proper force.

The weights are therefore connected by fpiral wire-fprings, with long levers 16, which are preffed down by a camm or rather tappet 17, fixed on the main axis. Thefe levers act before the lay is at liberty to move, and by preffing down the levers extend the fprings; confequently, as foon as the camm 15 fuffers the lever 14 to rife, the fprings act inftantaneoufly, to throw the lay and the reeds forwards to beat up the weft.

The inftant after the blow has been given, the lay is drawn back again by the camm 15, and returned into the vertical pofition, in which fituation the lay muft continue whilft the fhuttle is thrown; for this purpofe, the outfides of the camms 15 are portions of circles. This completes the third motion.

As faft as the cloth is fabricated by the foregoing movements, it is gathered upon the cloth-roll E. This is turned flowly round by a fmall crank 19, on the extreme end of the main axis A; the crank moves a fmall rod 20 up and down, in order to turn a fmall ratchet-wheel round one tooth each revolution of the main axis; the return of the ratchet is prevented by a click. On the axis 21 of the ratchet-wheel is an endlefs fcrew, to engage the teeth of a cog-wheel upon the end of the cloth-roll, and give it a flow motion.

The yarn is kept to a proper degree of tenfion by the friction occafioned by a line 28 paffed twice round the yarn-roll, one end being faftened to the frame, and the other to a lever 30, loaded with a weight.

The framing of the loom is too evident to need defcription. In the conftruction of the machine, the principal circumftance to be attended to, is the figure of the different camms; alfo that they are placed upon the axis A in the proper pofitions relative to each other. Thefe cautions will enfure the accurate performance of the machine.

The camm R or S, for throwing the fhuttle, is formed with a fudden beak or projection, that it may ftrike the levers T down inftantaneoufly, and throw the fhuttle; from this beak the curve continues circular for fome diftance, that the lever may be held ftationary; the remainder of the camm gradually diminifhes its radius like a fpiral, and quits the lever, in order to leave it at liberty to rife up when its correfponding lever is forced down by the beak of the other fimilar camm S.

The camm L for the heddles is made circular where it is to come in contact with the lever, and which is all the time it is in action. This occafions the levers and heddles to be ftationary whilft the fhuttle is thrown.

The inventor ftates that, by the addition of fome fimple improvements, his looms have the following advantages; *viz.* 300 or 400 of them may be worked by one water-wheel, or fteam-engine, all of which will weave cloth in a fuperior manner to what can be done in the common way. They will go at the rate of 60 fhoots in a minute, making two yards height of what is called a nine hundred web in an hour. They will keep regular time in working, ftop and begin again, as quick as a ftop-watch. They will keep conftantly going, except at the time of fhifting two fhuttles, when the weft on the pirns is exhaufted. In general, no knots need be tied, and never more than one in place of two, which are requifite in the common way when a thread breaks. In cafe the fhuttle ftops in the fhed, the lay will not come forwards, and the loom will inftantly ftop working. They will weave proportionally flower or quicker, according to the breadth and quality of the web, which may be the broadeft now made. They may be mounted with a harnefs or fpot-heddles, to weave any pattern, twilled, ftriped, &c.

There is but one clofe fhed, the fame in both breadths, and the ftrain of the working has no effect on the yarn behind the rods.

The fell and temples always keep the fame proper diftance. There is no time loft in looming, or cutting out the cloth; but it is done while the loom is working, after the firft time.

The weft is well ftretched, and exactly even to the fabric required.

Every piece of cloth is meafured to a ftraw's breadth, and marked where to be cut at any given length.

The loom will work backwards in cafe of any accident, or of one or more fhoots miffing. Every thread is as regular on the yarn-beam as in the cloth, having no more than two threads in the runner. If a thread fhould appear too coarfe or fine in the web, it can be changed, or any ftripe altered at pleafure. They will weave the fineft yarn more tenderly and regularly than any weaver can do with his hands and feet.

When a thread, either of warp or weft, breaks in it, the loom will inftantly ftop, without ftopping any other loom, and will give warning by the ringing of a bell. A loom of this kind occupies only the fame fpace as a common loom; the expence of it will be about half more; but this additional expence is more than compenfated by the various additional machinery employed for preparing the yarn for the common loom, and which this loom renders entirely unneceffary.

The preparatory proceffes of reeling, winding, warping, beaming, and looming, and the interruptions occafioned by combing, dreffing, fanning, greafing, drawing bores, fhifting heddles, rods, and temples, which is nearly one-half of the weaver's work, do not happen in thefe looms. The general wafte accompanying the above operations is ftated at about fix *per cent.* of the value of the yarn, all which occur in the operations of the common loom. The power-loom, without further trouble, performs every operation after the fpinning, till the making of the cloth is accomplifhed, by which a faving is effected of about 20 *per cent.* of the yarn.

The heddles, reed, and brufhes, will wear longer than ufual, from the regularity of their motion. More than one-half of workmanfhip will be faved; one weaver and a boy being quite fufficient to manage five looms of coarfe work, and three or four in fine work.

Mr. Miller's Power-Loom.—A patent was taken out for this in 1796. It is fo much like Mr. Auftin's in its general principle, that it is unneceffary to enter into the defcription. The motions are all produced by camms fixed on a horizontal axis, and operate upon a number of horizontal levers, difpofed beneath the loom, in the fituation of treadles: in other refpects the arrangement of the parts is very different. This is fometimes called the wiper-loom, wiper being a different name for a camm.

Crank Loom by Power.—In this the treadles are actuated by cranks, inftead of camms or wipers. The reciprocating motion produced by a crank is not uniform, but accelerated at one time, and retarded at another. This is an advantage in fome of the operations of a loom. It is true, that, by means of wipers, any required law of acceleration may be produced; but in a crank, the acceleration muft proceed according to one law. The fuperiority of cranks arifes from

from the circumftance, that they will communicate motion in both directions; whereas a camm will only pufh a lever in one direction, and the return of the motion muft be made by a fpring or counterweight. Now, if this counterweight is too large, it makes unneceffary lofs of power and friction; and if it is too fmall, there is fome uncertainty in the return of the lever.

Mr. Todd of Boulton had a patent, in 1803, for improvements in power-looms.

Mr. Horrocks of Stockport had three fucceffive patents for this kind of machinery, in 1803, 1805, and 1813. The machine defcribed in the latter is a crank-loom; that is, the lay is actuated by a crank to beat up the weft. The principal improvement confifts in a fyftem of levers, which tranfmit the action of this crank to the lay, and fo modify it, that the lay will advance quickly, and give an effective ftroke to the weft, and then withdraw quickly to a ftationary pofition, in which it will remain whilft the fhuttle is thrown. The advantages which are ftated are, that a large fhuttle may be ufed, fufficient to hold a full-fized cop of weft: the wafte and lofs of time by renewing the cop will, therefore, be lefs. From the fmartnefs of the ftroke, lefs weight will be required on the yarn-beam, and this will occafion the heddles to work more lightly, fo as to break fewer threads. From the fame caufe, more threads of the weft may be laid in an inch, and make clofer work.

Mr. Johnfon of Prefton had a patent in 1805, and another in 1807, for a power-loom, in which the warp is ftretched on a vertical plane, inftead of horizontal, as in former machines. The advantages of this are ftated to be, 1ft, that it takes lefs fpace; 2d, the reed ferves for the fhuttle-race, becaufe the fhuttle runs upon the reed itfelf, and, therefore, makes no friction upon the yarns; 3d, alfo in dreffing, picking, and clearing the warp, the attendant always remains in front of the machine, and can continue to watch the machine; whereas, in the other looms, he muft quit his poft in front, and go round behind the looms for thefe operations. When the dreffing is to be applied to the warp, whilft it is in the loom, that part of the warp is conducted horizontally for that purpofe, and a fan is applied to dry the warp.

The lateft inventions of power-looms are Mr. Peter Ewart's patent, 1813; and Mr. Duncan's loom, which he calls a vibrating loom.

The Indian Loom.—This is a ftriking contraft to our power-looms; it confifts merely of two bamboo rollers, one for the warp, and the other for the finifhed cloth; and a pair of heddles. The fhuttle performs the double office of fhuttle and reed: for this purpofe, it is made like a large netting-needle, and of a length fomewhat exceeding the breadth of the piece of cloth which is to be woven.

This apparatus the weaver carries to any tree which affords a fhade moft grateful to him: under this he digs a hole large enough to contain his legs, and the lower part of the geer or heddles; he then ftretches his warp, by faftening his bamboo rollers at a due diftance from each other on the turf, by wooden pins; the balances of the geer or heddles he faftens to fome convenient branch of the tree over his head; and two loops underneath the geer, in which he inferts his great toes, ferve inftead of treadles; his long fhuttle, which performs alfo the office of a batten, draws the weft, throws the warp, and afterwards ftrikes it up clofe to the web. In fuch looms as this are made thofe admirable muflins, whofe delicate texture the Europeans can never equal, with all their complicated machinery.

The weaving, even of their fineft muflins, is thus conducted in the open air, expofed to all the intenfe heat of their climate. We know well that this would be impracticable with fine work in this country, even in an ordinary fummer day, on account of the fudden drying of the dreffing. It is not known what is the fubftance which the Indian weavers employ for dreffing their warps. It might be of ufe to our manufacturers, were this inveftigated in a fatisfactory manner. It is faid to be a decoction of rice, formed by boiling the rice in a fmall quantity of water, and expreffing the juice: when this is cool, it forms a thick glutinous fubftance, which undergoes fome kind of fermentation before it is ufed.

Figure-weaving.—Having given an account of the nature and procefs of plain weaving, we muft notice the fanciful and ornamental parts of the bufinefs. The extent to which this fpecies of manufacture is carried renders it an object of very great national importance, and deferving a more minute defcription than our limits will admit.

Figures or patterns are produced in cloth, by employing threads of different colours, or of different appearance, in the warp, or in the weft. By the weaving, the threads muft be fo difpofed, that fome colours will be concealed and kept at the back, whilft others are kept in the front; and they muft occafionally change places, fo as to fhew as much of each colour, and as often as it is neceffary, to make out the figure or pattern.

The weaver has three means of effecting fuch changes of colour: Firft, by ufing different coloured threads in the warp, or threads of different fizes and fubftances; thefe are arranged in the warping, and require no change in the manner of weaving. This is confined to ftriped patterns, the ftripes being in the direction of the length of the piece.

Secondly, by employing feveral fhuttles charged with threads of different colours or fubftances, and changing one for another every time a change of colour is required. This makes ftripes acrofs the breadth of the piece; or, when it is combined with a coloured warp, it makes chequered and fpotted patterns of great variety.

Thirdly, by employing a variety of heddles, inftead of two, as we have hitherto defcribed; each heddle having a certain portion of the warp allotted to it, and provided with a treadle. When this treadle is depreffed, only a certain portion of yarns which belong to that heddle will be drawn up, and the reft will be depreffed; confequently, when the weft is thrown, all thofe yarns which are drawn up will appear on the front or top of the cloth; but in the intervals between them, the weft muft appear over thofe threads which are depreffed. The number of threads which are thus brought up may be varied as often as the weaver choofes to prefs his foot upon a different treadle, and by this he produces his pattern.

All thefe means may be combined together, and give the weaver the means of reprefenting the moft complicated patterns.

The principal varieties of woven cloth, including only thofe which require a different procefs for their fabrication, are the following:

Stripes are formed upon the cloth either by the warp or by the woof. When the former of thefe ways is practifed, the variation of the procefs is chiefly the bufinefs of the warper; but in the latter cafe, it is that of the weaver, as he muft continually change his fhuttle.

By unravelling any fhred of ftriped cloth, it may eafily be difcovered whether the ftripes have been produced by the operation of the warper or thofe of the weaver.

When the fly-fhuttle is ufed, the changing of the fhuttle is very readily effected by a fimple contrivance. One of the fhuttle-boxes or troughs, as we have before called them,

(*Plate*

(*Plate* II. *Weaving*, *fig.* 2.) is made in two parts, fo that a part of the trough I near the pecker, where the fhuttle lies during the time it is at reft, can be removed, and another trough fubftituted, which contains a different fhuttle. For the purpofe of making the change with facility, a moveable fhuttle-box *n* is fufpended by two perpendicular ftems *o* from a wire or centre of motion *m* attached to the lay, as is fhewn by the dotted lines. The moveable box is juft on the fame level with the fhuttle-trough I, and is divided by partitions into two or three feparate troughs, each exactly the width of the regular trough, and as long as is neceffary to contain a fhuttle. The pecker *k*, and the wire upon which it flides, remain exactly as before defcribed; but by fwinging the moveable box *n* on its centre any one of its compartments may be brought to line with the real place for the fhuttle-trough in which the pecker runs. The moveable box muft have proper catches to hold it exactly in its true pofitions.

In working with this contrivance a fhuttle of a different colour muft be placed in each cell or divifion of the moveable box *n*; and when the weaver defires to change the fhuttle he pulls the connecting ftring. This moves the fhuttle-troughs either backwards or forwards, fo as to carry away that fhuttle which had been juft before in ufe, and place another before the pecker. Then if he pulls the pecker-handle *y* the new fhuttle will be thrown acrofs the fhuttle-race, juft as the old one was in the former inftance. If only one moveable fhuttle-box is ufed there will be fome limitation in the pattern, becaufe the ftripes of different colour muft always confift of an even number of the fame coloured thread, as two, four, fix, &c. This may be obviated, and a greater change of fhuttles may be introduced, by ufing two moveable fhuttle-boxes, one at each end of the fhuttle-race: in that cafe the two moveable boxes are provided with cranks and ftrings, fo that the weaver can reach either of them with eafe.

Checks are produced by the combined operations of the warper and the weaver.

Tweeled cloths are fo various in their textures, and fo complicated in their formation, that it is difficult to convey an adequate idea of the mode of conftructing them without the aid of feveral drawings.

In examining any piece of plain cloth, it will be obferved that every thread of the weft croffes alternately over and then under every thread of the warp which it comes to; and the fame may be faid of the warp: in fhort, the threads of the warp and weft are thus interwoven at every point where they crofs each other, and are therefore tacked alternately.

Tweeled cloth is rather different, for only the third, fourth, fifth, fixth, &c. threads crofs each other, to form the texture.

Hence two, three, four, or more, of the fucceffive threads or fhoots of the weft will be found to pafs under or over the fame thread of the warp; or, in other words, by tracing any thread of the warp it will be found to pafs over two, three, four, or more threads of the woof at once, without any interweaving the warp. Then it croffes and paffes between the threads of the weft, and proceeds beneath two, three, four, or more threads, before it makes another paffage between the threads of the weft.

Tweeled cloths are of various defcriptions, and produce different kinds of patterns; becaufe at all the interfecting points where the threads actually crofs or interweave both threads of warp and weft are feen together, and thefe points are therefore more marked to the eye, even if the warp and weft are of the fame colour. Thefe points in plain tweels form parallel lines extending diagonally acrofs the breadth of the cloth, with a different degree of obliquity, according to the number of weft-threads over or under which the warp-threads pafs before an interfection takes place. In the coarfeft kinds every third thread is croffed: in finer fabrics they crofs each other at intervals of four, five, fix, feven, or eight threads; and in fome very fine tweeled filks the croffing does not take place until the fixteenth interval.

Tweeling is produced by multiplying and varying the number of heddles, or, as the weavers exprefs it, the number of leafes in the harnefs, which is the name given to the whole number of heddles employed in a loom; by the ufe of a back-harnefs or double-harnefs, by increafing the number of threads which pafs through each fplit of the reed, and by an endlefs variety of modes in drawing the yarns through the heddles; alfo by increafing the number of treadles, and changing the manner of treading them.

The number of treadles requifite to raife all the heddles which muft be ufed to produce very extenfive patterns, would be more than one man could manage; for if he placed his foot by miftake on a wrong treadle he would disfigure his pattern. In thefe cafes, recourfe is had to a mode of mounting or preparing the loom, by the application of cords to the different heddles of the harnefs; and a fecond perfon is employed to raife the heddles in the order required, by pulling the ftrings attached to the refpective heddles of the back-harnefs, and each heddle is returned to its firft pofition by means of a leaden weight underneath. This is the moft comprehenfive apparatus ufed by weavers, for all fanciful patterns of great extent, and it is called the DRAW-*Loom*. See that article.

The manner of mounting the harnefs of looms, to produce all the principal varieties of fabrics, is detailed in our articles DESIGN, DRAUGHT, and CORDING *of Looms;* alfo DAMASK, DIAPER, DIMITY, DORNOCK, FUSTIAN, and TAPESTRY. A perufal of thofe articles will render it unneceffary for us to proceed farther on that fubject in the prefent article. We fhall however defcribe a moft valuable invention, which has of late years come into ufe, as a fubftitute for the fecond perfon or draw-boy, who muft be employed in the draw-loom, by which loom alone all the complicated patterns can be woven.

Machine called the Draw-Boy, becaufe it performs the Office of a Draw-Boy in Weaving.—The faving of labour is not the only advantage of this machine; the certainty of its operation and fecurity from miftake are obvious. The weaver produces the required action upon the moft complicated harnefs by two treadles only, which he works alternately, juft with the fame motion as in plain cloth-weaving. The machine, when once fet up, performs every thing elfe.

Like moft other inventions, this was at firft imperfect, but has been gradually improved. We do not know its hiftory, but we have feen great numbers of machines, for carpet-weaving and coarfe goods, which have been fome years in ufe. The machine is fituated in a fmall fquare frame, not larger than a chair, which ftands at the fide of the loom, and cords from all the different heddles are conducted from the draw-loom down to this frame, where they are arranged in order. Each cord has a knot anfwering to the handle, which the boy muft pull in the common draw-loom; and there is a piece of mechanifm actuated by the treadles which at every ftroke felects the proper cord, and draws it down fo as to raife the heddles belonging to it. The next time it changes its pofition and takes another cord, and fo on until the whole number of cords has been drawn and the pattern completed.

Thefe original machines have a great defect, *viz.* that they only proceed with regularity to raife up all the beddles, until all the cords have been drawn, and one feries of changes has

has been gone through; but when this is completed, and a repetition of the pattern is wanted, the weaver muft ftop and reftore the machine to its original pofition by pulling a ftring. This appears very eafy, but it diverts his attention; and if he does not do it at the exact moment his pattern may be fpoiled. This defect was remedied by Mr. Alexander Duff, who received a fmall and inadequate premium from the Society of Arts in 1807, probably becaufe they were not aware of its value and importance; but in 1810 we find them with a liberality truly difcouraging to real merit, giving an equal reward to another perfon, for the moft trivial alteration of Duff's machine. The latter machine is alone defcribed in their Tranfactions; fee vol. xxviii.

Mr. Duff's Draw-Boy.—Fig. 4. *Plate* II. *Weaving*, is a plan of this machine, and *fig.* 2. a perfpective view. It is fixed at the fide of a draw-loom, in the fame place as a draw-boy would ftand, and H fhew the cords which are to draw the harnefs. The fame letters are ufed in both figures. A A is a fquare wooden axis, mounted fo as to turn backwards and forwards in the frame B B, on points or centres of motion. At one end of it a pulley D is fixed, to receive a line *a a* faftened to it at the higheft point, by means of which the axis receives motion from the two treadles of the loom, one of the treadles being attached to one end of the line, and the other to the oppofite end of it. E E are two rails of wood, fixed acrofs the frame parallel to the axis; and *e e* are two brafs plates fcrewed to the rails, and pierced with a great number of holes to receive as many cords. Each cord is tied by one end to a central rail F of the frame beneath the axis; and after paffing through one of the holes in the above plate *e*, and turning over a round wooden rod G, has a lead weight fufpended to the other end of it. Thefe weights are fhewn at *b b*. The rods G G are fufpended by ftrings at their ends from the ceiling of the room. To each of the above cords another is tied juft before it paffes over G. Thefe are reprefented by H, and hang loofely. The upper ends of thefe cords are tied to horizontal cords extended acrofs the ceiling of the room, and made faft to the ceiling at one end; the other ends pafs over pulleys fituated at the top of the loom, in a frame called the table of mullets, and the harnefs or heddles are fufpended by them.

By this arrangement it will be feen, that when any one of the cords faftened at F is pulled down, it muft draw one of the ftrings H, and raife fuch an arrangement of the harnefs or heddles as is proper to produce the figure which is to be woven. The weight *b* draws the cord fo as to keep it ftraight; all that is therefore neceffary is to draw down the cords at F one at a time, but to take a different one each time, and thus raife a different feries of the heddles each time; this is the bufinefs of the machine, and which it accomplifhes in the following manner.

The bar, or axis, A A, has an iron femicircle, *d*, grooved like a pulley, and each of its ends divided, fo as to form a cleft-hook or claw.

Each of the ftrings made faft at F has a large knot tied in it, juft beneath where it paffes through the brafs plate *e e*, and which knot ftops the farther afcent of the cord, in confequence of the pull of the weight *b*. Now when the axis A vibrates backwards and forwards by the treadles of the loom, as before mentioned, the hook of the femicircle *d* feizes the knot of one of the cords F, and draws down that cord, and raifes the heddles belonging to it. The weaver throws the fhuttle, and then returns the treadles, and the axis A with the femicircle returns back again, and allows the cord F to take its original pofition. When the femicircle *d* inclines over to the other fide, its oppofite hook takes hold of the cord F, which is next to the one oppofite to that which it juft quitted; it draws down this cord, and the weaver again throws his fhuttle, then returns the femicircle to the oppofite fide, and it will take the cord next to the oppofite one, and fo on; fo that the femicircle will in fucceffion take every alternate cord in each of the rows *e e*, and leave every other.

This is effected by the femicircle fliding along its axis A every time, by means of two wooden racks, *h* and *i*, in the plan, which are let into grooves in the axis A; thefe racks have teeth like faws, but inclined in contrary directions. The racks move backwards and forwards in their grooves, the extent of a tooth at each vibration of the axis, by the action of two circular inclined planes of iron faftened to the frame at L M, againft which the ends of the racks are thrown by fpiral fprings concealed beneath each rack. The femicircle is fixed on a box or carriage N, which flides upon the axis A, and has two clicks upon it; one at *l*, which falls into the teeth of the rack *h*; the other at *m* for the rack *i*: *n* is a roller fixed over the box, and connected with the two clicks *l* and *m*, by threads wound in oppofite directions; fo that one click is always raifed up, and difengaged from its rack, while the other is in action. O is a piece of wire fixed to the frame, fo as to intercept a fmall wire projecting from the roller when the axis is inclined, and turn the roller a fmall quantity; P is another wire for the fame purpofe, but fixed to a crofs bar, Q, which is moveable, and can be faftened at any required place, farther or nearer from the end of the axis. Suppofe the roller *n* to be in fuch a pofition that the click *m* is down, and *l* drawn up, the action will be as follows: the femicircle firft inclines to the direction of *fig.* 2., its hook taking down one ftring; during this motion the end of the rack *i* comes to the inclined part of the circular inclined plane M, and moves by its fpring towards D, the fpace of one tooth, which the click *m* falls into. On the return of the axis, the rack *i* is thruft back, and the box N and femicircle with it towards L, caufing the hook to take the next oppofite ftring: in this manner it proceeds, advancing a tooth each vibration, till it gets to the end of its courfe; the tail of the roller *n* then ftrikes againft the pin P, and turns the roller over, raifes the click *m*, and lets down the other, *l*, into the teeth of the rack *h*; this was all the time moving in a contrary direction to *i*, by its inclined plane L, but had no action, as its click *l* was drawn up; this being let down, the femicircle is moved back, a tooth at a time, towards M, until it meets O, which upfets the roller *n*, and fends the femicircle back again.

Tweeled Silks.—In weaving very fine filk tweels, fuch as thofe of fixteen leafes, the number of threads required to be drawn through each interval of the reed is fo great, that if they were woven with a fingle reed, the threads would obftruct each other in rifing and finking, and the fhed, or opening of the divided warp, would not be fufficiently open to allow the fhuttle a free paffage. To avoid this inconvenience, other reeds are placed behind that which ftrikes up the weft; and the warp-threads are fo difpofed, that thofe which pafs through the fame interval in the firft reed are divided in paffing through the fecond, and again in paffing through the third. By thefe means the obftruction, if not entirely removed, is greatly leffened.

In the weaving of plain thick woollen cloths, to prevent obftructions of this kind arifing from the clofenefs and roughnefs of the threads, only one-fourth of the warp is funk and raifed by one treadle, and a fecond is preffed down to complete the fhed between the times when every fhot of weft is thrown acrofs.

Double Cloth is compofed of two webs, each of which confifts

confifts of feparate warps and feparate wefts, but the two are interwoven at intervals. The junction of the two webs is formed by paffing each of them occafionally through the other, fo that any particular part of both warps will be found fometimes above and fometimes below.

This fpecies of weaving is almoft exclufively confined to the manufacture of carpets in this country. The material employed is dyed woollen, and as almoft all carpets are decorated with fanciful ornaments, the colours of the two webs are different, and they are made to pafs through each other at fuch intervals as will form the patterns required. Hence it happens that the patterns at each fide of the carpet are the fame, but the colours are reverfed. Carpets are ufually woven in the draw-loom, or with the machine called the draw-boy before defcribed.

Marfeilles is a fabric woven of cotton, which is a double cloth. The loom for weaving Marfeilles is fomewhat fimilar to the diaper loom. A good idea of the manner in which it is prepared may be had, by conceiving two webs woven one under the other in the fame loom, which are made to intermingle at all the depreffed lines, and form the reticulations on the furface, in imitation of the quilting performed by hand.

When the fpecies of Marfeilles, called Marfeilles quilting, is made, a third warp, of fofter materials than the two others defcribed, lies between them, and merely ferves as a fort of ftuffing to the hollow fquares formed by them.

Quilting is another fort of cotton ftuff, folely appropriated to quilts, which fhould, in ftrictnefs, be fet down exclufively to the cotton manufacture, although there is nothing to prevent its being made of other materials.

The weft of thofe quilts is of very coarfe and thick yarn, which is drawn out by a fmall hook into little loops, as it is woven, that are fo arranged as altogether to form a regular pattern; every third or fourth fhoot of the fhuttle, the weaver has to ftop to form thofe loops from a draft, which caufes the weaving of thofe quilts to take up more time than that of any other ftuff, except tapeftry; which accounts for the greatnefs of the price at which they are fold, in proportion to the value of the materials of which they are principally compofed.

Gauze differs in its formation from other cloths, by having the threads of the warp croffed over each other, inftead of lying parallel. They are turned to the right and left alternately, and each fhot of weft preferves the twine which it has received.

This effect is caufed by a fingular mode of producing the fheds, which cannot eafily be defcribed without the aid of drawings.

Crofs, or *Net Weaving*, is a feparate branch of the art, and requires a loom particularly conftructed for the purpofe.

Spots, brocades, and lappets, are produced by a combination of the arts of plain, tweeled, and gauze weaving, and as in every other branch of the art are produced in all their varieties by different ways of forming the divifion of the warp by the application of numerous heddles, and their connections with the treadles which move them. Indeed the great fkill of the art confifts in the proper management of this part of the apparatus of a loom.

Ribband Weaving.—This was formerly performed by a fmall common loom, weaving one ribband at a time. Ribbands are commonly ftriped in the length by laying a ftriped warp, and patterns are produced by changing the colour of the weft occafionally; fometimes an ornamented edging is formed by a fucceffion of open loops at the borders of the ribband. Figured ribbands are alfo woven by a great number of treadles, but as they rarely extend to a greater number than the weaver can manage by his feet, they feldom employ a draw-loom.

Engine-Loom for weaving Ribbands.—The weavers at Coventry, which is the principal feat of the ribband trade, univerfally employ what they call an engine-loom: it is worked by the hands and feet like a common loom, but weaves twelve, fixteen, or even twenty ribbands at once. The fhuttles are of courfe fly-fhuttles, and are driven by what is called a ladder, becaufe it is a fmall frame exactly like a ladder, which flides horizontally in a groove in the lay; and every crofs-bar of the ladder acts upon one fhuttle in the manner of a pecker: the ladder has a handle to give it motion.

Another peculiarity of this loom is, that the ribbands are taken away as they are woven, with very few interruptions to wind up the work: for this purpofe they conduct the warps over pulleys, and the ribbands alfo, fo that both hang down in long loops. Thefe looped parts are conducted through pulleys, which are loaded with weights, and tend always to draw the loops down, and keep the warp tight. The weight which is thus fufpended by the finifhed ribband tends to draw it forwards at every ftroke which the lay makes; and the weight which is fufpended by the yarn of the warp is drawn up. When thefe weights have run through their refpective courfes, the weaver muft ftop to wind up the finifhed ribband, and unwind a frefh length of yarn. In fome looms this is rendered unneceffary by a fimple mechanifm, which continually winds up the ribband as faft as it is woven.

In 1801 the Society of Arts rewarded Mr. Thomas Clulow, for an improved loom for weaving figured ribbands.

This loom differs from the common figured ribband-looms in the method of forming the figure, which, in the old mode, was tedious, from the work being ftopped, whilft the figure was drawn by hand.

In the prefent loom, the tire-cords which form the figure are drawn or worked by a cord or leather-ftrap fixed to the centre-treadle, which ftrap paffes over two vertical and one horizontal pulley to the back of the loom, and has a weight hung to the end thereof. Upon this ftrap above the weight is fixed an iron, of a bevel or floping form, which when the ftrap is pulled up by preffing with the foot upon the treadle, raifes a wire-lever placed acrofs the main-wheel of the movements placed vertically, and allows this main-wheel to move one-fourth of its circumference, where it is ftopped by an iron pin, placed on its rim, and prevented from returning by a clitch or catch on the edge of the wheel on its right fide.

Within the rim of the main-wheel is a fmall catch-ftrap connected with the ftrap above-mentioned; this catch-ftrap pulls forward the main-wheel one-fourth of its circumference, until it is ftopped by the wire-lever and one of the pins on the rim, of which there are four in number in the ground.

There are alfo four iron pins projecting from the left fide of the main-wheel in oppofite quarters of it: thefe act on a hanging lever, to the lower part of which a ftring is attached, which paffes behind the box containing the whole machinery, and raifes four clicks or catches on four rollers, which permits any one of the four rollers to run back as the figure may require, each roller by fuch motion drawing up the number of threads neceffary to form the figure, by cords extending from thefe rollers over pulleys to the pafs-cords, which draw the figure.

Machine Loom for Ribbands.—We have before mentioned M. Vaucanfon's loom for weaving ten ribbands by a rotatory motion. We do not know that this is in ufe in this country.

Mr. James Birch invented an improvement on the fwivel-loom, fo as to weave fatin-guard or figured laces, and received a reward from the Society of Arts in 1804.

This loom is worked by a circular motion of the hands, without treadles, or any application of the feet.

A wooden bar, to which the hands are applied, works two cranks on a large iron axle, extending the width of the loom ; one crank is near each end of the above axis. A fly-wheel is attached to one of the ends of the axis, to regulate the motion of the machinery ; an endlefs fcrew is placed upon the axis, works a ftar-wheel underneath it, which turns a barrel that has a refemblance to that of a hand-organ, and has wooden pegs fixed in different parts around it : thefe pegs catch upon levers, which draw forward the cords that form the figure, and pull them down by a claw, which fecures the cords thus brought within its power, and by thofe means raife the upper geer connected with the cords.

In this loom fourteen pieces of fatin-guard or bed-lace are wove at the fame time, either one pattern and breadth, or all of different patterns and breadths, as may be required. The figure may be extended to any number of fhoots defired.

The loom takes up no more fpace than a common fwivel-loom, fuch as is employed in plain-work. It appears to work with eafe and expedition, to make good work, and to be eafily managed. It does not break or chafe the filk during its working. The weaver can move to any part of the front of the loom to infpect the work, and to continue the motion during that time ; and the figure or pattern may be formed double the length of thofe ufually done in the engine-loom. The loom can be ftopped when required, at any one fhoot of the fhuttle ; and it will anfwer to weave articles made of filk, wool, cotton, or linen, or mixtures of thofe articles, or gold or filver lace, and performs its work in half the time of an engine-loom.

The want of uniformity in the technical phrafeology of the art of weaving, and the intricacy of the fubject, have compelled us to render our defcriptions far more intricate and difficult than they otherwife would have been.

We muft acknowledge the affiftance which we have derived from the very excellent "Effays on the Art of Weaving," by Mr. Duncan, 1808, in 2 vols. 8vo. It is a moft curious and valuable publication, embracing almoft every thing neceffary to be known concerning the art on which it profeffes to treat ; if we except fome of the recent improvements in machine-weaving, which are only flightly noticed.

The French have long excelled in the various branches of figure-weaving ; but this is more from dexterity of their weavers than from their machinery. Defcriptions and drawings of all looms ufed by them, with every detail of their ftructure, will be found in the different articles of L'Encyclopede Methodique, and Les Arts et Metiers, D'Art de Fabriquer le Soie, &c.

Web, *Spider's*, or *Cob-Web*, is a very delicate and wonderful plexus, which that infect fpins out of its own bowels ; ferving it as a fort of toil, or net, to catch flies, &c. See Spider.

For the manner in which the fpider fpins his web, the admirable mechanifm of the parts fubfervient to it, and the ufes of it, fee Silk, and *Ductility of Spider-*Webs *infra.*

Dr. Lifter tells us, that, attending nearly to a fpider weaving a net, he obferved it fuddenly to defift in the mid-work ; and turning its tail to the wind, it darted out a thread, with the violence and ftream we fee water fpout out of a jet : this thread, taken up by the wind, was immediately carried to fome fathoms long ; ftill iffuing out of the belly of the animal. By-and-bye the fpider leaped into the air, and the thread mounted her up fwiftly. After this difcovery he made the like obfervation in near thirty different forts of fpiders, and found the air filled with young and old, failing on their threads, and doubtlefs feizing gnats and other infects in their paffage : there being often manifeft figns of flaughter, legs and wings of flies, &c. on thefe threads, as well as in their webs below.

Dr. Hulfe difcovered the fame thing about the fame time. In a letter of Dr. Lifter to Mr. Ray, he thinks there is a fair hint of the darting of fpiders in Ariftotle, Hift. An. lib. ix. cap. 39. and in Pliny, lib. x. cap. 74. But with regard to their failing, the ancients are filent, and he thinks it was firft feen by him. In another letter to Mr. Ray, dated January, 1670, fpeaking of the height fpiders are able to fly to, he fays, "Laft October, &c. I took notice that the air was very full of webs ; I forthwith mounted to the top of the higheft fteeple on the minfter (in York), and could there difcern them yet exceeding high above me."

*Ductility of Spider-*Webs. M. Reaumur obferves, that the matter of which fpiders and filk-worms form their threads, is brittle when in the mafs, like dry gums. As it is drawn out of their bodies, it affumes a confiftence, much as glafs-threads become hard, as they recede from the lamp, though from a different caufe. The ductility of this matter, and the apparatus for this purpofe, being much more extraordinary in fpiders than in filk-worms, we fhall here only confider the former. Something alfo has already been faid of each under Silk.

Near the anus of the fpider are five or fix papillæ, or teats. The extremities of the feveral papillæ are furnifhed with holes, that do the bufinefs of wire-drawers, in forming the threads. Of thefe holes, M. Reaumur obferves, there are enough in compafs of the fmalleft pin's-head, to yield a prodigious quantity of diftinct threads. The holes are perceived by their effects: take a large garden-fpider ready to lay its eggs, and applying the finger on a part of its papillæ, as you withdraw that finger, it will take with it an amazing number of different threads. M. Reaumur has often counted feventy or eighty with a microfcope, but has perceived that there were infinitely more than he could tell. In effect, if he could fay, that each tip of a papilla furnifhed a thoufand, he is perfuaded he fhould fay much too little. The part is divided into an infinity of little prominences, like the eyes of a butterfly, &c. each prominence, no doubt, makes its feveral threads ; or rather, between the feveral protuberances, there are holes that give vent to threads ; the ufe of the protuberances, in all probability,

bility, being to keep the threads at their firft exit, before they are yet hardened by the air, afunder. In fome fpiders thofe protuberances are not fo fenfible; but in lieu thereof there are tufts of hair, which may ferve the fame office, *viz.* to keep the threads apart. Be this as it will, there may threads come out at above a thoufand different places in every papilla; confequently, the fpider having fix papillæ, has holes for above fix thoufand threads. It is not enough that thefe apertures are immenfely fmall: but the threads are already formed before they arrive at the papilla, each of them having its little fheath or duct, in which it is brought to the papilla from a confiderable diftance.

M. Reaumur traces them up to their fource, and fhews the mechanifm with which they are made. Near the origin of the belly he finds two little foft bodies, which are the firft fource of the filk. Their form and tranfparency refemble thofe of glafs-beads, by which name we fhall hereafter denote them. The tip of each bead goes winding, and makes an infinity of turns and returns towards the papilla. From the bafe, or root of the head, proceeds another branch much thicker; which winding varioufly, forms feveral knots, and takes its courfe like the other, towards the hind part of the fpider. In thefe beads and their branches, is contained a matter proper to form the filk, only that it is too foft. The body of the bead is a kind of refervoir, and the two branches two canals proceeding from it. A little farther backwards, there are two other leffer beads, which only fend forth one branch a-piece, and that from the tip. Befide thefe, there are three other larger veffels on each fide of the fpider, which M. Reaumur takes for the laft refervoirs, where the liquor is collected. The biggeft is near the head of the infect, and the leaft near the anus. They all terminate in a point; and from the three points of thefe three refervoirs it is, that the threads, at leaft the greateft part of the threads drawn out at the three papillæ, proceed. Each refervoir fupplies one papilla. Laftly, at the roots of the papillæ, there are difcerned feveral flefhy tubes; probably, as many as there are papillæ. Upon lifting up the membrane, or pellicle, that feems to cover thefe tubes, they appear full of threads, all diftinct from each other, and which, of confequence, under a common cover, have each their particular one; being kept like knives in fheaths. The immenfe quantity of threads contained here, M. Reaumur concludes, upon tracing their courfe, does not wholly come from the points of the refervoirs; but fome from all the turns, and angles; nay, probably from every part of it. But by what conveyances the liquor comes into the beads, and out of the beads into the refervoirs, remains yet to be difcovered.

We have already obferved, that the tip of each papilla may give paffage to above a thoufand threads; yet the diameter of that papilla does not exceed a fmall pin's-head: but we were there only confidering the largeft fpiders.

If we examine the young growing fpiders produced by thofe, we fhall find, that they no fooner quit their egg, than they begin to fpin. Indeed their threads can fcarce be perceived; but the webs may: they are frequently as thick, and clofe, as thofe of houfe-fpiders; and no wonder: there being often four or five hundred little fpiders concurring to the fame work. How minute muft their holes be? the imagination can fcarce conceive that of their papillæ! The whole fpider is, perhaps, lefs than a papilla of the parent which produced it.

This is eafily feen; each big fpider lays four or five hundred eggs; thefe eggs are all wrapped up in a bag; and as foon as the young ones have broke through the bag, they begin to fpin. How fine muft their threads at this time be!

Yet is not this the utmoft nature does: there are fome kinds of fpiders fo fmall at their birth, that they are not vifible without a microfcope. There is ufually found an infinity of thefe in a clufter, and they only appear like a number of red points. And yet there are webs found under them, though well nigh imperceptible. What muft be the tenuity of one of thefe threads; the fmalleft hair muft be to one of thefe what the moft maffive bar is to the fineft gold-wire.

The matter of which the threads are formed, we have obferved, is a vifcid juice. The beads are the firft receptacles where it is gathered, and the place where it has the leaft confiftence. It is much harder when got into the fix great refervoirs, whither it is carried by canals from the former; this confiftence it acquires in good meafure in its paffage; part of the humidity being diffipated in the way, or fecreted by parts deftined for that purpofe.

Laftly, the liquor is dried ftill farther, and becomes thread, in its progrefs through the refpective canals to the papillæ. When thefe firft appear out at the holes, they are ftill glutinous; fo that fuch as fpring out of neighbouring holes ftick together. The air completes the drying.

By boiling the fpider, more or lefs, the liquor is brought to a greater or lefs confiftence, fit to draw out into threads; for it is too fluid for that purpofe while yet inclofed in its refervoirs.

The matter contained in thefe refervoirs, when well dried, appears a tranfparent gum, or glue, which breaks when much bent: like glafs, it only becomes flexible by being divided into the fineft threads. And probably it was on this account nature made the number of holes fo immenfe. The matter of filk formed in the bodies of fpiders being much more brittle than that formed in filk-worms, needed to be wound fmaller. Otherwife we do not conceive, why they fhould form a great number of threads, which were afterwards to be re-united: a fingle canal might elfe have done.

The thread of a fpider being ftrong enough to bear five or fix times the weight of the fpider's body, is compofed of feveral finer threads, that are drawn out feparately, but unite together at the diftance of two or three hairs' breadth from the body of the fpider. The threads are coarfer or finer, according to the fize of the fpider that fpins them. Mr. Leewenhoeck computes that 100 of the fineft threads of a full grown fpider, are not equal to the diameter of the hair of his beard; and confequently, if the hair be round, 10,000 fuch threads are not bigger than fuch a hair. He calculated farther, that when young fpiders firft begin to fpin, 400 of them are not larger than one that is full-grown; and therefore the thread of fuch a little fpider is 400 times fmaller than the thread of a full-grown one; allowing this, four millions of a young fpider's threads are not fo big as the fingle hair of a man's beard.

Web, in *Ship-Building*, the thin partition on the infide of the rim, and between the fpokes of an iron or brafs-fheave.

Web *of a Coulter*, in *Agriculture*, that part of it which is drawn out thin and fharp, in order to cut and feparate the ground, in oppofition to the others which are thick and blunt. In the fock, too, any thin fharp part has the name of web or wing.

WEBB, PHILIP-CARTERET, in *Biography*, a member of the society of antiquaries, was born in 1700, and admitted an attorney in 1724, and distinguished for his acquaintance with the records of the kingdom, and with constitutional and parliamentary law. He was returned in 1754, and again in 1761, as a member for the borough of Haslemere; and being attached to the then existing administration, he obtained the place of secretary of bankrupts in the court of chancery, and in 1756 became one of the joint solicitors of the treasury. He was employed in 1763 in conducting the prosecution against Mr. Wilkes, for writing a number of the North Briton; and printed on that occasion "A Collection of Records about General Warrants," and "Observations on discharging Mr. Wilkes from the Tower." He died at his house in Busbridge, Surrey, in June 1770, and left a valuable library, and curious collection of coins, medals, and relics of antiquity, which were sold by auction. He had sold 30 MSS. of the rolls of parliament to the house of lords, and a number of other MSS. were sold to lord Shelburne, and afterwards to the British Museum. Among his publications we may reckon "A Letter to the Rev. Mr. Warburton, on some passages of his Divine Legation;" "Various Pieces relative to the State of the Law in this Kingdom;" "Account of some Particulars concerning Domesday Book;" "A short Account of Danegeld;" "Account of a Copper Table, discovered near Heraclea." Mr. Webb was twice married, and by his first wife left a son of his own name. Nichols's Lit. Anecd. Gen. Biog.

WEBB *Pond*, in *Geography*, a town of the district of Maine, in the county of Oxford, containing 318 inhabitants.

WEBBER, JOHN, in *Biography*, who accompanied captain Cook in his last voyage to the South sea, in the capacity of draughtsman, was a native of London, though his father was a Swiss. He was born in 1752, and was sent young to Paris for his education as an artist. After his return he studied at the Royal Academy, of which in 1785 he became a member. His talents for drawing landscape recommended him to the lords of the admiralty, who appointed him to go with captain Cook on his voyage of discovery; and when the vessels returned in 1780, they also commissioned him to superintend the engraving of the prints from his own drawings of the scenes he had beheld. When these were completed, he was permitted to publish a work consisting of other views which he had made, which he etched and aquatinted himself, and published on his own account; and these produced him a handsome remuneration. He afterwards applied himself to painting, but his pictures are weak and unsubstantial, without colour or effect, or any great degree of merit, though they please from their neatness and minuteness. He died in 1793, aged 41.

WEBERA, in *Botany*, owes its name to Schreber, who dedicated this genus to the memory of George Henry Weber, late professor of medicine and botany at Kiel; an excellent cryptogamic botanist, most celebrated for his *Spicilegium Floræ Goettingensis*, published in 1778, and one of the classical books in that department of the science. He died in 1786, at the age of 35. Hedwig had previously commemorated Weber in a genus of Mosses, some species of which are now referred to *Bartramia*, others to *Bryum*. (See MUSCI and FRINGE *of Mosses*.) It is to be regretted that *Webera* did not take place of *Bartramia*, the person after whom the latter was named, however meritorious, being scarcely at all conversant with mosses.—Schreb. Gen. 794. Willd. Sp. Pl. v. 1. 1224. Mart. Mill. Dict. v. 4. Ait. Hort. Kew. v. 1. 371. (Chomelia; Linn. Gen. ed. 2. 72.) Class and order, *Pentandria Monogynia*. Nat. Ord. *Rubiaceæ*, Juss.

Gen. Ch. *Cal.* Perianth superior, of one leaf, divided half way down into five erect, acute, permanent segments. *Cor.* of one petal, funnel-shaped; tube cylindrical, longer than the calyx: limb in five ovate-oblong, reflexed segments. Nectary a fleshy ring, surrounding the base of the style. *Stam.* Filaments five, very short, inserted into the margin of the tube; anthers linear, incumbent, spreading. *Pist.* Germen roundish, inferior; style simple, longer than the tube of the corolla; stigma club-shaped, with ten furrows. *Peric.* Berry nearly globular, of two cells, crowned with the permanent enlarged calyx. *Seeds* from two to four in each cell, angular.

Eff. Ch. Calyx superior, in five permanent segments. Corolla funnel-shaped, five-cleft. Stamens in the mouth of the tube. Stigma club-shaped, with ten furrows. Berry inferior, of two cells. Seeds several, angular.

A genus of evergreen East Indian shrubs, with opposite branches and leaves; and axillary or terminal, aggregate flowers, which are occasionally augmented in the number of their divisions and stamens, from five to six. *Canthium* of Lamarck's Dict. v. 1. 602. Juss. 204. Cavan. Ic. v. 5. 21, confounded by Willdenow with this genus, is certainly very distinct in its habit, peltate stigma, solitary seeds, and four-cleft flowers.

1. W. *corymbosa*. Corymbose Webera. Willd. n. 1. Ait. n. 1. (Rondeletia asiatica; Linn. Sp. Pl. 244. Cupi; Rheede Hort. Malab. v. 2. 37. t. 23. Raii Hist. v. 2. 1494.)

Leaves elliptic-oblong. Corymb terminal, forked, many-flowered.—Native of sandy ground in the East Indies; cultivated by Miller in the stove at Chelsea, in 1759, but it is not recorded by Mr. Aiton to have flowered, nor do we recollect having ever seen the plant in any collection. A wild specimen from Dr. Rottler is before us. The *stem* is shrubby, about the height of a man, with smooth, leafy, somewhat compressed, *branches*. *Leaves* on short thick stalks, entire, coriaceous, very smooth, four inches long, rather acute, with a stout rib, and numerous reticulated veins; their upper side shining; lower paler. *Stipulas* intrafoliaceous, triangular, short, pointed. *Flower-stalks* hairy. *Flowers* three-quarters of an inch long, whitish, agreeably fragrant, turning yellowish as they fade. *Berries* firm, the size of a currant, blackish, sweetish, but not eatable. Rheede describes 7 or 8 *seeds* in each fruit.

This plant has the appearance of an *Ixora* or *Pavetta*, as we have observed at the end of our article RONDELETIA; but perhaps the *stigma*, very important in this natural order, may keep it distinct.

2. W. *cymosa*. Cymose Webera. Willd. n. 2.—"Leaves ovate, pointed. Cymes axillary, stalked, many-flowered."—Native of the East Indies. "A *tree*, with round downy *branches*. *Leaves* stalked, ovate, obtuse with a point, entire, very smooth, rigid, simply veiny; shining above. *Cymes* convex. *Flower-stalks* downy. *Corolla* half the size of the former. *Style* much longer than the corolla. *Stigma* capitate, cloven. *Berry* the size of Juniper."—*Willdenow*, from a dried specimen.—We have not seen this species. The description of the *stigma* does not answer to the generic character.

WEBHAMET, in *Geography*, a river of the district of Maine, which runs into the Atlantic, near Wells.

WEBUCH, Cape, a cape on the E. coaſt of Labrador. N. lat. 55° 21′. W. long. 58° 10′.

WECHMAR, or Warihmar, a town of Germany, in the principality of Gotha; 4 miles S.E. of Gotha.

WECHQUETANK, a Moravian ſettlement in Pennſylvania; 30 miles N.W. of Bethlehem.

WECHSELBURG, a townſhip of Germany, in the lordſhip of Schonburg; 4 miles N.N.E. of Penig.

WECHSTEN, a town of Germany, in the county of Verden; 12 miles S.E. of Verden.

WECHTERBACH, a town of Germany, in the county of Iſenburg; 7 miles S.E. of Budingen.

WECHTERSWINCKEL, a town of the duchy of Wurzburg; 3 miles N.N.W. of Neuſtadt am Saal.

WECKHOLM, a town of Sweden, in the province of Upland; 22 miles S.W. of Upſal.

WED el Casaab, a river of Algiers, which runs into the Mediterranean, 5 miles S. of Cape Falcon.

Wed *el Kibbeer*, a river of Algiers, anciently called *Ampſaga*, which runs into the Mediterranean, 15 miles S. of Sebba Rous. N. lat. 36° 57′. E. long. 6° 28′.

Wed *el Mailah*, *i. e.* the *Salt River*, a river of Algiers, which runs into the Mediterranean, 10 miles S.S.E. of Cape Figalo.

Wed *el Shaier*, a river of Africa, which riſes about 12 miles E. from the mountain of Zeckar, in the Sahara, and after a north-eaſt courſe about 30 miles changes its name to Mailah, and finally loſes itſelf in the Short.

WEDDER, the name of a certain ſtate of ſheep. See Wether-*Sheep*.

WEDDRA, in *Commerce*. See Vedro.

WEDEKINSTEIN, in *Geography*, a town of Weſtphalia, in the principality of Minden; 3 miles S.W. of Minden.

WEDEL, George Wolffgang, in *Biography*, an eminent phyſician, was born in 1645, at Golzan, in Luſatia, and ſtudied phyſic and took his doctor's degree at Jena, in 1667, where, after a temporary exerciſe of his profeſſion at Gotha, he became medical profeſſor, in which ſtation he continued with reputation for almoſt fifty years. He combined with his medical ſkill a conſiderable acquaintance with mathematics and philology, as well as with the oriental and claſſical languages. He was an aſſociate to the Academy Naturæ Curioſorum, and to the Royal Society of Berlin, phyſician to ſeveral German ſovereigns, a count palatine, and an imperial counſellor. Notwithſtanding theſe high offices and numerous engagements, he was attentive to the poor, and aſſiduous in his literary labours. His pathology was derived from the ſyſtems of Helmont and Sylvius; in his practice he depended much on abſorbents, and the volatile ſalts of vegetables. Wedel was addicted to aſtrology; but he is chiefly celebrated for his pharmaceutical knowledge, and his elegance of preſcription, ſo that many of his compoſitions have been adopted in diſpenſatories. Of his works, beſides his academical diſſertations, the principal are the following; *viz.* "Opiologia;" "Pharmacia in Artis formam redacta;" "De Medicamentorum Facultatibus cognoſcendis et applicandis;" "De Morbis Infantum;" and "Exercitationes Medico-Philologicæ." Haller. Eloy.

Wedel, in *Geography*, a town of Holſtein; 13 miles N.W. of Hamburg.—Alſo, a town of the New Mark of Brandenburg; 11 miles E. of Reetz.

WEDELIA, in *Botany*, was ſo called by Jacquin, in honour of Dr. John Wolffgang Wedel, of Jena, whom he celebrates as a highly meritorious botaniſt, and who wrote a *Tentamen Botanicum*, publiſhed at Jena in 1747, with a preface by his friend Hamberger. The deſign of this work is to combine the ſyſtems of Rivinus and Linnæus, the claſſes of the latter making ſubdiviſions of the former. We preſume that no ſcheme could be leſs natural or uſeful, whatever the botanical ſkill of the author might be; of which indeed we are not diſpoſed to think highly, as he made a point of excluding the fruit from his principles of claſſification. He wrote a German eſſay againſt Haller, on the ſubject of botanical terms, of which the latter ſpeaks as full of taunts and reproaches. Wedel died in 1757, at the age of 49. Some others of the ſame name, and probably the ſame family, who were Profeſſors at Jena, appear full as well entitled to botanical honours; eſpecially George Wolffgang Wedel, who died in 1721, aged 76, and has left behind him numerous diſſertations on botany and the materia medica.—Jacq. Amer. 217. Willd. Sp. Pl. v. 3. 2334. Juſſ. 189. Gærtn. v. 2. 435. (Alcina; Cavan. Ic. v. 1. 10. Ait. Hort. Kew. v. 5. 164.)—Claſs and Order, *Syngeneſia Polygamia-neceſſaria*. Nat. Ord. *Compoſitæ oppoſitifoliæ*, Linn. *Corymbiferæ*, Juſſ.

Gen. Ch. *Common Calyx* ſimple, of four or five large leaves. *Cor.* compound, radiant. *Florets* of the diſk perfect, numerous, funnel-ſhaped, five-cleft; thoſe of the radius from eight to twelve, roundiſh-ovate, cloven. *Stam.* in the florets of the diſk. Filaments five, capillary ſhort; anthers united into a tube, as long as the partial corolla. *Piſt.* in the ſame florets, Germen minute, imperfect; ſtyle thread-ſhaped, the length of the anthers; ſtigma ſimple or divided: in thoſe of the radius, Germen oblong, quadrangular; ſtyle thread-ſhaped; ſtigmas two, revolute. *Peric.* none, the calyx remaining unaltered. *Seeds* in the diſk imperfect; in the florets of the radius ſolitary, obovate, gibbous, crowned with four, five, or ten teeth. *Recept.* chaffy, ſlightly convex; the ſcales ovate, concave, as long as the florets.

Eſſ. Ch. Receptacle chaffy. Seed-crown of from five to ten teeth. Calyx ſimple, of four or five leaves.

Obſ. This genus is ſeparated from Polymnia, (ſee that article,) on account of its ſimple calyx, and the preſence of a crown to the ſeeds, which appear to us ſufficient characters.

1. W. *fruteſcens*. Shrubby Wedelia. Willd. n. 1. Jacq. Amer. 217. t. 130. (Polymnia Wedelia; Linn. Mant. 118. Poiret in Lam. Dict. v. 5. 506.)—Stem ſhrubby. Leaves diſtinct, ſtalked, lanceolate. Seed-crown of ten teeth.—Native of Carthagena, South America, in buſhy woody places, flowering in July and Auguſt. *Stem* ſhrubby, climbing, with round leafy branches, rough in our ſpecimen with minute points. *Leaves* acute, two or three inches long, ſomewhat ſerrated, briſtly on both ſides; the upper rough with callous points; lower paler. *Footſtalks* linear rough, hardly half an inch in length, combined at the baſe by a narrow annular *ſtipula*. *Flowers* terminal, ſtalked, ſolitary, yellow, near an inch broad, with a rough *calyx*; the outer ſcales of their *receptacle* looking like a coloured inner calyx. *Seeds*, according to Jacquin, each with a little cup-ſhaped crown, having about ten teeth.

2. W. *perfoliata*. Perfoliate Wedelia. Willd. n. 2. (Alcina perfoliata; Cavan. Ic. v. 1. 11. t. 15. Ait. Hort. Kew. v. 5. 164.)—Stem herbaceous. Leaves rhomboid, tapering at the baſe, perfoliate. Seed-crown of five teeth.—Native of Mexico, from whence its ſeeds were brought to Madrid, and thence diſperſed through the botanic gardens of other parts of Europe. This is an annual plant, with nothing to attract the attention of floriſts. It flowers late, and does not always ripen ſeed in England. The *ſtem* is four feet high, angular or furrowed, leafy, branched, nearly ſmooth, often purpliſh. *Leaves* three or four inches

long,

long, including their narrow base, pointed, serrated, triple-ribbed, light green, roughish. *Flowers* yellow, stalked, much smaller than the foregoing. *Calyx* broad, extending far beyond the rays. *Seeds* of the marginal *florets* large, tumid, each crowned with four, five, or more, irregularly placed tubercles, or teeth, not agreeing precisely with the crown of the first species, but scarcely affording sufficient reason to form a generic distinction.

WEDENSCHWEIL, in *Geography*, a town of Switzerland, and principal place of a bailiwick, in the canton of Zurich, on the S.W. coast of lake Zurich; 9 miles S. of Zurich.

WEDGE, Cuneus, in *Mechanics*, the last of the five powers, or simple machines.

The wedge is a triangular prism, whose bases are isosceles acute-angled triangles.

Authors are divided about the principle whence the wedge derives its power.

Aristotle considers it as two levers of the first kind, inclined toward each other, and acting opposite ways. Guido Ubaldus, Mersennus, &c. will have them levers of the second kind. But Fr. de Lanis shews, that the wedge cannot be reduced to any lever at all.

Others refer the wedge to the inclined plane. Others, again, with De Stair, deny the wedge to have scarce any force at all; and ascribe much the greatest part to the mallet that drives it.

Its doctrine (according to some writers) is contained in this proposition. "If a power be applied to a wedge, in such manner, as that the line of direction C D (*Plate* XL. *Mechanics*, *fig.* 1.) perpendicular to A B, is to the resistance to be overcome, as A B to C D; the power will be equal to the resistance."

Or thus: "If the power directly applied to the head of the wedge, be to the resistance to be overcome by the wedge, as the thickness of the wedge is to its height; then the power will be equivalent to its resistance; and, if increased, will overcome it."

In proof of this proposition, they allege, that the firmness by which the parts of the obstacle, suppose wood, adhere to one another, is the resistance to be overcome by the wedge; and that while the wedge is driven into the wood, the way or length it has gone is B H (*fig.* 2.); and D C is the way or length gone in the same time, by the impediment; that is, the parts C and D of the wood are so far divided asunder: and according as the wedge is driven down farther and farther along its height; so the parts C and D of the wood are divided more and more, along the thickness of the wedge.

But Dr. Desaguliers has proved, that, when the resistance acts perpendicularly against the sides of the wedge, the power is to the whole resistance as the length of both sides of the wedge, taken together, is to the thickness of its back.

According to the preceding theory, if the thickness of the wedge (that is, the way of the impediment, and consequently its velocity) be to the height of the wedge (that is, the way, and consequently the velocity of the power) as the power to the impediment, or resistance; then the momentum of the power, and the impediment, will be equal the one to the other: and consequently the power, being increased, will overcome the resistance.

Hence, 1. The power equivalent to half the resistance, is to it as A C to D C, (*fig.* 1.) that is, as the whole sine to the co-tangent of half the angle of the wedge A D C. And 2. As the tangent of a less angle is less than that of a greater, the power must have a greater proportion to half the resistance, if the angle be greater than if less; consequently, the acuter the wedge is, the more does it increase the power.

The above proportion is adopted by Wallis, (Op. Math. vol. i. p. 1016.) Keil, (Int. ad Ver. Phys.) and S'Gravesande (El. Math. lib. i. cap. 14.); but S'Gravesande, in his Scholium de ligno findendo (ubi supra), observes, that when the parts of the wood are separated before the wedge, the force by which it is thrust in is to the resistance of the wood as a line, drawn from a point in the middle of the base to the side of the wedge, and at right angles with the side of the separated wood continued, to the height of the wedge; but when the parts of the wood are separated no farther than the wedge is driven in, the equilibrium will be, when the power is to the resistance as the half base of the wedge to its side.

To this method of estimating the power of the wedge it has been objected that, by allowing each part of the weight to have moved through a space equal to half the back of the wedge, whilst the power has moved through its height, and the whole weight to have moved through a space equal to the whole back, the whole is made to move farther than its parts.

M. Muschenbroeck states the proportion of the power to the weight in a simple wedge, or half the wedge (*fig.* 1.) bisecting it by a plane passing through C D, as its back is to its length, or in that case as A C to C D: and in a double wedge or the wedge A B D, as A B to 2 C D. Int. ad Phil. vol. i. p. 132.

Mr. Ferguson estimates the power of the wedge, in the two cases mentioned by S'Gravesande, in the following manner. When the wood does not cleave at any distance before the wedge, there will be an equilibrium (he says) between the power impelling the wedge downward, and the resistance of the wood acting against the two sides of the wedge, if the power be to the resistance as half the thickness of the wedge at its back is to the length of either of its sides; and if the power be increased so as to overcome the friction of the wedge, and the resistance arising from the cohesion or stickage of the wood, the wedge will be drove in, and the wood split asunder.

But when the wood cleaves at any distance before the wedge (as it generally does), the power impelling the wedge will be to the resistance of the wood as half its thickness is to the length of either side of the cleft, estimated from the top or acting part of the wedge: for supposing the wedge to be lengthened down to the bottom of the cleft, the power will be to the resistance as half the thickness of the wedge is to the length of either of its sides; or, which amounts to the same thing, as the whole thickness of the wedge is to the length of both its sides.

In proof of this proportion we may suppose the wedge divided lengthways into two equal parts, and then it will become two equally inclined planes; one of which, as *a b c* (*fig.* 3.) may be made use of as a half-wedge for separating the moulding *c d* from the wainscot A B. When this has been driven its whole length *a c* between the wainscot and moulding, its side *a c* will be at *c d*, and the moulding will be separated to *f g* from the wainscot.

From the property of the inclined plane, it appears, that to have an equilibrium between the power impelling the half-wedge and the resistance of the moulding, the former must be to the latter, as *a b* to *a c*; that is, as the thickness of the back which receives the stroke is to the length of the side against which the moulding acts. Consequently, since the power upon the half-wedge is to the resistance against its side, as the half back *a b* is to the whole side *a c*, it is plain,

plain, that the power upon the whole wedge (where the whole back is double the half back) muſt be to the reſiſtance againſt both its ſides, as the thickneſs of the whole back is to the length of both the ſides, ſuppoſing the wedge at the bottom of the cleft; or as the thickneſs of the whole back to the length of both ſides of the cleft, when the wood ſplits at any diſtance before the wedge. For when the wedge is driven quite into the wood, and the wood ſplits at ever ſo ſmall a diſtance before its edge, the top of the wedge then becomes the acting part, becauſe the wood does not touch it any where elſe. And ſince the bottom of the cleft muſt be conſidered as that part where the whole ſtickage or reſiſtance is accumulated, it is plain from the nature of the lever, that the farther the power acts from the reſiſtance, the greater is the advantage.

Some writers have, indeed, advanced, that the power of the wedge is to the reſiſtance to be overcome, as the thickneſs of the back of the wedge is to the length only of one of its ſides; but this, ſays Mr. Ferguſon, ſeems very ſtrange; for, if we ſuppoſe A B (*fig.* 4.) to be a ſtrong inflexible bar of wood or iron fixed into the ground at C B, and D and E to be two blocks of marble lying on the ground on oppoſite ſides of the bar; it is evident that the block D may be ſeparated from the bar to the diſtance *d* equal to *a b*, by driving the inclined plane or half-wedge *a b o* down between them; and the block E may be ſeparated to an equal diſtance on the other ſide, in like manner, by the half-wedge *c d o*. But the power impelling each half-wedge will be to the reſiſtance of the block againſt its ſide, as the thickneſs of that half-wedge is to the length of its acting ſide. Therefore the power to drive both the half-wedges is to the reſiſtances, as both the half backs are to the length of both the acting ſides, or as half the thickneſs of the whole back is to the length of either ſide. And, if the bar be taken away, the blocks put cloſe together, and the two half-wedges joined to make one; it will require as much force to drive it down between the blocks, as is equal to the ſum of the ſeparate powers acting upon the half-wedges when the bar was between them. Ferguſon's Lect. p. 40, &c. 4to. See alſo Deſag. Exp. Phil. vol. i. p. 107, &c.

Mr. Ludlam, in an Eſſay on the Power of the Wedge, printed in 1770, propoſes, with a particular view to the machines deſcribed by S'Graveſande, Deſaguliers, and Ferguſon, for eſtimating the power of the wedge, to determine this power, when two equal forces act on the ſides of an iſoſceles triangle in directions parallel to the back but oppoſite to each other, and are ſuſtained by a third force acting perpendicularly on the back of the wedge. For this purpoſe, let A B C (*fig.* 5.) be an iſoſceles wedge, whoſe angular point is C, ſides A C and B C, back A B, and perpendicular height H C: let F E repreſent the quantity and direction of the force applied to one of the ſides; this may be reſolved into two other forces F D and D E, the former parallel and the latter perpendicular to the ſide A C; and the oblique force F E will have juſt the ſame effect upon the wedge as a leſs perpendicular force D E; the former being to the latter as A C is to H C. But this laſt perpendicular force on the ſide A C is to that on the back which balances it as A C is to A H; whence compounding theſe ratios, the oblique force againſt one ſide of the wedge is to the perpendicular force on the back which balances it, as AC^2 is to $AH \times HC$. The oblique force *f e* on the other ſide of the wedge, being equal to F E, will require another perpendicular force on the back to balance it equal to the former perpendicular force; whence the whole force on both ſides of the wedge is to the whole force on the back as AC^2 is to $AH \times HC$; or as the ſquare of the ſide of the wedge to the rectangle under half the back and the perpendicular height.

For other methods of eſtimating the effect of the wedge in various caſes, ſee Mechanical *Powers*.

The wedge is a very great mechanical power, ſince not only wood but even rocks can be ſplit by it; which it would be impoſſible to effect by the lever, wheel and axle, or pulley; for the force of the blow or ſtroke, ſhakes the cohering parts, and thereby makes them ſeparate the more eaſily.

To the wedge may be referred all edge-tools, and inſtruments which have a ſharp point, in order to cut, cleave, ſlit, chop, pierce, bore, or the like; as knives, hatchets, ſwords, bodkins, &c.

Wedge, in *Ship-Building*, a triangular ſolid made of wood or iron. It is one of the mechanic powers, the moſt ſimple, and of the greateſt force.

WEDGE Island, in *Geography*, a ſmall iſland in the North Pacific ocean, near the E. coaſt of the Prince of Wales's Archipelago, in the Duke of Clarence's Strait. N. lat. 55° 8′. E. long. 228° 20′.

WEDGES, in *Agriculture*, are a ſort of levers or diſtending powers that are of great uſe to the farmer on many occaſions, as in tearing and ſplitting wood of all ſorts, the roots of trees in taking them out of the ground, ſtones, and many other ſorts of hard materials. About farm-houſes of any extent, it is always of advantage to have a proper mallet and ſet of wedges for tearing up wood and other matters.

WEDGWOOD, Josias, in *Biography*, was the younger ſon of a Staffordſhire potter, and born in July 1730. His education was reſtricted, but his mental powers were of a ſuperior kind, ſo that by the fixed and perſevering exerciſe of them he made very conſiderable improvement in the art of pottery to which his attention was directed, and gave a name as well as reputation to the place of his nativity. (See Pottery and The Potteries.) His patrimony was ſmall, but by his ſuper-eminent ſkill and ſteady application he was the founder of his own fortune as well as fame. The principal ſeat of the potteries of Staffordſhire was Burſlem; and there is reaſon to believe that they have exiſted in or near this place for many centuries, and even, as ſome ſay, ſince the time of the Romans. But they had continued for a long time in the ſame rude ſtate in which Plot found them when he ſurveyed this county. The merit of introducing into this country improvements in the art of pottery muſt be aſcribed to two brothers of the name of Eders, who came hither from Holland about the year 1700, and ſettled in the neighbourhood of the Staffordſhire potteries. They manufactured a red unglazed porcelain from a clay, which they found in the eſtate on which they ſettled, called "Bradwell;" but this was only the brown ſtone ware, in the compoſition of which no flint is uſed; but they made uſe of ſalt in glazing it: this ſalt, or muriate of ſoda, was thrown into the oven at a certain ſtage of the firing proceſs, and the pieces of ware were ſo diſpoſed as to receive the fumes of it on every part of their ſurfaces. The fumes, however, occaſioned an alarm in the neighbourhood, which obliged them to leave the country. A ſimilar manufactory, however, was ſoon after eſtabliſhed at Shelton, in the Potteries, by one of their workmen, whoſe name was Aſtbury, and who had poſſeſſed himſelf of their ſecret; and as it was found very uſeful, it was tolerated by the inhabitants, though on the day of glazing, the denſe offenſive fumes from fifty or ſixty manufactories filled the valleys, and covered the hills through an extent of ſeveral miles. The white ſtone ware, and

and the ufe of ground flints in pottery, were introduced at a later period, and, as it is faid, (fee Parkes's Chem. Catechifm,) in confequence of the following incident. About the year 1720, a potter, fuppofed to be the above-mentioned Aftbury, ftopped at Dunftable in his way to London, and fought a remedy for a diforder in his horfe's eyes; and the oftler of the inn by burning a flint ftone reduced it to a fine powder, which he blew into them. The potter, obferving the beautiful white colour of the flint after calcination, inftantly thought of applying the difcovery to the improvement of his art, and afterwards introduced the white pipe-clays found on the fouth fide of Devonfhire, inftead of the iron-clays of his own country, and thus produced the white ftone ware. At firft the flints were pulverized to the great injury of the perfons employed; till the famous Brindley, in the early period of his life, conftructed the mills that are now ufed for grinding them in a moift ftate. It is farther faid, that an ingenious mechanic, named Alfager, afterwards improved the conftruction of the potter's wheel, fo as to give much greater precifion and neatnefs to the work. But ftill the French pottery exceeded in beauty that of Staffordfhire; and about the year 1760, a confiderable quantity of it was imported, and purchafed by perfons of opulence to the great detriment of the Englifh manufacture. Mr. Wedgwood directed his attention to this article, and made feveral improvements with regard to the forms, colours, and compofition of his manufacture; and in the year 1763 invented a kind of ware for the table, which gave a turn to the market, and under the name of queen's ware, conferred upon it in confequence of the patronage of her majefty, came into very general ufe. Its materials were the whiteft clays from Devonfhire and Dorfetfhire, mixed with ground flint, and covered with a vitreous glaze. By varying and repeating his experiments, Mr. Wedgwood difcovered the mode of manufacturing other fpecies of earthenware and porcelain, excellent and beautiful, and adapted to various purpofes both of ufe and ornament. With a view of profecuting his improvement in pottery he applied to the ftudy of chemiftry, and for his farther affiftance engaged the ingenious Mr. Chifholme, who had been employed in a fimilar department by the celebrated Dr. Lewis, author of the "Commercium Philofophico-Technicum;" for whom he not only built a comfortable habitation near the manufactory, but liberally afforded him an annuity for his fupport under the decays of age, which he continued till his death. Aided alfo by the claffical tafte of his partner, Mr. Bentley, potteries were furnifhed which ferved as models for various articles, formed of other materials, that were held in high eftimation. We learn from Dr. Bancroft, that almoft all the finely diverfified colours which Mr. Wedgwood applied to his pottery were produced only by the oxyds of iron. In the manufacture of his beautiful jafper ware, which rivalled the productions of antiquity, and which found its way into the collections of the curious in all parts of Europe, he employed the native fulphate of barytes, and from this ufe of it he derived great profit, until by the infidelity of a fervant the fecret was difclofed and fold, fo that others employed inferior workmen at a reduced falary, and thus prevented Mr. W. from employing his exquifite modellers on that branch of the manufacture.

Among other curious productions of this inventive manufacturer we may mention his imitation of the Barberini or Portland vafe, which was difcovered in the tomb of Alexander Severus, and for which the late duchefs of Portland paid 1000 guineas. The fubfcription for Mr. W.'s manufacture was at the rate of 50*l.* each for fifty vafes, but fuch were the expences of its execution, that the partners loft money by the undertaking. Mr. Webber, it is faid, received 500 guineas merely for modelling it. See VASE.

We cannot forbear in this connection noticing two cameos of Mr. Wedgwood's manufacture; one of a flave in chains, of which he diftributed many hundreds, with a view of exciting the humane to affift in the abolition of the flave-trade; and the other a cameo of Hope, attended by Peace and Art and Labour, which was made of argillaceous earth from Botany Bay, to which place he fent many of them, in order to fhew what their materials were capable of, and to encourage the induftry of the inhabitants.

To this brief account of fome of the numerous productions of Mr. Wedgwood, we fhall fubjoin the tribute paid to his induftry and genius by an elegant modern poet:

"Gnomes! as you now diffect with hammers fine
The granite rock, the noduled flint calcine;
Grind with ftrong arm, the circling chertz betwixt,
Your pure kaolins and petuntfes mixt;
O'er each red faggar's burning cave prefide,
The keen-eyed fire-nymphs blazing by your fide;
And pleafed on Wedgwood ray your partial fmile,
A new Etruria decks Britannia's ifle.
To call the pearly drops from Pity's eye;
Or ftay Defpair's difanimating figh,
Whether, O Friend of Art! the gem you mould
Rich with new tafte, with ancient virtue bold;
Form the poor fetter'd flave on bended knee
From Britain's fons imploring to be free;
Or with fair Hope the brightening fcenes improve,
And cheer the dreary waftes of Sydney-cove;
Or bid Mortality rejoice and mourn
O'er the fine forms on Portland's myftic urn.
Whether, O Friend of Art! your gems derive
Fine forms from Greece, and fabled gods revive;
Or bid from modern life the portrait breathe,
And bind round Honour's brow the laurel wreath;
Buoyant fhall fail, with Fame's hiftoric page,
Each fair medallion o'er the wrecks of age;
Nor Time fhall mar, nor Steel, nor Fire, nor Ruft,
Touch the hard polifh of the immortal buft."

The demand for Staffordfhire ware very much increafed, and it became a commercial article of exportation of very confiderable value.

The diftrict which Mr. Wedgwood inhabited became by his means the feat of population and abundance. The vicinity was enriched, and a new canal of importance, called the Grand Trunk canal, and connecting the Trent and the Merfey, was obtained and executed by his influence. The ample fortune which he acquired was liberally enjoyed, and benevolently applied to many purpofes of private charity and public utility. Chemiftry and the arts in their mutual connection were objects of his attention; and he contrived an inftrument for meafuring high degrees of heat, called a pyrometer, of which he gave an account in the Phil. Tranf. for 1782, 1784, and 1786. See THERMOMETER.

The difpofition and manners of Mr. Wedgwood were no lefs eftimable than the powers of his mind; fo that he was as much the object of admiration and efteem for his moral as for his intellectual qualities. So much was he refpected, and fo defirable was the continuance of his ufeful life, that he died, univerfally regretted, at his houfe in Staffordfhire, to which he gave the name of Etruria, in January 1795, in the 65th year of his age. Aikin's Chem. Dict. Gent. Mag. Parkes's Chemical Catechifm. Parkes's Effays.

WEDINOON, in *Geography*, a diftrict of Sufe in the fouthern divifion of Morocco, inhabited by a tribe of Arabs. This

This territory is adjacent to the river Akaffa, called by fome Wed Noon, that is, the river of Noon. Jackfon ftates the population of Wedinoon at 200,000 perfons. In this diftrict the fovereignty of the emperor of Morocco is fcarcely acknowledged; and the difficulty of paffing an army over that branch of the Atlas, which feparates Sufe from Haha, fecures to the Wedinoonees their arrogated independence. Wedinoon is a kind of intermediate depot for merchandize on its way to Soudan, and for the produce of Soudan conveyed to Mogodor. Gums and wax are produced here in abundance; and the people, living in a ftate of independence, indulge in the luxuries of drefs, and ufe many European commodities. A great quantity of gold duft is bought and fold at Wedinoon. The inhabitants fometimes trade to Mogodor, but prefer felling their merchandize on the fpot, as they do not wifh to truft their perfons with property within the territory of the emperor of Morocco. With Tombuctoo they carry on a conftant and advantageous trade, and many of the Arabs are immenfely rich. They alfo fupply the Moors of Morocco with (ftatas) convoys through the defert, in their travels to Tombuctoo. The coaft of Wedinoon extends a long way to the fouthward, nearly as far as Cape Bojador. The river Akaffa, commonly called the river of Non or Nun, and in fome maps Daradus, is a large ftream from the fea to the town of Noon, which is about fifteen miles inland, and about two miles in circumference: from hence the river becomes fhallow and narrow; and it is to the fouthward of this river that fhips are generally wrecked. The diftrict of Wedinoon is nominally in the dominions of the emperor of Morocco; but lately an army having been fent farther fouth than Terodant, and the Pacha Alkaid Mahommed ben Delamy being dead, that diftrict has fuffered neglect, and the people pay no tenth, according to the mode of raifing taxes in Weft Barbary, *viz.* ten *per cent.* on the produce of the land, and two *per cent.* on that of cattle; and the emperor has recently ordered his Pacha of Haha to purchafe the Britifh flaves that had been wrecked there. This place being only thus nominally in his dominions is another impediment to the redemption of the failors who happen to be fhipwrecked about Wedinoon; for if the emperor had the fame authority over this diftrict, that he has over the provinces north of the river Sufe, meafures might be adopted by the conful, acting under his orders, for their delivery, without pecuniary difburfements. Jackfon's Morocco. See Vled de Nun.

WEDLOCK. See Marriage, Wife, Husband, &c.

WEDNESBURY, in *Geography*, an ancient market-town in the fouth divifion of the hundred of Offlow, and county of Stafford, England, is fituated at a fhort diftance from the fource of the river Tame; 19 miles S.S.E. from the county-town, and 125 miles N.W. from London. In the time of the Mercians, this place had a noble caftle, which was fortified by Adelfleda, who was for fome time governefs of this extenfive kingdom: but no part of the fortrefs now remains, except a few traces of its foundations. At the Norman Conqueft, the manor became a portion of the royal demefnes. Henry II. beftowed it on the family of the Heronviles, from whom it paffed, after various fucceffions, to the Beaumonts. The town is diftinguifhed for its numerous and valuable manufactures, the principal of which are of guns, coach-harnefs, iron axle-trees, faws, trowels, edge-tools, bridle-bits, ftirrups, nails, hinges, fcrews, and caft-iron works of every defcription. For their proficiency in thefe various branches, the inhabitants are chiefly indebted to the abundance and excellence of the coal obtained in the immediate vicinity. This coal is indifputably the beft in the kingdom for the fmith's forge, on account of the intenfe heat which it produces. It extends in a variety of feparate veins or ftrata, which are particularized by the miners with the greateft accuracy. Here is alfo found that peculiar fpecies of iron-ore denominated blond-metal, ufed in the manufacture of horfe-fhoes, hammers, axes, and heavy tools. Some fpots likewife abound with a fort of reddifh earth, called hip, employed in painting and glazing veffels of various kinds. A weekly market on Wednefday affords the town a plentiful fupply of all kinds of provifions. The population of the parifh, in the return of the year 1811, was ftated to be 5372, the number of houfes 1004. One of the collateral branches of the Birmingham canal, entering this parifh, affords the inhabitants great facility of commercial communication. The church is an ancient ftructure, and fome writers abfurdly relate, that it was built in the year 711, by Dudo, lord of Dudley. At one end rifes a tower, fupporting a lofty fpire: the interior is divided into a chancel, nave, and two aifles; the latter are feparated from the nave by a range of arches, fupported by octagonal pillars. In the chancel are feveral prebendal ftalls, ornamented with exquifite carved work. Here is alfo a variety of monuments in honour of the anceftors of the Dudley and Harcourt families, and feveral other ancient tombs and memorials. Round the church-yard fome veftiges of the caftle may be diftinctly traced.—Shaw's Hiftory of Staffordfhire, folio, 1798. Beauties of England and Wales, vol. xiii. Staffordfhire, 1811.

WEDNESDAY, the fourth day of the week, formerly confecrated by the inhabitants of the northern nations to Woden or Odin, who, being reputed the author of magic and inventor of all the arts, was thought to anfwer to the Mercury of the Greeks and Romans, in honour of whom they called the fame day *dies Mercurii.*

Wednesday, *Afh.* See Ash-*Wednefday.*

WEDNOCH, in *Geography*, a river of England, which joins the Wever, near Northwich, in Chefhire.

WEDUM, a town of Sweden, in Weft Gothland; 18 miles S. of Skara.

WEE-CHAUNG-HOO, an extenfive lake of China, which divides the province of Shan-tung from that of Kiang-nan, and fupplies an adjoining canal when it is deficient of water. This lake affords a charming profpect, particularly at fun-rife; when its borders fringed with wood-houfes and pagodas on the floping grounds behind, and the furface of the water almoft covered with veffels croffing it in different directions, and by all the various modes of navigation that poles, paddles, oars, and fails, could furnifh, are exhibited to advantage. Fifhing forms a confiderable part of the occupation of the people on this lake, and they have various modes of conducting it. Befides nets, which are in moft common ufe, they have another method, which is more fingular: to one fide of a boat a flat board, painted white, is fixed at an angle of about forty-five degrees, the edge inclining towards the water on moon-light nights; the boat is fo placed that the painted board is turned to the moon, from whence the rays of light ftriking on the whitened furface give it the appearance of moving water, on which the fifh being tempted to leap as on their element, the boatman raifing with a ftring the board, turns the fifh into the boat. Water-fowl are alfo taken upon this lake by a peculiar device. Empty jars or gourds are fuffered to float upon the water, that fuch objects may become familiar to the birds; the fifherman then wades into the lake with one of the empty veffels on his head, and walks gently towards a bird, and lifting up his arm draws it down below the furface of the water, without difturbing or alarming the reft, and thus prefently fills the bag with which he was provided for fecuring his prey. A fimilar practice exifts, as we learn from Alloa, among the nations of Carthagena, upon the lake Cienego de Terias. Staunton's Embaffy, vol. ii.

WEED, in *Agriculture* and *Gardening*, any fort of uncultivated and unprofitable plant or vegetable which grows in ground, and which, in confequence of the mifchief it does, requires to be extirpated and deftroyed.

Weeds may be diftinguifhed, according to the different periods of their duration, into the *annual*, *biennial*, and *perennial* kinds.

The firft divifion comprehends all fuch as die after perfecting their feeds in the firft year. Weeds of this clafs, though abundantly productive in feeds, and confequently in plants, are capable of being deftroyed without any great difficulty.

The fecond divifion includes all fuch weeds as endure a greater length of time than one year, and which after perfecting their feeds in the fecond year perifh. Thefe, like the former, are in general abundant in the production of feeds as well as plants, but they are deftroyed with greater difficulty.

The third divifion comprifes all thofe weeds which are capable of continuing many years. Some of which have the property of perfecting their feeds annually, without being thereby deftroyed: while others, lefs prolific in feeds, have the faculty of reproduction in their vivaceous roots; and there are others that are capable of increafe both by feeds and roots. The plants of this clafs are therefore much more troublefome and difficult of deftruction than the others.

In the nature and vegetation of the feeds of weeds of different forts, there is confiderable diverfity. Some are found to fprout forth as foon as they have a fufficient degree of moifture, fending down their roots though not in exact contact with the earth; others only begin to germinate when they are depofited and inclofed in a fuitable foil, and have the proper influence of the atmofphere; and there are many of thefe kinds of feeds, even of the very fmall fort, which are capable of remaining in a dormant or inactive ftate for a very confiderable length of time, and afterwards vegetate on being placed in a favourable fituation, in regard to the influence of the air, and other matters.

There are other feeds of weeds, too, which are provided with a foft feathery material which performs, in fome meafure, the office of wings, by which they are conveyed from their native fituations, and differninated over lands and places at a confiderable diftance.

There is likewife a difference of fome confequence in the vivaceous roots of vegetable weeds; fome being branched, others entire; fome defcending directly downwards, others inclining; fome fibrous, others tuberous; fome creeping, others knotted or jointed, &c.

The great variety and multiplicity of weeds render it a difficult matter to arrange them in any ufeful manner for the purpofes of the farmer, as different forts of them are found to prevail in different fituations and kinds of land. A late intelligent writer has, however, confidered them as affecting gardens; corn-fields and tillage-lands; meadows and paftures; wafte and uncultivated grounds; the hedges of inclofures; and woods and plantations.

Weeds injurious to garden grounds are chiefly thefe:

Couch-grafs, or which in fome places is known by the names of twitch, fquitch, and many others, and which not unfrequently comprehends the creeping roots of the hardy perennial graffes, which are particularly tenacious of growth, as dog's-grafs, white bent-grafs, tall oat-grafs, and fome others. Of which, the two firft are readily diftinguifhed by their flowering ftalks, as well as by the ears which contain the feeds; and the laft has been obferved to have a bulbous-jointed root, that affords fhelter to various deftructive grubs, worms, and infects: they fhould all be carefully rooted out and deftroyed. Thefe are to be deftroyed in gardens by carefully picking out the roots in digging, and as carefully rooting up whatever remaining fragments of the roots may fend out a fhoot above the ground. Thefe fhould never be allowed to get to any height, but be exterminated as foon as poffible. See TRITICUM *Repens*, AGROSTIS *Alba*, AVENA *Elatior*, &c.

Suffolk-grafs, or dwarf meadow-grafs, is another grafs, which, though ufeful in paftures, is a very pernicious weed in gardens and places about houfes. It is common in places where the furface is not liable to be often difturbed by means of cultivation. Its prolific quality, in refpect to feeds, is fo great, that it is faid to be capable of producing and reproducing itfelf four times in the courfe of one fummer. It may be deftroyed by rooting it out before its feeds are perfected and fhed about, otherwife the vegetation of them will be fo abundant and extenfive as almoft to bid defiance to the powers of the weeder. See POA *Annua*, &c.

Catchweed, or what in different fituations is called goofegrafs, cleavers, hariff, &c. is fometimes a troublefome garden weed, but it is more common in the hedges. This is a weed that may be readily deftroyed in garden-grounds, by pulling it up before the feeds are perfected.

It is faid that young geefe are very fond of the tender branches of this weed; and that the feeds of it are capable of being ufed inftead of coffee. See GALIUM *Aparine*.

Garden night-fhade is faid to be a common weed in the garden-grounds about Chelfea and Brompton, but which is feldom found in thofe in the country, though fometimes met with on dung-hills, and other fuch places. See SOLANUM *Nigrum*.

Goofefoot, which is a weed of the wild orache defcription, is common and luxuriant in many garden-grounds, being very prolific in feeds, and in the produce of weeds therefrom, if not rooted out before the feeds are fcattered about on land under cultivation. Thefe, like all other annual feedling weeds, is to be deftroyed only by rooting up before the feeds of it are fcattered. See CHENOPODIUM *Album*, *Viride*, and *Hybridum*.

Wild orache, or fat-hen, is a weed nearly allied to the above, and from which it is diftinguifhed only by fome of the flowers having pointals only, while others on the fame weed-plant have both chives and pointals, in common with the above fort of weeds. The flowers are fmall, fo that this diftinction can only be afcertained by the microfcope. It is a weed which grows much in kitchen-gardens, on rubbifh, and on dung-hills; is an hardy annual, very fertile in feeds; and which is to be prevented or deftroyed in the fame way as the above kinds. See ATRIPLEX *Haftata*.

Fools' parfley, or leffer hemlock, is a weed common in gardens, and which, in its early growth, has much refemblance to parfley, for which it is often miftaken, and when eaten occafions ficknefs, fwelling, and uneafinefs about the ftomach: it fhould always be rooted out of garden-ground, when it is running to feed, as at that time it is eafily known and beft deftroyed. See ÆTHUSA *Cynapium*.

Knot-grafs is a weed that fometimes grows much on the gravel-walks of gardens and pleafure-grounds, trailing to a confiderable length in all directions, being very prolific in feeds, which readily take root. It is, therefore, neceffary to root it well up before they become ripe: hogs are

are ſaid to be very fond of eating it. See POLYGONUM *Aviculare.*

Ground-aſh is ſaid to be a very troubleſome weed in the garden-grounds in the neighbourhood of London; but which ſome ſuppoſe to be moſtly confined to the ſhade of hedges. It is believed to be perennial in its nature. In order to get rid of it, the beſt mode is to cut it up on its firſt appearance. See ÆGOPODIUM *Podragraria.*

Chickweed is a weed that ſometimes grows with great rapidity, and in a very luxuriant manner on garden-ground that is much pulveriſed and reduced by operoſe cultivation by the ſpade, and which is much enriched by good manure: it is an annual weed, very productive of ſeeds, and where it abounds much, it is perhaps improper to give the land or ground a fine culture until it in ſome meaſure diſappears: ſwine are extremely fond of this weed, and it is ſaid to be a grateful food for young chickens. See ALSINE *Media.*

Black-bind-weed in ſome places is called bear-bind. It is a paraſitical weed-plant, often climbing up bean and other garden crops: it is hardy, and extremely prolific in ſeeds. To keep garden-ground clear of it, the ſeeds ſhould never be ſuffered to ſhed or ſow themſelves: the ſeeds contain a white flower, and are ſaid to be good for pigeons, poultry, and ſmall birds of different kinds. See POLYGONUM *Convolvulus.*

Sun ſpurge is an annual weed, ſaid to be not very troubleſome or difficult of eradication, yet not uncommon in garden-grounds. See EUPHORBIA *Helioſcopa*, &c.

Red dead nettle, or dee nettle, is a weed of the annual kind, according to ſome, but which others conſider as a perennial. It is common in garden-grounds, flowering early, and for the greater part of the year. The ſeeds ſhould not be ſuffered to ſhed or diſperſe themſelves over the ground, but the weeds be cut up as ſoon as they appear. See LAMIUM *Purpureum.*

Henbit is an annual garden-weed, that ſhould likewiſe be weeded out before the ſeeds of it are perfected and ſcattered. See LAMIUM *Amplexicaule.*

Nettle hemp is a weed of the luxuriant, diſagreeable, garden kind, that ſhould always be rooted out of the ground, and kept under in time to prevent its future miſchief. See GALEOPSIS *Tetrahit.*

Garden ſow-thiſtle is a common weed of luxuriant growth, doing great injury to the cultivated crops. It is directed that the ſeeds of this weed ſhould never be ſuffered to ſhed and ſpread themſelves in any ſituation; for, being furniſhed with feathers, they fly over a country with the wind, diſſeminating themſelves widely, and vegetate on the firſt looſe or cultivated ground on which they ſettle. It is a favourite food with rabbits and hogs. See SONCHUS *Oleraceus*, and THISTLE.

Fumitory is a common, though not very injurious or hurtful weed. It is an annual, and may, conſequently, be deſtroyed by preventing its ſeeding in an effectual manner. See FUMARIA *Officinalis.*

Common thiſtle is a diſagreeable and troubleſome weed; the ſeeds of which are numerous, and provided with a downy material to carry them any diſtance before the wind. They ſhould be drawn up by the roots in moiſt weather with forceps or tongs for the purpoſe, as they cannot be pulled by the naked hand.

Garden-grounds are always to be kept well freed from weeds of this ſort by all proper means. See SERRATULA *Arvenſis*, and THISTLE.

Groundſel, which is another very common and troubleſome weed in garden-grounds, and the ſeeds of which are feathered, as in the former caſe, being capable of ſowing and ſpreading themſelves far and near, with this farther chance of propagating themſelves, that the plant or weed is extremely quick of growth. The eradication of this weed from gardens muſt conſequently require unremitting attention, by cutting up the young plants as ſoon as ever they can be diſcovered, and letting them run to ſeed as little as poſſible. See SENECIO *Vulgaris.*

Common nettle is a weed that generally grows in hedges or other ſhady places, but which ſometimes appears in other places and in garden-grounds; in which caſes, it muſt be deſtroyed by rooting it up in a complete manner. The leaves of this weed, when cut ſmall, may, it is ſaid by ſome, be mixed with the food of turkeys, and other poultry, with benefit. See URTICA *Dioica.*

Miſletoe may be ranked as a garden-weed, and is very common on fruit-trees, and it is ſaid to be very hurtful in preventing their bearing; it ſhould, of courſe, be pulled off in time, ſo as to prevent that ſort of injury. It is ſometimes, too, plucked off as a ſheep-food in the winter, in hard ſtormy ſeaſons. See VISCUM *Album.*

Cultivated early potatoe, though it cannot be properly ranked as a weed, is often troubleſome in gardens. It is ſaid, that however valuable as a crop, it is very apt to remain in the ground, and intrude itſelf among other after-crops, to their injury, as well as giving a ſlovenly appearance to the culture. As, however, it is now found that the ſhoots of this root will crop well after being tranſplanted, it would ſeem to be the beſt way to have them taken up from among other crops as they appear, taking the advantage of ſhowery weather, and putting them into a bed by themſelves, where they may ſucceed ſome early crop, ſuch as winter greens, ſpinach, forward cabbage, and ſuch like, by which means other crops may be rendered clean, and theſe roots be provided without any expence of ſeed or ſets. See SOLANUM *Tuberoſum*, and TRANSPLANTING.

Weeds injurious in Tillage and Corn Lands.—The principal of thoſe weeds which decidedly infeſt and injure grounds under the plough are thoſe given below.

Ivy-leaved chickweed is a weed that is ſaid ſometimes to abound very much amongſt wheat very early in the ſpring, but that as feeding and leaving the ground early, may perhaps not much injure the crop: the ſeed is aſſerted to ripen in twenty-eight days from the firſt vegetation of it and the ſpringing up of the plant, which moſtly appears in the month of March, and often ſends forth a plentiful produce of ſeeds, which will lie in the gronnd many years, ready to vegetate the next time the land is broken down and pulverized early in the ſpring: this ſort of work ſhould, therefore, in this caſe, be done in the fallow, where that practice is in uſe, which would occaſion the ſeeds to vegetate; but in other caſes it may be deſtroyed by being ploughed under before the ſeeds of it begin to ripen. See VERONICA *Hederifolia.*

Lamb's lettuce, or corn-ſallad, is a weed that has lately been obſerved to be more frequent in ſome diſtricts than formerly. It has been found in a hard tilled field in great abundance. It is an annual weed; and, though not very formidable, ought to be removed from tillage-lands, as it takes away a portion of the nouriſhment belonging to the cultivated crops. This may pretty readily be done by pulling or cutting it up, or turning it under by the plough, where it can be uſed, before the ſeeds of it be perfectly formed. See VALERIANA *Locuſta.*

Couch of tillage-land is the produce of the three graſſes already noticed in a ſimilar title, under the head of garden-weeds, with the addition of the roots of the creeping ſoft

graſs,

grafs, and probably fome others. It is faid to be the plague of arable cultivation; and that the roots of thefe weeds are fometimes fo interwoven together in the land or foil in ground that has been under hard tillage and bad management, as to form a perfect matting, and to choak the plough: they abound moft, it is obferved, in light and mixed foils, not infefting ftrong clays in an equal manner. The arable land fquitch-grafs, which is the moft general, is, it is faid, of the *agroftis* family; but to which particular fpecies or fort that the moft complained of by farmers belongs, is not yet well agreed upon. Some refer it to the fine bent, while others affert it to be a variety of the white. And there are others of great authority who think this fquitch-grafs has never yet been rightly fpecified or referred. The ear or awn of this grafs has, however, been often obferved to have the general habit of the *agroftis*; and that it is very probable that more fpecies than one of this genus have the property of running in the roots, and producing couch.

It is noticed, in addition, that the creeping red-ftalked bent grafs, and the creeping foft grafs, are common fquitch or couch-graffes on ftrong or cold wet tillage-lands; and that the tall oat-grafs is a very ufual fquitch-grafs, on the light gravelly foils of fome neighbourhoods; that its roots are compofed of a bunch of bulbs, which afford fhelter to pernicious vermin, as already feen; and that it is difficult of eradication, and very pernicious to crops, efpecially in wet feafons.

The *dog-grafs couch*, which, in the county of Salop, is often termed *fcutch*, is very common every where, and well-known to the coft of the farmers.

Withering, after obferving that it can only be deftroyed by fallowing in a dry fummer, ftates, that at Naples the roots are collected in quantity, and difpofed of in the market to feed horfes. The tafte is much fimilar to that of liquorice, dried and ground into meal, which has been made into bread in years of fcarcity. They have befides a detergent quality, and may be ufeful in the difeafed livers of animals.

However, thefe graffes, though fo troublefome and injurious as weeds on arable lands, are yet probably good as affording meadow-herbage, where their roots are not fo liable to run or fpread themfelves as on tillage-land that is loofened, broken, and reduced, by being conftantly wrought by the plough, and other tools.

The deftruction of weeds of this fort on arable land, is chiefly effected by the free ufe of the plough, and other fuitable implements, when the weather is in a proper ftate of heat for the purpofe: fome think the bufinefs can only be effected by giving an early and complete fpring and fummer fallow, by repeated ploughings in time of hot weather, with fufficient harrowings between each ploughing, to work out the fquitch, and bring it to the top; and that unlefs the fummer prove dry for fome length of time, even this will be infufficient; in which cafe, many active and induftrious farmers have it forked together by hand and burnt: others have it collected and carried into heaps to rot; and it is fometimes mixed with quick-lime, and reduced into a fort of compoft heap, which is a practice to be much commended, as wholly deftroying it, and at the fame time converting it to ufe: it fhould not, however, be forgot, that the great increafe of the roots of thefe weeds is occafioned by hard tillage, or bad management, and often by both. In the county of Gloucefter, it is faid by the writer of the corrected account of the agriculture of that diftrict, to be a moft troublefome and almoft unconquerable weed on clay-lands, but that on light lands and loams it may be dragged out and finifhed by hand-picking with tolerable eafe; while on the ftiff foils, and particularly in the wet furrows, nothing but repeated ploughings and expofure to the heat of the fun during the fummer can check the increafe of it; hence, in that county, the vale-lands, after a wet fummer, are generally foul. A crop of fpring-vetches is faid to be well fuited to fmother and keep it down, and other fmothering green crops may be had recourfe to in the fame intention. See Triticum *Repens*, &c. Alfo Agrostis *Stolonifera*, Holcus *Mollis*, &c.

Wild oat, or haver, is a common weed on hard tilled land, and when abundant, very unfightly and injurious to a crop. It has been obferved by Dr. Anderfon, it is faid, that this weed-plant abounds fo much in the corn-fields in moft parts of Aberdeenfhire, as in many cafes to conftitute nearly one-half of the bear or fix-rowed barley-crop, which is much grown in that part of the kingdom: it may be deftroyed or greatly reduced by the turnip-culture, or by well-managed early fallowing; and prevented by fhort tillages, and frequent feeding down to grafs. Dr. Withering, and the Flora Ruftica, have ftated, that the awns of it are ufed for hygrometers, and the feeds inftead of artificial flies in fifhing for trout. The author of the Corrected Report of the Agriculture of the County of Gloucefter ftates, that it is the growth of particular diftricts, and that it cannot be deftroyed; that in fields where the greateft care has been taken to hand-pull every ftalk, it has appeared in the following year in equal abundance. That in new broken up leys, which have been in turf or fward beyond the memory of man, thefe weeds often fpring up with as much luxuriance as if they were the natural produce of the foil. When the land is planted with beans or peas, hoeing will check and reduce them; but when they grow among wheat, it is not eafy to diftinguifh the plants while young; and that in this cafe, they are left until they are nearly in ear, and are then drawn out by the hand. See Avena *Fatua*.

White darnel is a weed not unfrequently found in wheat-crops, though, it is believed, almoft always produced from the feed of it fown with that grain, to prevent which, confequently, great attention fhould be paid to clean feed-wheat, and particularly that it contain none of the feeds of this weed, as it is extremely prolific, very injurious to a crop while growing, and to the value of the produce at market. It is an annual weed, which has never been recollected to have been feen growing, except in a crop, and but rarely there without neglect in the management of the feed grain, and in other ways. See Lolium *Temulentum*.

Goofe-grafs, or catchweed, &c. is a weed in tillage-land, the feeds of which are roundifh, rough, two from each flower, fo large as not all to be eafily feparated from the grain in dreffing. This weed is not very common in well-managed lands and crops, being more generally reftricted to the hedge banks. It is obferved, in the Gloucefter Corrected Agricultural Survey, to be a troublefome and frequent weed, on all forts of foils among corn, and which is not eafily deftroyed, except by much early care and attention. See Galium *Aparine*, and *Spurium*.

Field fcabius is a weed found fometimes in corn-fields, as well as paftures, though not very abundant. See Scabiosa *Arvenfis*.

Parfley-piert is a diminutive weed of but fmall account, though fometimes too much abounding in tillage-lands. This weed might probably be weakened and leffened when in too great quantity by pulverifing and reducing the foil well when in fallow, very early in the fpring feafon, and by ploughing

ploughing it under in due time, fo as to prevent its feeding. See APHANES *Arvenfis*.

Dodder is a parafitical weed, that is faid not to be uncommon, in fome diftricts, in the corn-lands. This weed has been obferved twining round the ftems or ftalks of a bean crop in the county of Buckingham, climbing in a fpiral direction round them, from which, by means of veffels for the purpofe, it draws its nourifhment and fupport, and muft, confequently, very much fret and injure any plant to which it may attach itfelf: it is called in different places, as ftated by writers on hufbandry, beggar's-weed, hell-weed, and devil's guts, names which fufficiently fhew in what fort of eftimation it is held by farmers. It is an annual weed, and produced from feed, which takes no root in the earth, but in fome part of its fofter-plant. It is remarked, by the author of the Corrected Report on Agriculture for the County of Gloucefter, to be a great enemy to beans, vetches, and fome other fuch plants, but is never there feen among wheat, barley, or oat-crops. That as foon as it has fixed itfelf upon the plant, it feparates from the root, and, like other parafitical weeds, draws all its nourifhment from the plant it has fo fixed upon and embraced. Large quantities of beans are, it is faid, often ruined completely by it, fo as not to carry a fingle pod; and that no method has yet been difcovered to deftroy it; for though the root cannot be found, yet it furely returns, it is thought, in fome part of the field where it has once begun to grow, whenever the plants on which it feeds, form the crop of the feafon. Sheep, in fome cafes, have been found ufeful in leffening it, by feeding upon it and breaking its runners, when they can be turned into the land where it prevails. See CUSCUTA *Europæa*.

Corn bind-weed is another troublefome parafitical weed in arable-land, often growing amongft wheat, and, when abundant, twining round the ftalks of the corn, and very much injuring the crop, when the wheat has been laid by heavy rain. It is faid not to be fo common in fome of the midland counties, as in fome of thofe nearer the metropolis, whence they are in the habit of procuring and being fupplied with feed-wheat; on which account it has fometimes been feared that it might be introduced more abundantly by fuch means: but as the feeds are fmall, they may eafily be dreffed out in cafe of fuch accidents. It is a perennial weed, and much addicted to running in the root. It has been proved by an experienced writer, that cutting it off, even below the furface of the ground, only tends to fpread it farther: it muft be reduced and deftroyed, if poffible, by means of fallowing, and ufing the fame procefs as for couch or fquitch. In fome diftricts this weed is moft frequently found in clays and deep loams, in which the roots ftrike fo down, that even trenching two fpits and an half deep will not, it is faid, reach their extremities; and that the fmalleft bit of a root left in the ground will fpring and rife to the furface. It entwines round and entangles all plants in fuch a manner, as either to bring them to the ground, or check their vegetation, by injuring their ftructure on the furface of it. See CONVOLVULUS *Arvenfis*.

Wild carrot is a common and fometimes a troublefome weed, in dry tillage-land. It is a biennial weed-plant, producing feed in a plentiful manner. Though fome, as Withering, affert that this, in its cultivated ftate, is the common well-known garden carrot; yet others, as Miller, contend that the wild carrot could never be improved fo as to render the roots in any degree comparable with the cultivated carrot. However this may be, where it is found in quantity, it fhould be prevented from feeding, in order to reduce it, and bring it properly under, which may be effected by cutting or pulling it up in its early growth. See DAUCUS *Carota*.

Shepherd's needle, or beggar's needle, is a weed fometimes abounding in hard tilled land, and the feeds of which are not wholly feparable with eafe from grain in dreffing. It is a fmall annual weed, that produces a plentiful crop of feeds, each feed being furnifhed with a fpike or beak of from one to two inches long, whence its name of needle. It feldom abounds much in well cultivated and managed land. See SCANDIX *Pecten*.

Chickweed is, in fome cafes, a troublefome weed in a crop on land which has been rendered fine by tillage, and from which it fhould, therefore, be rooted out. It has been remarked by the Rev. Mr. Shaw, it is faid, that this weed is an excellent out-of-door barometer:—that when the flower expands boldly and fully, no rain will happen for four hours or upwards; that if it continue in that open ftate, no rain will difturb the fummer's day; that when it half conceals its miniature flower, the day is generally fhowery; but that when it entirely fhuts up, or veils the white flower with its green mantle, let the traveller put on his great coat, and the ploughman with his beafts of draught reft and retire from their labour. In Gloucefterfhire it is ftated that it grows moft plentifully on the good and well cultivated lands. It there mats fo clofely round the plants, and covers the furface fo completely, as to keep out the influence of the fun and air; and confequently requires to be removed, which is moftly beft performed by the hoe. It may be thus kept under, if not wholly removed and deftroyed. See ALSINE *Media*.

Curled dock is a mifchievous weed in tillage-land, and fhould never be fuffered on any account to feed its feeds, and fpread them on any land, but be rooted up and carried off in time, to prevent injury. In arable ground, the roots are beft picked off with care during the time the land is in tillage, as they will otherwife produce vigorous luxuriant plants which will draw much nourifhment from the foil, to the great injury of the ground, and of the intended crop. It is a hardy perennial weed, which is very tenacious of growth by its roots, and producing a wonderful increafe of feeds: too much caution cannot, therefore, be ufed to avoid fowing it, nor too much pains be beftowed in its extirpation and deftruction. Withering afferts it to be the peft of clover-fields in Norfolk. See RUMEX *Crifpus*.

Arfmarts, or lake weeds, are plants of this kind, fometimes met with on the wetter forts of arable lands. They abound moft in wet feafons, on the heavier and more moift forts of ground; and as being hardy annuals, producing a plentiful fupply of feeds, are apt to fhew themfelves in the crops of grain. They are weeds which are to be deftroyed by proper fallowing, by the removing of the wetnefs of the land, and by the rooting out of the plants in proper time to prevent their feeding. See POLYGONUM *Perficaria*, and *Penfylvanicum*.

Knot grafs is fometimes a tillage-weed; trailing in its habit of growth; flourifhing moft by the way-fides: when out of the fmothering crops, it is very prolific in feeds. It fhould be got under by preventing its feeding, by rooting it out fufficiently early for the purpofe. See POLYGONUM *Aviculare*.

Bearbind, or black bindweed, is a parafitical weed that twines round any thing it can lay hold of, and which is fometimes found among field crops, to their great injury. It is very productive of feeds, which, being angular, are not eafily feparated from grain in dreffing or winnowing it. It is nearly allied, it is faid, to buck-wheat, and to which it is preferred by Dr. Withering, who afferts that the feeds are

are quite as good for ufe as thofe of that wheat, are produced in greater quantity, and the plant bears cold better. From its twining hurtful nature, when among crops, it fhould be early deftroyed, and prevented from feeding and multiplying itfelf. See POLYGONUM *Convolvulus*, and *Sagopyrum*.

Knawell is a diminutive weed, but prolific in feeds, and of vigorous growth; it is often found on pieces of poor thin foil, when in tillage, but is not believed to be very pernicious: it may probably, when neceffary, be weakened, reduced, or deftroyed, by an early fpring working of the land when in fallow. See SCLERANTHUS *Annuus*, and *Perennis*.

Bladder campion is a weed that is common in wheat and barley crops, growing in tufts, with many ftalks from each root; which, when the cafe, fhould be rooted out by the hand, or other convenient method. It is a perennial weed, and has the habit and property of increafing from the roots. See CUCUBALUS *Behen*.

Cockle is a luxuriant, vigorous, annual weed; perfecting many feeds, and drawing much from the foil or land: care fhould, therefore, be taken not to fow the feed of this injurious weed. The feeds are fo large, that they cannot all be dreffed out from the grain, it is faid: the plant fhould, therefore, be plucked out by hand, before the feeds ripen and fhed themfelves. It is a common weed among wheat and other crops, in many diftricts. See AGROSTEMMA *Githago*.

Red and white campion are weeds of the perennial kind, growing occafionally in hedges, corn-fields, and paftures. When they become abundant and injurious, they may be weakened, reduced, or deftroyed, by well-managed fallows, in moft cafes. See LYCHNIS *Dioica*.

Moufe-ear is a weed that has fomewhat the habit of chickweed, but is of a duller appearance: it is frequent amongft corn-crops, and in paftures, but perhaps not very injurious to the former. See CERASTIUM *Arvenfe*.

Corn fpurry, or yarr, is a frequent weed in corn-fields, though not very bulky or luxuriant, yet quick and tenacious of growth, and producing feeds in a plentiful manner. Dr. Anderfon has ftated, that in Aberdeenfhire it is a pernicious weed, growing in fuch abundance among the crops as to choke the grain: it has often been feen fo thick, that over a vaft extent of furface a pin could not have been put down, without touching a plant of it; and that the farmers there think it indeftructible: and it is added, that whenever any of the land had been poached, by being ufed as a road, efpecially in wet weather, none of this weed appeared there: that it was evident that this was occafioned by the clods, thus produced, not giving room for the fmall feeds to germinate freely; which fuggefted, that if, therefore, he could contrive to bring the ground into a cloddy ftate, when fown, he fhould be free of the weed for that crop. As a crop of bear or fix-rowed barley in one field was entirely loft, the foil or mould being in a loofe, mealy, incoherent ftate when fown; it was refolved to delay ploughing it the next feafon as long as poffible, and to plough it at laft when it was very wet. Fortunately it came a violent rain in the beginning of the month of March, and it was ploughed when nearly in the ftate of a puddle, turning over more like mud than foil or earth: dry weather fucceeding, this mud bound, it is faid, a little on the furface, and produced a kind of clod; the corn was then fown; it got a very flight harrowing, barely to cover the feeds, in an imperfect manner, and to leave the field as rough as poffible: none of the weed appeared, and the crop at harveft was one of the moft luxuriant that had ever been feen by the writer. The fuccefs of this cafe is not, however, fufficient to recommend it as a general practice.

It has been fuggefted, that as fmall birds are very fond of the feeds of this weed, it is probable that, by the furface of the ground being left undifturbed through the winter, a large portion of the feeds would be picked up and devoured by them. It is believed too, that in all cafes of a ftubble very full of fmall feeds, it is well to defer the ploughing as long as it conveniently can, on this account. In refpect to land rendered very fine by tillage, it is well underftood, it is faid, by the farmers of fome diftricts, as thofe of Staffordfhire, to be a fault, and that it is much better left only knappy, as they call it, that is, in fmall lumps. This is attained in fallows, by working the land early in fummer, and letting it lie to confolidate through the latter part of it; and in the turnip culture, by the treading of fheep and cattle: and it is one great reafon, it is fuppofed, why land fhould not have too many ploughings, but only a proper number judicioufly timed; however, that ploughing in general, particularly of broken land, is much beft done when the land is dry.

By fome means of this kind, this fmall weed may be kept under without much difficulty. See SPERGULA *Arvenfis*.

Bafe rocket is a weed of the annual kind, that does not abound very much, though it is met with in fome places. It has been obferved among corn in the county of Gloucefter. See RESEDA *Lutea*.

Dwarf fpurge is a weed that is common in corn-fields, and generally in fingle plants, but is not very injurious to the crops. See EUPHORBIA *Exigua*.

Corn-poppy is an annual weed that produces numerous feeds, and is fometimes very abundant in corn-fields, being a pretty fure indication of a light crop. It has been queftioned, whether the lightnefs of the crop be occafioned by the abundance of this weed, or the increafe of this weed encouraged by the lightnefs of the crop; and fuggefted, that probably both are the cafe. In a full crop it is fcarcely to be found; its flowers appear in July. In the Corrected Report on Agriculture for the County of Gloucefter, it is ftated to be common in all light and fandy foils, particularly in the neighbourhood of that town. But that fince the practice of hoeing has become more general, this weed has been much diminifhed in quantity. It abounds much, too, on chalky ftone-brafh poor foils, in fome cafes. And in fome parts of Berkfhire, it is faid, in the account of its agriculture, that the poppy almoft conceals the corn, when it is in bloffom. It is fuppofed that it might without doubt be weakened, reduced, or wholly deftroyed, in fallows, by promoting an early vegetation in common with other feedling plants. See PAPAVER *Rhœas*.

Corn crowfoot is a weed that is fometimes very abundant, and injurious to a wheat-crop, on ftrong moift land. It is an annual weed of early growth, which can only be brought into a full ftate of vegetation in the fallow by an early tillage; otherwife the growth of the feeds is, it is faid, deferred to the next fpring, to the great injury of the crop. In the Flora Ruftica it is noticed, that in fome countries it has the name of hunger-weed, whence it is fuppofed to indicate a barren foil. The orthography, however, is not, it is faid, derived from the nature of the foil, but from the hungry profpect it holds out to the farmer. In the county of Gloucefter, it is faid to grow moft abundantly in ftrong loamy or clayey foils; and that deep and frequent ftirrings with the hoe are to be had recourfe to, as the moft proper means for reducing it, and keeping it under. See RANUNCULUS *Arvenfis*.

Dee nettle, or dead nettle, is a weed that much abounds among

among tillage-crops, on ſome lands, eſpecially in moiſt ſeaſons. As the weeds are perennial, and produced both from ſeeds and the roots, great pains are neceſſary to be uſed in their extirpation and deſtruction. There are ſometimes different ſorts met with among crops. See LAMIUM *Album*, and *Purpureum*.

Calves' ſnout is a weed in tillage-lands, in different diſtricts. It has been obſerved not to be uncommon among the corn-crops in Hampſhire, in ſome ſummers. It would appear too from Withering, that ſeveral other ſpecies of this genus are common in corn-fields, which are annuals; but the nature of them, or how far they are injurious to cultivated corn-crops, has not yet been determined. See ANTIRRHINUM *Orontium*, *Elatine*, *Spurium*, *Arvenſe*, and *Minus*.

Shepherd's purſe, or pouch, which, with ſome others, are well-known weeds, are ſometimes troubleſome on arable land. They are annuals of early appearance, and continue a great part of the year. They are to be reduced and deſtroyed by early and well-directed fallowing, or by being rooted up from the ground at an early period. See THLASPI *Arvenſe*, *Campeſtre*, and *Burſa Paſtoris*.

Whitlow graſs is ſaid to be a weed among corn, in ſome caſes and ſorts of land, early in the ſpring; but how far injurious is not well aſcertained: it ſhould, however, when in quantity, be kept well under. It is but ſmall, though quick in growth, and exhauſted in a ſhort time. See DRABA *Verna*.

Codded mouſe-ear is another diminutive weed, that ſhews itſelf early ſometimes among corn in tillage-lands; but being rapid in its vegetation and decline, is not of much importance as a weed to farmers.

Smooth and rough-leaved and pale-flowered chadlocks, &c. are weeds that are extremely troubleſome and diſtreſſing to farmers on tillage-lands, in ſome places. The writer of the paper on weeds alluded to above has ſtated, that theſe three plants are ſometimes confounded together by farmers, under the general name of chadlock, pronounced in the diſtrict where he lives kedlock, and in ſome others ketlock, though they are as diſtinct to the inveſtigating inquirer as wheat, barley, and oats. That they are all extremely common, or nearly equally ſo, if a large range of country be examined; though the different ſorts are more or leſs abounding in different places; that in his neighbourhood he can generally gather the three kinds in the ſame field, but the muſtard is much the moſt abundant. In the vicinity of Litchfield, where chadlock is indeed very abundant, it is almoſt univerſally wild rape. Some years ago, the writer obſerved, in the common fields of the county of Rutland, that the whole ſurface was tinged over with the flowers of the wild radiſh. They are all great nuiſances, and, when ſuffered in abundance to ripen their ſeeds, muſt of neceſſity draw much from the ſoil, to the great injury of the crop among which they are; and that as they are very quick of growth, and perfect their ſeeds expeditiouſly, it is not uncommon for theſe weeds to ſhed their ſeeds at the rate of ſeveral buſhels on the acre; and as it is well known that the ſeeds are capable of vegetating, after lying many years in the ground, it is no wonder they ſhould produce a plentiful crop; yet, being ſimply annuals, they are not difficult of deſtruction, if due attention and proper means be uſed. In order to deſtroy theſe, as well as all other ſeedling weeds, the land in tillage ſhould, it is thought, be pulveriſed and reduced early in the ſpring by ploughing and harrowing, after which warm weather and rain will ſoon cauſe all the ſeeds that are near the ſurface to vegetate; they may then be permitted to grow until they begin to flower, when they are to be ploughed in, and the land again harrowed; and the next rain will then cauſe moſt of the remaining ſeeds to ſhoot, which are in due time to be ploughed under as before; and if any ſhould afterwards appear amongſt the crop, they ſhould be hoed or hand-weeded out: by this means, in one or two tillages, theſe weeds may be totally eradicated; but if they be permitted to ſhed their ſeeds, their increaſe cannot be wondered at, when their prolific nature is conſidered, as well as the extreme hardineſs of their ſeeds. The ſeeds, when dreſſed from grain, have, it is underſtood, been frequently manufactured into oil.

The weed called charlock, in many places, is ſaid to be the moſt common of any in the vale of the county of Glouceſter. It is moſt probably the ſame with the wild muſtard, juſt noticed. It is ſaid, that during the ſummer, both on the fallows and in the planted fields, its yellow bloſſoms predominate over every other plant, and that unleſs deſtroyed in this ſtate, leave an immenſe crop of ſeeds behind. In order to check the increaſe of this weed, the attentive farmer ſuffers it to come into bloſſom on the fallows, and then turns it in with the plough. This is not always, however, effectual; as frequently the plants being merely moved, but not from the roots, and two or three inches of the tops left above ground, ſoon recover the injury they have ſuſtained, and go on to feed before the next ploughing. Women and children ſhould, therefore, go over the ground with the hoe a few days after the ploughing, and cut up the reviving plants; or lambs ſhould be kept on ſuch fallows, which are ſaid to eat off the tops with avidity. In the planted fields they are hoed and weeded, but as ſome will unavoidably eſcape, women are put in among the corn, after it is grown to a conſiderable height, to pull out the weeds in bloſſom with the hand. Though the farmer will certainly diminiſh the quantity, and prevent any new acceſſion by this attention, yet many years of good huſbandry muſt elapſe, before the ill effects ariſing from the negligence of former cultivators can be conquered; for the ſeeds being ſtrongly charged with eſſential oil, will continue in the ground for an incalculable length of time uninjured; and as often as the ſoil is turned up, a quantity of them will be brought ſufficiently within the influence of the atmoſphere to vegetate. In 1804, in the pariſh of Brockthorpe, in the above county, a conſiderable portion of the land in the common field was ſeen completely covered with this weed, and the ſeeds perfectly ripe and ſcattering on the ground. The ploughing had been neglected until nearly the autumn, and as the land was not cropped, the charlock grew in great abundance, and left more ſeeds than the good huſbandry of half a century will be able to eradicate.

It has been ſtated, that what is vulgarly called charlock in the vale of the above diſtrict, is in reality the common wild muſtard grown in the north for its flour. That it is there often collected by the country-people for the ſame purpoſe; and before the ſimple mode of living among the ancient farmers fell into diſuſe, few farm-houſes were without a cannon-ball and bowl, in which the muſtard-ſeeds were bruiſed, and the flour ſaved for the table with the black huſks unſeparated from it.

The name charlock is not unuſually applied by farmers to different plants of the weed kind, that are equally noxious and hurtful in arable lands, and ſome of them perhaps more frequent in ſuch ſituations than ſome of the above, ſuch as wild muſtard and rape, &c. See BRASSICA *Napus*, SINAPIS *Arvenſis et Nigra*, RAPHANUS *Raphaniſtrum*, &c.

Wild rocket is a weed found in tillage-lands in ſome diſtricts. It is ſaid, that this weed has made great progreſs in the corn-fields in ſome places, and is conſidered as a very formidable

formidable and hurtful plant of that kind. All the parts of this are confiderably acrid, and have a rank difagreeable fmell; whence it is called by thofe farmers who have it in their lands *ftinkweed*. It may, it is fuppofed, doubtlefs, be reduced and deftroyed by the proceffes already recommended for the deftruction of chadlock. See BRASSICA *Muralis*.

Fumitory is an annual weed, that is not uncommon or unufual in corn-fields, though not very greatly pernicious in them. It fhould, however, be kept well under where it is in any quantity. See FUMARIA *Officinalis*.

Reft harrows are weeds fometimes met with in tillage-lands. They are chiefly two forts, the former of which is faid not to be uncommon in arable lands, where there are no very defirable plants. It is common in fome diftricts among corn-crops, and an hardy perennial weed. In its deftruction, if the root can be got rid of in the fallow, there is little danger, it is faid, from the feeds: the roots are fometimes fo ftrong as almoft to ftop the plough, unlefs the team be pretty ftrong. The latter is frequently met with in fome places, but is unknown in fome of the midland counties. See ONONIS *Arvenfis*, or *Spinofa*.

Tare, particularly in the wild ftate, is a weed very injurious to corn-crops. It is faid to be a terrible enemy to a wheat-crop, where it abounds in confiderable quantity. Withering fays, that in wet feafons whole fields of corn have been overpowered and wholly deftroyed by it. Care fhould be taken, that feed-wheat be perfectly free from the feeds of tares; and all land fubject to them fhould be got, if poffible, fo forward in the fallow, as to bring on the vegetation of this weed previoufly to the fowing of the wheat: the feeds of this weed are faid to be good food for pigeons, poultry, and many other forts of birds. See ERVUM *Tetrafpermum*, and *Hirfutum*.

Rape, in fome cafes, is a very injurious weed in arable land. It fhould, in all cafes where it prevails much, be prevented from ripening and fhedding its feeds, as when this is not the cafe, the farmer has long to regret the confequence of his neglect. See *Chadlock fupra*.

Melilot is a weed very troublefome in tillage-land. The writer of the paper already noticed fays, that it is a very injurious corn-weed in many parts of the kingdom. That Miller marks Cambridgefhire, and Gerard, Effex, as abounding in it. That it has been heard of in Bedfordfhire, and feen among corn in Gloucefterfhire and Rutlandfhire: that in the latter county, five or fix fhillings the acre have fometimes been faid to be expended in weeding it out, without fully effecting the purpofe. According to the Flora Ruftica, there cannot be a worfe weed among bread corn, for a few of the feeds ground with it fpoil the flour, by communicating their peculiarly ftrong tafte to it. That it flowers in June and the following month, and the feeds ripen with the corn; and that it is probably capable of propagating itfelf, both by its roots and feeds, but might doubtlefs be much weakened and reduced by proper fallowing: that horfes are very fond of it; cows, fheep, and fwine, eat it; and bees are very fond of the flowers: it is, therefore, though a corn-weed, a good pafture plant. It is faid to be common in the vale part of the county of Gloucefter, in the arable lands; and it has been fuggefted, that if the feeds did not afford an unpleafant tafte to the flour of wheat with which it may happen to be mixed, it might probably be cultivated with advantage, as all domeftic animals are fond of it in fome degree. See TRIFOLIUM *Melilotus officinalis*.

Sow-thiftle is a very common and troublefome weed in tillage-land: it is a perennial, and common among corn-crops in fome diftricts; which, in all cafes, when it happens to be fo abundant, fhould be drawn up by the hand or other proper means before it ripens and fpreads its feeds; which, as being furnifhed with a feathery down, would otherwife fly over the whole country and diftrict, as has already been feen. See SONCHUS *Arvenfis*, and THISTLE.

Common thiftle, curfed thiftle, or fow-wort, is, in many cafes, a troublefome and difagreeable weed in and about corn-lands and crops. It is commonly called thiftle, growing almoft every where: when injurious in corn-crops, it may, it is faid, be weakened and reduced by good tillage and weeding, but not totally deftroyed, in perhaps thefe or any other ways, otherwife than by univerfal agreement to root it up, before its feeds ripen and become fpread, or by fome regulation of police enforcing the fame. This mifchievous weed is produced by its numerous fibrous roots, which are hardy and ftrictly perennial, and which if feparated in parts or pieces in ploughing, digging, or working the land, each part will, when left frefh in the foil, often grow or vegetate, and produce a new plant; and by its ftill more numerous feeds which are feathered, will fly and be carried to a great diftance by the wind; and when it becomes calm alighting upon cultivated land, will there vegetate and rife luxuriantly, fo that it would be in vain for any perfon to attempt clearing his land of this weed, unlefs his neighbours did the fame likewife: however, the roots of this weed may, it is faid, be pretty effectually deftroyed by a well-managed fummer-fallow, as they will not furvive repeated ploughings up in hot weather; and if due attention were beftowed to prevent the feeding of the weed, its numbers might be diminifhed very greatly: it is found very hurtful to all field-crops. Some think it eafily conquered, however, by proper management and attention in tillage-lands, and that it may either be drawn by the tool for that purpofe, or be cut off deep by the hoe or fpeed-hook.

It is fuppofed, on the authority of the Flora Ruftica, that the goat and the afs will eat it; that horfes will fometimes crop the heads while young and tender; but that no other fort of cattle touch it growing. That when burnt, it is faid to yield a very pure vegetable alkali. See SERRATULA and THISTLE.

Spear, *bur*, or *boar thiftles*, are weeds of a very pernicious nature in corn-lands, in many inftances and parts of the kingdom. They are faid to be called by the laft of thefe names in Staffordfhire, to diftinguifh them from the above weeds, which are likewife termed thiftles. There are feveral forts of them, and they often abound about the hedge-fides and borders of corn-fields, whence they fhould be rooted up after rain as much as poffible, before their feeds ripen and are ready to fpread, otherwife fuch feeds are liable to fly all over the country, as has been feen: thefe are weeds that grow very luxuriantly, drawing much from the ground or foil, when among the crops, as is frequently the cafe in many places. They fhould always be drawn out as much as can be done in fuch cafes in hot weather: they are moftly weeds of the annual or biennial kinds. It is faid by Withering, in fpeaking of the ufes of them, that fhould a heap of clay be thrown up, nothing would grow upon it for feveral years, did not the feeds of the fpear thiftle, wafted by the wind, fix and vegetate thereon; that under the fhelter of thefe, other vegetables appear, and the whole foon becomes fertile.

They are never to be trufted among crops, but be kept well cut or pulled up in their early growth. See CARDUUS *Lanceolatus*, *Pratenfis*, and *Acaulis*. Alfo THISTLE.

Colt's-foot is a weed that is very apt to abound in hard tilled land. It has been faid that the only time to deftroy this weed, is by cutting it up in thofe months when it begins to throw out its flower, at which time, if fo cut, it will

will bleed to death; these months are February and March, at which time all land in fallow, which is subject to this weed, should undoubtedly be ploughed and harrowed down, which would, without doubt, check the growth of, and very much weaken the weed; but when neglected at this period, it will soon afterwards ripen its seeds, which furnished by nature with feathers, fly all over the country, and establish themselves very quickly on cultivated land, and banks of earth newly thrown up. This weed may, it is said, be considerably weakened by repeated summer ploughing, and be afterwards, for the most part, weeded out by hand, as the ground is thus rendered light. It is a weed which in Gloucestershire is not found, except on soils that are poor in their nature, and subject to moisture. The obvious remedies are consequently fertilization by manure and the removal of wetness by draining. See Tussilago *Farfara*.

Groundsel is a mischievous and troublesome disgusting weed, not unfrequently found in fallows, on good free soils rendered fine by cultivation, as its seeds ripen quickly in such cases, and fly over the country with the wind: it is a weed that should be got quit of in time by being pulled out, or turned under by the plough, and the seed of it be by no means permitted to ripen and disperse. See Senecio *Vulgaris*.

Corn marigold, goulans, goul, or buddle in Norfolk, is an extremely troublesome weed in some soils: it is an annual, producing seeds plentifully, which vegetate whenever the land is cultivated, and very commonly in the crops of corn: it would, without doubt, it is supposed, be destroyed, as other annual seedling weeds, by early and complete fallowing to bring the seeds into vegetation in due time, and afterwards ploughing them under. According to Withering, in Denmark, there is a law to oblige the farmers to root it up: and it is said to be stated in the second volume of the "Statistical Account of Scotland," that the late sir William Grierson, of Lag, held *goul* courts as long as he lived, for the purpose of fining such farmers on whose growing crop three heads or upwards of this weed were found; and it has been observed, that some regulation of police for fining those who harbour weeds, the seeds of which may be blown into their neighbour's grounds, has no injustice in the principle of it.

It is stated in the Berkshire Corrected Report on its Agriculture, that it may be destroyed by the application of chalk as a manure, as well as by extirpation.

On the authority of the Flora Rustica it is noticed, that if this weed be cut when young in flower, and dried, horses will eat it. See Chrysanthemum *Segetum*.

Corn mint is a weed that is said by the writer of the Corrected Report of the Agriculture of the County of Gloucester, to be common on damp soils; and that it increases fast by the root, where, for want of frequent ploughing, dragging, and other tillage, it is neglected. See Mentha *Arvensis*.

Corn camomocle is a weed that is sometimes prevalent in corn-fields: it is very prolific in seeds, which should never be suffered to shed, as in that case it would be multiplied to an almost endless degree. See Anthemis *Arvensis*.

Stinking May-weed is a plant of this kind that is common in corn-fields among the crops, but which is often confounded with the above and other weeds of that sort, from which it is to be distinguished by its disagreeable smell: it is very injurious to corn-crops, and should be prevented or destroyed by good fallowing, or by being timely rooted out of the land. The Gloucester Report on its Agriculture states, that maithe or mathern there often overruns a whole field, particularly when planted with peas, so that only the white blossom of the weed is to be seen. The only chance of destroying this stinking weed is, it is supposed, by the drill husbandry, where room is left for the free use of the hoe. In the broadcast mode the weeds must be pulled out by the hand, which is not only tedious, but, in some measure, dangerous, as there is a noxious quality in the plant which is liable to injure the hands of the weeders, if they happen to have sores on them. See Anthemis *Cotula* and Matricaria *Chamomilla*.

Blue bottle is a weed that is common in corn where the tillage of the land has been imperfect, or too long carried on, and continued without cleaning by means of turnips or fallow: it is an annual weed with a somewhat elegant blue flower. It is very common in the corn-fields of Shropshire and Lancashire, as well as in some other counties. It is said that, in Gloucestershire, blue bonnet, knapweed, or corn flower, is a weed common in some fields, principally where the soil is loamy and mixed with pebbles. It is advised to be extirpated at first by the hoe, and, when grown to blossom, by the hand. See Centaurea *Cyanus*.

Great knapweed is a perennial corn weed, growing in tufts of many stems or stalks from the same root; and which is to be destroyed in the fallow, or by being weeded out of the crop. See Centaurea *Scabiosa*.

Pansy is an annual flower weed that is often found among corn-crops in different districts, where it is produced by seeds that have not been destroyed in the preparation for the corn-crop. It is seldom very hurtful, but when abundant should be weeded out in some way or other. The beauty of the colours of its flowers has gained it a place as an ornamental plant. See Viola *Tricolor*.

Corn horse-tail is a weed often met with in corn-land, the fertile stem of which appearing early in the spring, with that of colt's-foot, and decaying before the other part of the plant appears. The author of the paper already noticed states, that Loesel says, if ewes in lamb eat it, abortion is the consequence; but it is believed that sheep or cows will not eat it, unless compelled by hunger. It is to be destroyed by the same kind of tillage and extirpation, as that recommended for colt's-foot. In the Gloucester Report on Agriculture, it is stated to be found only on moist soils, and cannot be easily overcome, but by draining and completely removing the wetness. See Equisetum *Arvensis*.

Fern is a weed not uncommon in corn-fields on dry sandy land: it is a hardy perennial plant, tenacious of growth, and striking a long tap root into the ground, beneath the reach of the plough, which shoots up vigorously when the sun becomes powerful: it prevails largely and strongly on some deep dry hazel loamy soils. In order to destroy it, after soaking rain, it should be drawn or deeply ploughed up; though, in some cases, it will require much pains and attention to get quit of it, especially on land where it has been established for a great length of time. See Pteris *Aquilina*.

There are different other weeds which are occasionally met with in lands of this sort, but which, as their nature, habits, and effects, have not been well or fully ascertained, they have not been noticed here.

Weeds injurious in Meadow and Pasture Lands.—From its not having yet been fully and exactly decided which are to be considered as noxious and hurtful, and which beneficial and useful plants, in the herbage of grass-lands, it may be proper and of utility to consider them under the heads of such as are really found prejudicial in such situations, and such as have not been discovered to be actually so, and the particular qualities of which are not well known.

Of the firft fort are thofe which are defcribed below, on the authority of the writer of the paper on weeds mentioned above, and that of fome others.

Cotton grafs, hare's-tail, or mofs crops, are weeds that grow in bogs or boggy meadows; and with the down of which poor people ftuff their pillows, and make the wicks of candles. This weed is a certain indication that drainage has been neglected, and that it is of courfe neceffary to be attended to and practifed, in order to reftore the meadow or other fuch land to the proper ftate for the growth of good herbage. See ERIOPHORUM *Vaginatum*, and *Polyftachion.*

Hog weed, or cow parfnip, is a weed often found in meadows, but which is too coarfe and of too weedy a nature and appearance to be fuffered to abound in well cultivated and managed grafs-land, though, it is believed, that cattle will eat it either green or in the ftate of hay: it is thought that it may probably be weakened or deftroyed, by annually cutting up in its early growth. See HERACLEUM *Anguftifolium*, and *Sphondylium.*

The latter is frequently met with, efpecially in moift meadows in Chefhire.

Wild cicely, or cow-weed, is a common weed in orchards, hedges, meadows, and paftures. Cattle are faid to be fond of it in the fpring, but it is too coarfe to be permitted or encouraged among good herbage of the grafs kind; and as it flowers, and ripens its feeds before the graffes, it is a bad and improper addition to the grafs-plants of both meadow and pafture lands: it is frequent in the meadows of Chefhire. It has been fuggefted, that this and the laft noticed plant may probably be worthy of a trial in cultivation by themfelves, as being of luxuriant growth, they would yield a large produce: their value has not, however, yet been fully afcertained; nor efpecially in this method of culture and management. See CHÆROPHYLLUM *Sylveftre.*

Garlick, in the wild ftate, is a weed that is frequently found in meadows and pafture lands, and which is confidered as greatly injuring the latter when ufed for cows. It is faid to give a difagreeable flavour to the produce of the dairy, as butter and cheefe, but it does not feem that cows much diflike or refufe to eat it. It is fuppofed, however, that this may probably happen on account of its being fo much blended and intermixed with the other graffes, that they cannot avoid cropping it a little. This weed is frequent in the cow paftures of fome parts of Lancafhire, Gloucefterfhire, and moft probably many others. See ALLIUM *Ampeloprafum.*

Ramfon is a weed that is found in fome meadows and other grafs-lands, but more commonly in the hedges; other plants will not, it is faid, flourifh near it: cows eat it, but it, like the above weed, gives their milk and its produce a garlic flavour: it fhould, of courfe, be weeded out of grafslands as foon as difcovered and be deftroyed. See ALLIUM *Urfinum.*

Rufhes of different forts are a fort of weed-plants which are not unfrequently met with in meadows and paftures, efpecially when of the cold clayey kind, and which are a fure indication that the land, in fuch cafes, wants the fuperfluous wetnefs removed; which, when it has been effected, always gives way to better herbage, though their extirpation and deftruction afterwards will be promoted and accelerated by top dreffings of afhes and other matters. In the Gloucefter Report on its Agriculture, it is ftated, that the common rufh is an inhabitant of foils that are moift and ftrong, that it abounds in the furrows of pafture-lands, and on the *meers* or ftrips of grafs-land left between the grounds in the vale of that county, as the dividing mark of different properties, and that it is deftroyed in the manner above. See JUNCUS, different forts. Alfo RUSH.

Docks are weeds that are found in ftrong four heavy land of the meadow and pafture kind. As thefe weeds are refufed by moft forts of domeftic animals, they fhould be rooted up after rain, and every pains be taken to deftroy and remove them from grafs-land, which they injure greatly by their fhade, and by caufing the herbage about them to become rank. They are faid to be eaten only by fallow-deer, by which their flourifhing in parks and pleafure-grounds is prevented. It is remarked that in Gloucefterfhire docks are extremely injurious to the herbage of pafture-lands, but that if taken in time they may be eafily conquered. If, however, they are permitted to ripen, they leave an immenfe quantity of feed for future crops; and, that being perennial, the evil is increafing in fuch a multiplied proportion, as almoft to exclude the growth of all other plants. In a large meadow adjoining the county-town, thefe weeds have matured and fhed their feeds, it is faid, fo often, and for fo many years, that, at the time of mowing, the whole appears like a crop of docks. Where thefe weeds are not got up by the roots, it is ufeful, in fome cafes, to cut through the ftalks under the ground; and to repeat the practice as fhoots are again thrown up. See RUMEX *Crifpus*, *Acutus*, *Obtufifolius*, &c. Alfo WEEDING *Dock-Spit*, &c.

Biftort is a weed that, in fome places, occupies large portions or patches in meadows, to the injury and deftruction of better herbage: it is a perennial, but may without doubt be weakened or deftroyed by rooting up repeatedly. The root is one of the ftrongeft vegetable aftringents, and may probably be applied to many purpofes in the arts with benefit. It is the inhabitant of moift meadows in Chefhire. See POLYGONUM *Biftorta.*

Wild campions are weeds often found abundantly in paftures formed from ploughed lands: there are two forts, as thofe with white and red flowers. Care fhould be taken to exterminate them from fuch paftures by proper fallowing the land when in the broken up ftate. See LYCHNIS *Dioica*, &c.

Goofe-tanfy, filver-weed, or feathered cinquefoil, is a weed common in many paftures laid down from the arable ftate, but generally untouched by cattle: it fhould therefore be deftroyed and got rid of in the tillage ftate of the land, and by keeping it free of ftagnant wetnefs. See POTENTILLA *Anferina.*

Tanfey is a weed that is found in Gloucefterfhire, in fome paftures by the fide of the Severn, and in a few other places in that county, but not in abundance, as well perhaps as in fome others, efpecially in the northern parts of the kingdom. It is an unpleafant weed, it is faid, which fhould be eradicated by the fpade, or fome other proper means. See TANACETUM *Vulgare.*

Pilewort is a weed that flowers very early in the fpring, and abounds in fhady or moift pafture ground; it fometimes occupies much room in fome meadows, and chokes other plants which grow near it; and not being eaten by cattle, it fhould certainly be extirpated: nothing difcourages its increafe more than coal and wood-afhes, the writers of the Flora Ruftica fuppofe. See FICARIA *Verna*, and RANUNCULUS *Ficaria.*

Loufewort, or red-rattle, is a weed found in moift meadows and paftures, and, it is thought, rarely but where the land is in want of being rendered dry: it is faid to be very difagreeable to cattle, and injurious to fheep, giving them the fcab, and occafioning them to be overrun with vermin: it is believed, however, that thefe injuries are principally caufed

caufed by the unwholefome nature or ftate of the land on which it grows: it may be deftroyed, it is fuppofed, by removing the wetnefs and top dreffing. See PEDICULARIS *Sylvatica*.

Yellow-rattle is a weed that is faid to grow generally in moift meadows in the county of Gloucefter, and which ripens its feeds, and fheds them before the time of mowing, when the dry hufks make a rattling noife under the fcythe: at this time, it contains no nutritious juice at all, though, when green, oxen and horfes will fometimes eat it rather eagerly, and at other times refufe it. Having, however, no defirable quality to recommend its cultivation, and oftentimes overrunning large patches of ground, it fhould be eradicated and deftroyed; and being a biennial, this, it is thought, may eafily be done, by grazing the land for three or four years in fucceffion, and taking care that the ftalks that are left by the cattle be fkimmed off by the fcythe before they are ripe enough to fhed their feeds, or while they are in full bloffom. In regard to its removal, it is ftated, that a farmer near the northern borders of the fame county, fhewed the writer a floping piece of grafs-land which had been overrun with rattle: without any view to the deftruction of that he conducted the water of an adjoining ftream, as well as he could, over the piece which was not, however, wholly watered; but it proved that on the watered part, the rattle was deftroyed, while it continued to grow on the portion which had efcaped. No plant is more frequently found mixed with the graffes in the meadows of Chefhire than this; but as it has nothing to recommend it, and the farmers diflike it, the removal of it fhould be effected to make way for better herbage. See RHINANTHUS *Crifta-galli*.

Dyer's-broom is a weed that is feen very abundant in fome paftures on ftrong and moift land, whence, as it is often troublefome, it fhould be grubbed up, and be got quit of. Wood waxen, dyer's-weed, or bafe broom, grows abundantly, it is faid, in many parts of the vale of Gloucefterfhire, but generally on dry paftures: it is refufed by no cattle but fheep; yet, being inferior to good graffes, fhould be rooted out, except in places where, as in the neighbourhood of Briftol, it is collected and carried while in full bloffom to the manufacturers, who, by boiling and other means, extract a fine yellow colour from it. See GENISTA *Tinctoria*.

Reft-harrow, or commock, is faid to be a weed often found in paftures, where it is eaten by cattle, efpecially the younger fhoots of it; but that it is too coarfe and rubbifhy to be fuffered to increafe, and fhould confequently be rooted out or grubbed up as foon as poffible. In Gloucefterfhire it is faid, too, to be a moft troublefome weed, and a pretty fure proof of want of attention, culture, and manure; as by the two former it may be eafily cleared from arable land, as has been feen, and by well-rotted horfe-dung even pafture-lands may be affifted; but that rather than fuch a difgufting plant fhould continue to grow, where its place might be fupplied with good herbage, neither labour nor expence fhould be fpared. The little advantage it gives to fheep, which will eat the young fhoots before the prickles are formed, is not, it is fuppofed, a fufficient inducement in the calculation of a good farmer to leave it undifturbed. In the parifh of Elmore, in that county, there is, it is faid, a pafture-ground almoft covered with it, which lies too far from the farm-houfe to have manure eafily conveyed to it. In this cafe, the occupier tried the experiment of drawing it out by the roots, but difcontinued it from the idea that it came up with greater ftrength, and in more abundance the fucceeding year. The fact is, that the bufinefs is but half done, if the roots are not entirely removed, as every broken piece will throw out fhoots; and from long continuance of the plant on the fpot, and the annual fhedding of the feeds of it, it is probable that a new crop will arife in the following fpring: but the farmer fhould not be difcouraged, it is faid, on his firft attempt; fince, by continually watching the weeds in their early growth, and cutting them off with the hoe, they would gradually be deftroyed; and the procefs would be much affifted by well dreffing the places with rotten horfe-dung, as fuggefted above. See ONONIS *Spinofa*, and *Arvenfis*.

Common thiftle is a moft noxious weed among grafs herbage: it has ftrong roots which fhoot out in a lateral manner, and is a perennial plant of vigorous growth in fome foils. It may be got quit of by cutting it off within the ground, or by being rooted up; for the former fort of work the beft time is when the plants are coming into full bloffom, as they then become fooneft rotten and deftroyed in their hollow root parts; and for the latter in pafture-lands when the ground is well foaked with rain, and they can be drawn eafily. They are fometimes very hurtful to the hay lands in the vicinity of the metropolis, where the management is bad. See SERRATULA *Arvenfis*, and THISTLE.

Rough large thiftles, or boar-thiftles, are weeds of a very troublefome nature among grafs-crops, and which are always to be got rid of without delay. They are generally mown or otherwife cut over, but are much better rooted or drawn up. It is remarked by the writer of the Corrected Account of the Agriculture of the County of Gloucefter, that thiftles of all kinds are very unpleafant weeds in grafs-lands; either when green or dried with the hay, they annoy the cattle in feeding, and confequently fhould never be permitted to grow long on any fuch land; to prevent their growing at all, is, it is thought, perhaps impoffible, but the increafe of them may be checked by early attention: while, however, they are left to be mown with the grafs, or to remain undifturbed in the highways during the fummer, the feeds will be difperfed by the wind in various directions over the country: until a method be therefore adopted to correct the evil in its infancy, the labour beftowed by good farmers for the extirpation of this weed will not, it is faid, produce a complete effect, although it will prevent the plant from being carried to the mow in a ftate of equal maturity with the hay, and its feeds afterwards from being difperfed with the dung in the fields. Was every farmer to do the fame, the encouragement to perfevere in the practice would be powerful; but that it is not probable, that a farmer will expend much in doing what the negligence of a neighbour will render ineffectual. Some of thefe thiftle-weeds are annual, others biennial and perennial; confequently, where the diftinction is not known, the fafe method is, it is faid, to cut the root with a paddle, deep in the ground, or to draw up the root; and that this fhould be done for the firft time in the fpring, and again on the lattermath in autumn. See CARDUUS *Lanceolatus*, &c. Alfo THISTLE.

Cudweed, or chafeweed, is a weed faid not to be uncommon in paftures from arable land. It has been feen abundantly in an upland pafture after barley, where the clover had failed of fuccefs; cattle refufe it, but it has been fuppofed to be fuccefsful in the bloody flux of cattle and of the human fpecies: it feldom appears much in a grafs-crop, or efpecially when the artificial graffes fucceed well. See GNAPHALIUM *Germanicum*.

Ox-eye, white marigold, or great daify, is a weed common in fome paftures, and not grateful, but which feldom abounds fo as to be much injurious to the grafs, and which is eafily drawn out by the hand or other fuch means. See CHRYSANTHEMUM *Leucanthemum*.

Black

Black knap-weed is a common and abundant weed in ſome moiſt and cold meadows and paſtures, where it is a very bad plant, being coarſe, hard, and ſtubborn, ſeldom touched by cattle, either in the green or dry ſtate, and not extirpated from the ground without much difficulty: it is a perennial weed, which increaſes much by the root, according to the Flora Ruſtica. It is ſuppoſed that it might probably be much weakened and reduced, and be extirpated by degrees by drawing up after rain. It is ſtated too, that in Glouceſterſhire the common black knap or knob-weed, provincially hard heads, is a vile and worthleſs weed, which cattle of no kind will touch, in any ſtate; and yet it is ſuffered, on ſome paſtures, to grow and increaſe to ſuch a degree, as to exclude the appearance of almoſt every other plant, and, though uſeleſs, is mowed with the other herbage, and preſerved for winter fodder. That it is a weed which indicates poor land, though probably, by the uſe of ſoaper's aſhes, it might be conquered, otherwiſe the ground ſhould be ploughed up and converted to a better purpoſe. The writer of this article lately ſaw it wholly covering a poor paſture field in the north of Lancaſhire, to the excluſion of all uſeful graſſes. See CENTAUREA *Nigra*.

Sedge-graſſes, various ſorts, are weeds that are moſt common in cold, old, ſour, moiſt clayey lands of the meadow and paſture kind, undrained and unimproved; in which they are ſaid, in ſome places, to occupy the whole ſurface: they are extremely hardy, and flouriſh where ſcarcely any thing elſe will grow: ſeem produced by nature from this principle in her economy, that a bad plant is better than none, for theſe plants are not eaten by any ſort of cattle which can get any thing better; yet, upon getting quit of the ſuperfluous moiſture or wetneſs, and top-dreſſing the land, it will commonly give way to a finer and more valuable herbage. See CAREX.

They have provincially the titles of hard-graſs, iron-graſs, and carnation-graſs, ſometimes applied to them.

Common nettle is a weed ſometimes growing in tufts on paſture-land, where it ſhould always be rooted up, as it will prevent the growth of good herbage, and render the graſs rank near it: aſſes are ſaid to be fond of it, and cows eat it in the ſtate of hay. See URTICA *Dioica*.

Moſſes, various ſorts, are weeds that are ſometimes ſaid to ſpread on paſture and other graſs lands, and, it is believed, indicate that the herbage is ſtarving and torpid, and ſtands in need of a ſtimulus to quicken its growth: proper top-dreſſing ſhould be uſed, and the wetneſs be removed, if neceſſary. Treading by ſheep, and ſcratching the ſurface by means of fine-teethed implements, have likewiſe been found of great utility. See MUSCI, and MOSS.

Such plants as the above muſt be conſidered as proper and neceſſary to be extirpated from graſs-lands of moſt kinds; but there are various others which are of leſs importance, and the characters of which are more doubtful, and their uſes not ſo well determined and decided upon.

Of this latter ſort or claſs, the following may be noticed as being moſtly improper in ſuch ſituations.

Crowfoots, butter-flower, butter-cup, king-cup, or gold-cup, are plants almoſt every where found in meadow and paſture lands. The pile-wort is common in ſome places, and the bulbous-rooted ſort, it is obſerved, has knotty roots, riſes little above the ground, bloſſoms early in the ſpring, and is chiefly found in meadows that are rather moiſt, being eaten only by ſheep. The other ſorts are common in the meadows and paſtures everywhere, being very abundant in the hay-grounds near the metropolis. Their good qualities in ſuch lands have been much queſtioned and diſputed by many; but the writer of the paper already noticed is inclined to think favourably of them, eſpecially as promoting the digeſtion of the live-ſtock that feed in ſuch paſtures; and as not having been diſcovered to be injurious in ſuch ſituations by farmers in their long experience. The writer of the Glouceſter report, however, ſtates, that the ſeveral ſorts of crowfoot, provincially termed crazys, which in the ſpring throw a yellow veil over the meadows, are to be reckoned among the uſeleſs weeds, having little to recommend them to notice but their gaudy appearance. That the three latter ſorts are acrid and biting to the taſte, and are therefore rejected by cattle nearly alike. It is indeed ſaid, that the creeping crazy is more mild and palatable to ſome cattle, though it is to be ſuſpected that cattle eat it rather from neceſſity than liking; as from its ſpreading along the ſurface, it becomes ſo matted with the herbage, that it muſt be taken up, in ſome degree, with it. The ſtalks of the two others are left ſtanding when the ground is quite bare about them; yet, when made with the hay, they are ſaid to loſe the pungent quality; and the brightneſs of the bloſſom in the rick, is always a ſign of the whole having been well harveſted.

All the ſorts of this tribe of plants, though pleaſant to the eye in meadows and paſtures, in conſequence of their diſplay of yellow flowers, are, it is ſaid in the Berkſhire report, injurious to the herbage, and little reliſhed by animals of any kind. Although difficult to be eradicated, ſome of the larger ſorts of them may be reduced greatly by proper care and attention. See RANUNCULUS *Ficaria*, *Bulboſus*, *Repens*, and *Acris*.

Wild mint is a plant found in moiſt paſtures, and which prevents the coagulation of milk; ſo that when cows have eaten it, as they are apt to do largely at the end of ſummer when the paſtures get bare, their milk can hardly be made to yield cheeſe; a circumſtance which occaſionally puzzles the dairy-maids. It is a plant that ſhould be removed from paſtures, and which, it is ſuppoſed, may be weakened by effectually removing the wetneſs of the land. See MENTHA *Arvenſis*.

Marſh marigold is a plant that occupies much ſpace, and which is dangerous to cows. It ſhould conſequently be removed from paſtures and other graſs-lands. See CALTHA *Paluſtris*.

Water hemlock is a plant ſuppoſed poiſonous to horſes, and ſhould therefore be eradicated from paſture-lands. See THELLANDRIUM *Aquaticum*.

Water cowbane, meadow-ſaffron, and treacle-muſtard, are plants in paſture and graſs lands, that are ſaid to communicate an unpleaſant odour to the milk of cows, and to be ſometimes fatal to them. When abundant they ought to be removed from ſuch lands. See CICUTA *Viroſa*, COLCHICUM *Autumnale*, and THLASPI *Arvenſis*.

Mouſe-ear ſcorpion-graſs is a plant that often proves fatal to ſheep, it is ſaid, and ſhould of courſe be extirpated from ſheep-walks. See MYOSOTIS *Scorpoides*.

Rag-wort is a plant in graſs-land which cows and horſes refuſe, and which ſheep will only eat when very young: it is a plant that is ſtated, in the Cheſhire Report on Agriculture, to be regarded as worſe than uſeleſs both in meadows and paſtures. That it frequents rich ſoils only; and that the farmer there often exhibits the keddle-dock, as it is provincially termed, as a proof of the goodneſs of his land. That while his vanity is flattered by its preſence, he not only neglects to extirpate it, but frequently ſuffers it to ſpread over one of his beſt pieces of land, to the injury of himſelf and the annoyance of his neighbour. It is ſaid that by mowing it is prevented from propagating its ſeeds; but that the roots are not deſtroyed. That this is beſt effected

either

either by eating it down while young with ſheep, or pulling it up by the hand. This laſt ſhould be done when the ground is moiſt, in order that no conſiderable fibres may be loſt or left in the land, as if there are the roots will ſtrike again. See SENECIO *Jacobæa.*

Meadow ſorrel is a plant common in meadows, and eſpecially where the ſoil is ſtrong and rather wet: it is a coarſe plant that is injurious by its ſhade, and ſeeds in good graſs-lands. See RUMEX *Acetoſa.*

Wood or *meadow anemone* is a plant common in meadows, though diſregarded by farmers; the whole plant is ſaid to be acrid. Withering aſſerts, that when ſheep that are unaccuſtomed to it eat it, it brings on a bloody-flux. See ANEMONE *Nemoroſa.*

Eye-bright is a plant common in paſtures, and refuſed by cattle in general; conſequently occupying the place of a better plant. See EUPHRASIA *Officinalis* and *Odontitis.*

Dandelion is a diſagreeable plant, though common in graſs-lands in moſt diſtricts: it is ſaid to be conſiderably diuretic, and on that account may probably have a good effect on cattle at firſt going to graſs: it is coarſe, but good in hay with graſſes. See LEONTODON *Taraxacum.*

Yarrow, and ſneeze-wort, are plants common in paſtures, but indifferent to cattle-ſtock. The former has been recommended for poor land. The common yarrow has been found plentifully intermixed with the herbage in the vale part of the county of Glouceſter, where much fed with horſes. Some have, it is ſaid, ſuppoſed, that cattle are not averſe to it; but it has been obſerved, that this weed has remained uneaten until every blade of graſs has been cropped cloſe to the ground, and therefore that it ſhould be extirpated by the ſpade or ſome other means, ſuch as the three-pronged fork, at the expence of manual labour. See ACHILLEA *Millefolium* and *Ptarmica.*

Orchiſes of ſeveral ſorts are plants that are common in moſt meadows, having broad, entire, ſpotted leaves in general, and large bunches of pale or purple flowers. They generally remain untouched by moſt, or all ſorts of cattle-ſtock. See ORCHIS *Maculata*, *Biſolia*, &c.

Plants of this ſort have hitherto been much too little examined and inquired into, in ſo far as relates to their utility and importance, or the contrary, for the uſes of the farmer, to afford any thing ſatisfactory on the ſubject; but that a great many ſuch plants ſhould be rooted out of graſs-lands of different kinds there can be no ſort of doubt. This would render the meadows and paſtures much better for the purpoſes of hay, and the paſturing and feeding of live-ſtock of every ſort, and be greatly beneficial to the farmer in many ways.

Weeds injurious in waſte and uninclofed Lands.—It is ſtated by the writer of the paper on weeds, that thoſe conſidered as particularly hurtful to ſuch land, are not very numerous; for though many ſorts of plants, uſeleſs as the food of domeſtic animals, grow there, yet, as there is no poſſibility of introducing any thing better until ſuch lands are appropriated and improved by cultivation, they can hardly be conceived as noxious, ſo long as nothing better can be put in their ſtead. That, as ſuch lands in their preſent condition are uſeful only as ſheep-walks, or for producing fuel, the bettering of them, in the former reſpect, is an object deſerving of attention, particularly as ſuch amelioration would render them of greater value in caſe of incloſure, and would much ſhorten the buſineſs of bringing them into the ſtate of improvement. See WASTE *Land.*

The weeds that encumber ſuch lands, and reduce their value as ſheep-walks, are conſidered as of two kinds; the common upland rubbiſh, and the bog produce of plants: the former ſmothers the land, ſo as to prevent the growth of better herbage; and the latter are generally hurtful to animals that feed on them, either from their own nature, or becauſe the land on which they grow is uncomfortable for and unwholeſome to the health of them, eſpecially to ſheep.

Upland weeds are all thoſe that riſe in high barren ſituations, and which chiefly conſiſt of heaths of different ſorts; furze or gorſe, the petty whin, or hen-gorſe, and broom, but which is more commonly met with in neglected dry lands of the arable kind: theſe ſhould all, it is ſaid, where the ground is of tolerable ſtaple, or depth of mould, be burnt off, or grubbed up, early in the ſpring; and if the land be afterwards ſown with graſs-ſeeds of the hay kind in moiſt weather, it will much improve the herbage: the fern ſhould alſo be mown, and carried off in the ſummer, the value of it as litter being well worth the labour and trouble. See ERICA, ULEX *Curopæus*, GENISTA *Anglica*, SPARTIUM *Scoparium*, and PTERIS *Aquilina.*

Bog weeds are thoſe that ariſe in ſwampy places, and are cauſed by ſtagnant moiſture or wetneſs, being principally cotton graſſes, matt-graſs, ruſhes of ſeveral ſorts, red-rattle or louſe-wort, marſh, St. Peter's-wort, kingſpear, which laſt two are of but little conſequence in themſelves: they, however, indicate boggy land; and in their company are often found purple-flowered money-wort, ſedge graſſes of ſeveral ſorts, &c.: all which would give way to better herbage, upon the ſtagnant wetneſs of ſuch bogs being removed, which ſhould, it is ſaid, be done by a rate, levied on the inhabitants of the neighbourhood, having right of common upon ſuch waſtes. See ERIOPHORUM *Polyſtachion* and *Vaginatum*, NARDUS *Stricta*, JUNCUS, PEDICULARIS *Sylvatica*, HYPERICUM *Clodes*, NARTHECIUM *Oſſifragum*, ANAGALLIS *Tenetla*, and CAREX.

The diſeaſe, termed the rot, in ſheep, which ſo commonly ariſes in theſe ſituations, has been often attributed by ſtock-farmers and others to the ſun-dew, marſh penny-wort, and common butter-wort, weeds found in ſuch lands; but it is more probably cauſed by the flat inſect known by the name of flake, *faſciola hepatica*, which is not unfrequently met with in ſuch watery grounds, ſticking to different parts of the plants, and which has been diſcovered in the diſeaſed livers and bile ducts of ſheep thus affected. See DROSERA *Anglica*, HYDROCOTYLE *Inundata*, *&c.*

The writer juſt noticed ſuggeſts, that if the country ſhould not yet be ripe or ready for incloſing all the commons and waſte lands, the improvement of their ſtaple by meaſures of this kind, by deſtroying weeds and introducing better herbage, by removing the wetneſs of the bogs, and deſtroying the aquatic weeds growing thereon, would better their preſent ſtate, and improve their value to the public, would render them capable of maintaining a greater number of better ſheep, and preſerve the ſtock in better health, as well as render the land more ſuſceptible of a rapid and eaſy improvement by cultivation, whenever the time may arrive for their incloſure, and for ſuch full amendment of their condition.

Weeds injurious in Hedges and other ſuch Fences.—It is remarked in the paper on weeds and weeding, that all kinds of them are hurtful to young hedges, which conſtantly require to be well cleaned and freed from them for three or more years after planting, as otherwiſe the young quick or other plants would be choked and deſtroyed; and that there are alſo ſome kinds of weed-plants which very much injure old full-grown hedge-fences. That many kinds of weeds growing in hedges are a great nuiſance if the ſeeds be ſuffered to ripen, becauſe ſuch ſeeds are liable to be carried into cultivated

cultivated land by the wind; that there are fome kinds of hedge-weeds, too, which bear the character of being injurious to live-ftock; thefe, if the obfervation be well founded, ought, it is faid, to be well cleared from the hedges that fuch ftock frequent; and that, laftly, the improper fpecies of the vegetable kingdom, compofing or growing in hedges, may be termed hedge-weeds, becaufe they prevent the main object and end of fuch hedges, that of dividing, fencing out, and defending the land in a proper manner.

The moft hurtful weeds and plants of this fort are,

Catch-weed, or cleavers, a weed that has a tendency to choke and injure young hedges, by means of its numerous creeping and twining rough branches: it fhould, of courfe, be well cleaned out in due time, before it fpreads itfelf much in the bottom of the fence. See GALIUM *Aparine*.

Great bind-weed is a plant of this fort that is injurious in fome hedges, by twining round the growing quick or other plants, and reftricting their growth: its roots fhould confequently be extirpated from fuch fituations, which may probably be worth collecting for medicinal ufes, as the infpiffated juice of them compofe fcammony, a powerful purgative remedy. It is eaten greedily, too, by hogs without injury. See CONVOLVULUS *Sepium*.

Great wild climber is a weed-plant common in hedges, and which, in the chalk counties, is faid provincially to be called old man's beard, from the hoary appearance of the plant after flowering, the feeds being furnifhed with numerous grey hoary tails. It is very injurious to hedge-fences, as the leaf-ftalks twine about any thing they can lay hold of, and thus fupport the plant, which is large, luxuriant, and heavy, without any ftrength to fupport itfelf, and by its weight hauling down, obftructing the proper growth, and deforming the fences of this kind. Withering remarks, that the fine hairs that give the cottony appearance are, he apprehends, too fhort to be employed in manufacture, though, it is probable, they may be ufed to advantage for the ftuffing of chairs. See CLEMATIS *Vitalba*.

Wild hop, ladies' feal, or black bryony, and wild vine or bryony, are all weed-plants common in hedges, where they are fuppofed to be fomewhat injurious to the hedge-fences. They do mifchief in thefe fituations, by crowding and fmothering up the hedge-plants, and preventing their healthy and vigorous growth, as well as by taking away the proper nourifhment from their roots. See HUMULUS *Cupulus*, TAMUS *Communis*, and BRYONIA *Dioica*.

There are other fpreading, twining, and climbing weed-plants, which are occafionally very injurious and troublefome in hedges; fuch as the common ivy, which fpreads and creeps on the banks, and runs up and winds round the ftems of the plants, greatly injuring and impeding their growth and ftrength; the honey-fuckle, which binds itfelf clofely about the ftalks and branches of the hedge-woods, doing them much injury in different ways; and the briar, which extends its rampant fhoots in various directions, to the great annoyance and mifchief of the hedge-plants in many cafes. All thefe fhould be eradicated and cleared out from hedges in moft cafes, as they conftantly tend to weaken and render them in bad condition. See HEDERA *Helix*, LONICERA *Periclymenum*, and ROSA *Canina*.

Sow-thiftles, large rough thiftles, knap-weeds, and ragwort, are weeds that have been already noticed, and are great nuifances in hedges, if their feeds be fuffered to ripen in fuch fituations. The common nettle, too, is fometimes found in hedges to their great injury. They fhould all, therefore, be extirpated and cleared out from hedges in their early growth, to prevent future increafe.

In addition to thefe, the writer of the above paper has given the following, the feeds of which are furnifhed with feathers too, and they are capable of being carried to a great diftance.

Yellow devil's bit, wild lettuce, yellow hawk-weed, bufhy hawk-weed, and fmooth hawk's-beard, are weeds often troublefome in hedges, and which fhould be kept well weeded out at an early period. See LEONTODON *Autumnale*, LACTUCA *Virofa*, HIERACIUM *Murorum et Umbellatum*, and CREPIS *Tectorum*.

Burdock is a well-known plant of the weed kind, that fhould not be fuffered to perfect its feed in hedges, as it is of very luxuriant growth, and of courfe very injurious and difagreeable in fuch fituations. Withering afferts, that before the flowers appear, the ftems, ftripped of their rind, may be boiled and eat as afparagus; and that when raw, they are good with oil and vinegar. See ARCTIUM *Lappa*.

Dog's mercury is a weed faid to be noxious to fheep, and which is very common and abundant in fome hedges, appearing very early in the fpring, when fheep-food is the moft fcarce; on which account it is thought ftill more dangerous, if it be fo at all. When in very large quantity it may be hurtful to hedges, and fhould be kept under. See MERCURIALIS *Perennis*.

Barberry is a frequent plant in fome hedges; if found to really poffefs a blighting quality, it fhould be removed from the hedges of corn-fields. See BERBERRIS *Vulgaris*.

It is advifed by the author of the above paper, that thefe, as well as other plants of a fimilar nature, together with all luxuriant weeds and fhoots of the bramble kind, and whatever elfe grows beyond the bounds of the hedge-fence, fhould be brufhed out of fuch hedges about the middle of the fummer, as is very often done in fome counties, as Staffordfhire, for the fake of their afhes, which are worth all the labour and expence incurred in burning them, &c.

Weeds injurious in Woods and Plantations of different Kinds.—The weed-plants which are neceffary to be confidered under this head, are not very numerous: thofe which are given below are the chief of fuch as are peculiar to or commonly found in fituations of this nature, where no art has been ufed. They are the moft common herbs and plants which are fpontaneoufly produced in woods and plantations without attending to the timber and underwood forts; but many other kinds are to be met with, which are lefs common, and which have been lefs noticed and confidered.

Enchanters' night-fhade is a weed found in the woods of Bedfordfhire, and fome other counties, and by no means uncommon. See CIRCÆ *Lutetiana*.

Wood-reed is a weed met with in many woods. See ARUNDO *Arenaria*.

Woodroffe is a weed common in many woods about Enfield, in Staffordfhire, and Berkfhire. Sometimes very plentiful. See ASPERULA *Odorata*.

Wild angelica is a weed common both in woods and hedges, in many places. See ANGELICA *Sylveftris*.

Solomon's feal, or wood lily, is a weed found in woods in many different parts of the kingdom. See CONVALLARIA.

Englifh hyacinth, or hare-bell, and willow herbs, are weeds in fome woods. See HYACINTHUS *non Scriptus*, and EPILOBIUM.

Bilberry is a weed met with in moift woods in many parts of the country. See VACCINIUM *Myrtillus*.

Wintergreen is a weed-plant met with in the moor-land woods

woods in Staffordſhire, and ſome other counties. See PYROLA.

Wood-ſorrel is a weed very common in woods. See OXALIS *Acetoſella.*

Wood-ſpurge is a weed frequently met in woods, ſituated in a clayey ſoil. Plentifully in Needwood-foreſt, in Staffordſhire. See EUPHORBIA *Amygdaloides.*

Raſpberry, dewberry, and common bramble, are weeds common in moſt woods, in ſome of the ſorts. See RUBUS.

Wild Strawberry is a weed common in ſome woods. See FRAGARIA *Veſca.*

Tormentill is very common as a weed in ſome woods. See TORMENTILLA *Reptans.*

Herb bennet, and wood anemone, are common weeds in ſuch ſituations. See GEUM *Urbanum*, and ANEMONE *Nemoroſa.*

Wood crowfoot is a common weed in woods on a clayey ſoil. See RANUNCULUS *Auricomus.*

Stinking Hellebore is a weed in woods, in many parts of the kingdom. See HELLEBORUS *Fœtidus.*

Wood ſage, betony, hedge-nettle, and baſtard baum, are weeds of the common wood kind. See TEUCRIUM *Scorodonia*, BETONICA *Officinalis*, STACHYS *Sylvatica*, and MELITTIS *Meliſſophyllum.*

Cow-graſs, or cow-wheat, is very common in many woods, and ſaid to be an excellent cow-herbage; but little found in paſtures, in any ſituation. See MELAMPYRUM *Pratenſe.*

Fig-wort, and coral-wort, are weeds in ſome woods. See CROPHULARIA *Nodoſa*, and DENTARIA *Bulbifera.*

Pea-everlaſting is a luxuriant weed-plant, that has been ſeen with the ſtem five or ſix feet long, in a wood in Rutlandſhire. See LATHYRUS *Sylveſtris.*

Wood-vetch, wood-peaſling, St. John's wort, ſhrubby hawk-weed, ſow-wort, hoary groundſel, golden-rod, butterfly-orchis, friary-blade, ſedge-graſſes, and ſpurge-olive, or ſpurge-laurel, are all plants of the weed kind in woods in different places. See VICIA *Sylvatica*, OROBUS *Sylvatica*, HYPERICUM *Perforatum*, HIERACIUM *Sabaudum*, SERRATULA *Tinctoria*, SENECIO *Crucifolius*, SOLIDAGO *Virgaurea*, ORCHIS *Bifolia*, OPHRYIS *Ovata*, CAREX and DAPHNE *Mezereum* and *Laureola.*

It has been remarked, that as no ſort of cattle can be properly introduced into theſe ſituations, in the early growth of the woods, there appears no particular room for the choice of the under herbage; but all large coarſe growing weeds of theſe and other kinds, ſhould be removed or kept well under, and that briars and brambles, if they appear, ſhould on ſeveral accounts be grubbed up and deſtroyed. Ivy, too, as claſping, confining, fretting, and injuring the plants on which it riſes, ſhould be early cleared away to prevent the miſchief of its after removal.

It is hardly neceſſary to obſerve, as it muſt be evident, that this account is far from comprehending all the plants which have been conſidered as weeds by writers, and thoſe engaged in the cultivation of land; as ſuch as are known to be prejudicial or hurtful, in ſome way or other, to ſome ſorts of cultivation or other, have, for the moſt part, been only introduced.

Thoſe who may wiſh for further information on the ſubject, may conſult the paper on weeds, by Mr. Pitt, inſerted in the fifth volume of "Communications to the Board of Agriculture;" and alſo the new edition of Miller's Dictionary, by Martyn, in which a very large catalogue of weed-plants is given; as well as many of the Corrected Reports on the Agriculture of different Counties.

It is remarked by the writer of the above paper, that the plants we term weeds, conſidered as reſpecting mankind, are not totally uſeleſs; many of them have valuable medicinal, and, perhaps, other qualities and properties, and ſome of them may be applied to uſes ſo as to pay ſomething towards the expence of clearing them from the ground: thus, ſow-thiſtles are good for rabbits or hogs, the hog-weed is uſeful for either pigs or cattle: horſes are ſaid to be fond of young thiſtles when partially dried, and the ſeed may be prevented from ſpreading by gathering the down, which makes good pillows; however, there is ſome danger in truſting them to this ſtage of growth, as a high wind would and frequently does diſperſe them over a whole country, as has been ſeen already. Chadlock, when drawn, may be given to cows, who are very fond of it; and it is ſaid in the Oxford Report on Agriculture, that it can be converted into good hay. Further, that nettles, fern, and the more bulky hedge-weeds, may be collected and annually burnt, as has been ſeen above; their aſhes being afterwards formed into balls, which are of conſiderable value, as being uſed in compoſing a ley for ſcouring and cleaning linen and other cloths.

It is ſtated, too, that pigeons are of uſe in picking up the ſeeds of many weeds that would otherwiſe vegetate; and the writer has no doubt but that a prodigious quantity of the ſeeds of weeds are eaten by different ſorts of ſmall birds, particularly of thoſe of moſt of the lake-weeds, of ſpurry, and in ſevere weather, of the different ſorts of chadlocks, as well as of many other kinds. But that it has been obſerved, that bees have not thriven or done ſo well in this country ſince the extirpation of weeds has been more attended to, and become more general.

It is noticed, that in Japan, and in China, not a weed, it is ſaid, is to be ſeen; and that they make uſe of night-ſoil only as a manure, partly with the view of preventing any riſk of weeds being produced in that way.

In concluding, it may be noticed, too, that the ſame writer has remarked, that the vegetables we term weeds are more hardy and tenacious of growth than any others; nor can it indeed be otherwiſe than that thoſe plants, which ſucceed in ſpite of oppoſition, muſt be of the moſt hardy kind. But that the production or growth of weeds is equally conſiſtent with the divine goodneſs with that of the moſt valuable plant, for myriads of diminutive creatures, enjoying life and animation, are fed and ſupported by them, and to whom they are a more natural prey than the dietetic plants of mankind: and that man, poſſeſſed of reaſon, reflection, and intelligence, has powers and abilities to ſelect and cultivate ſuch vegetables as are adapted to his uſe, and proper for his ſuſtenance, and to deſtroy and extirpate others; and thus to appropriate to himſelf what proportion he may think proper of the earth's ſurface; which if he ſhould neglect to dreſs and cultivate properly, it will, in ſome degree, revert to its natural ſtate, producing the hardier and more coarſe and acrid plants for the ſuſtenance of numberleſs tribes of inſects and other little animals, and for an infinity of other known and unknown uſes and purpoſes; and that indeed were it otherwiſe, the indolence of the human race might, in ſome meaſure, ſuſpend the bounty of providence, and the fertile parts of the ſurface of the earth, inſtead of being covered with an univerſal verdure, would, by inexer ton or neglect, be rendered little different to the ſterile and barren deſert.

WEED, *Dyer's*. See DYER'*s Weed*, *Baſtard* ROCKET, and WELD.

WEED, *Fuller's*. See TEAZEL.

WEED-*Hook*, in *Agriculture*, a very uſeful implement for cutting up thiſtles, and other ſtrong plants of the ſame nature;

ture; but as thiftles, when cut either at an early period of the feafon, or before much rain falls, are apt to fpring up afresh, and produce four or five ftems in place of one; they fhould, perhaps in every inftance, be pulled up by the roots, or, if they be cut, the operation fhould be done with a chifel within the ground, which is formed with a divifion in the mouth of it, fo as to feize the ftem part of the plant, and cut it deep down. See WEEDING *Dock-Spit*.

WEEDING, in *Agriculture* and *Gardening*, the operation of freeing crops of any kind from noxious weeds. On the indifpenfible neceffity, and great utility of this practice, it is altogether needlefs to enlarge. See WEED.

There are obvioufly two different methods to be principally employed in the removal and deftruction of weeds; one of which occurs in the preparation of the land, and the other during the growth of the crop. In the former method it is neceffary that fuch weeds as are of the root kind fhould be diftinguifhed from thofe of the feedling defcription, as the deftruction and removal of them muft be effected in different ways, and upon different principles.

Weeding in garden-grounds is always a bufinefs that fhould be regularly and well performed in both the circumftances above-mentioned. Much may be frequently done in the former cafe by properly ridging or laying up the ground before the fevere winter-feafon fets in, and in reducing and breaking it down in the early fpring or other time, for levelling it, and making it ready for putting in the neceffary crop, as the root as well as the feedling weeds may be greatly extirpated and deftroyed in thefe different operations; the former affording the ready means of taking out the firft fort, and the latter by putting them in the fprouting ftate, giving the opportunity of deftroying the other. In the latter cafe, a great deal will be effected by the fteady and repeated application of the hoe while the crops are upon the ground; and by good and careful hand-weeding, before the weeds have had time to ripen and fhed their feeds.

It has been remarked with great truth, in regard to the extirpation and prevention of garden-weeds, that many will almoft conftantly appear, from the feeds being brought by the wind; as well as by being introduced by ufing raw dung, particularly of hogs and horfes, which often contains feeds poffeffing their vegetative power, and the litter intermixed therewith not unfrequently containing more; which ftrongly fhew that raw dung is very improper for gardens, though often ufed, particularly for early and other potatoe-crops, as it caufes much trouble and expence in weeding.

Much labour in weeding muft neceffarily be faved, too, by drawing up all feedling weeds in time, as they appear, and before they have fown their feeds.

The extirpation and removal of weeds from garden-grounds are fomewhat differently effected in various places: in fome they principally ufe the fpade, and the three-pronged or fanged fork, for cleaning out root-weeds; but the different kinds of hoes are employed for other purpofes, of which the common ones are moftly made ufe of for fcuffling over the furface, and thofe of the triangular and parallelogramic form, for cutting up weeds, moulding up and clearing growing plants, and loofening the furface of the ground for promoting the fprouting of any feeds that may be prefent, and other fuch ufes. With thefe the fcuffle or fcuffler is fometimes had recourfe to for cutting the weeds, and working the furface of the land over in large gardens. In the fmall planted broad-caft fown crops, the weeding can only be well accomplifhed by performing the work by the hand. See HOE, FORK, SPADE, SCUFFLE, &c.

In regard to deftroying and removing weeds in tillage-lands, it has been well obferved by Naifmith, in his "Elements of Agriculture," that when the ground is greatly overrun with weeds, a complete winter and fummer fallow will, for the moft part, be found unavoidable, in order to get entirely quit of them. Rib-fallowing, before the winter fets in, will, it is faid, prepare the foil for parting freely with the vivacious roots, the ploughing and harrowing requifite to tear them up when the fpring drought commences, will pulverife and reduce it, and provoke the dormant and inactive feeds to vegetate with the firft moifture; by repeated turnings, during the fummer, the greateft part may be made to vegetate, and be deftroyed as they rife; and the vivacious roots, which lie beyond the reach of the plough, by being long prevented from exercifing their vegetating powers, will be impared in vigour. When winter-wheat, or any crop which is to ftand through that feafon, is intended to be put in on fuch ground, it would be proper that the feed fhould be fown in drills, that by ftirring the intervals in the enfuing fummer, the tendency which moft foils have to condenfe or confolidate too much when greatly pulverifed or reduced in their parts, may be counteracted. If fpring-feed be intended, the laft ploughing fhould be given to the land before the winter's rain commences, and the field be accurately and fully furface or furrow-drained, and laid dry. The influence of the atmofphere during the winter will, by thefe means, communicate the happy medium of confiftence, on which fo much depends; and the foil, as foon as it gets dry in the early fpring, will be in the beft order for the reception of the feed at that time, and the weeds the moft fully and effectually deftroyed and removed.

But where ground has been under any tolerable management, drill culture will, it is faid, for the moft part, fuit all the purpofes of a clean fallow, or be the means of rendering the land wholly free of weeds. In repeatedly turning the intervals, moft of the annual weeds may be attacked in the group, and be expeditioufly deftroyed as often as they fpring up; and the roots of the perennial ones be turned up and expofed to the heat and drought, which, if not altogether extirpated, will have their progrefs checked and prevented. But the rows fhould alfo be hand-weeded, and the hand-hoe will not unfrequently be found an important implement in this work. Drill culture may thus be partially exercifed, in this intention, it is thought, every where with great advantage, adapting the application to any particular fituation or circumftances. For example, where alternate courfes of tillage and grafs crops are adopted, in a courfe of three years' tillage, the fecond might always be in the drill manner; or if there were manure to fpare, to keep a field in good condition in tillage-crops for four years, both the fecond and third might be in the drill method: the firft on account of the tough turf or fward; and the laft for the fake of fowing the land down with grafs-feeds would be more convenient in the broad-caft ftate: but the weeding in thefe cafes fhould not be neglected; the larger weeds efpecially; and all thofe which are moft prevalent, and moft productive of feed, fhould be taken out by hand labour, or fome fuch means, when they begin to flower. By fuch ftrict care and attention to weeding tillage-land and crops and ftocking the ground with proper perennial graffes when laid to reft, weeds would at length be fo much fubdued, it is fuppofed, as to be feldom injurious to the farmer.

The

The writer of the paper on weeding has ftated, that it is remarked by the author of the Effays on Rural Affairs, that there is only one mode of extirpating annual weeds, the feeds of which are indeftructible ; which is to put the ground into fuch a ftate as to induce them to fprout or germinate, and then to deftroy the young plants by harrowing them up, or ploughing them under. This, it is believed, is ftrictly true ; but the author of the paper juft noticed does not exactly agree with the writer of the effays in the procefs to be purfued for the purpofe ; the ground, in this intention, in his opinion, fhould be ploughed before winter, but not harrowed, it being better to lie rough through that feafon, fo as to have the greateft extent of furface poffible expofed to the action and mellowing effects and influence of frofts ; that, as foon as it becomes dry, in or about March, it fhould be crofs-ploughed and harrowed well down ; many of the feeds and roots will then vegetate, which fhould in due time be ploughed under, and the land harrowed again, and this fort of procefs be repeated as often as neceffary : this, it is faid, is the true ufe and manner of fummer-fallow in this view, which, to have its full and proper effect, fhould always, it is thought, be attended to early in the feafon, when the powers of vegetation are the greateft, and the heat of the fun is powerful ; as under fuch circumftances the greater number of weeds will be brought into a ftate of growth.

It is thought that the great defect in the management of fummer-fallows in the intention of deftroying weeds would feem to be the neglect of working them early in the feafon, by which omiffion the vigorous annual feedling-weeds are not brought into vegetation in due time ; as, after which, they will not grow until the fpring following, when they appear in fuch abundance among the wheat or other crop, as fometimes to choke it up : this is the reafon, it is faid, why the field poppy, the corn-crowfoot, the tare, and many other annual weeds, make fuch havoc among wheat, when by a proper and judicious early working of the fallow, they might have been brought to exhauft themfelves in the following fummer : this appears very clear from the effect, for if no wheat were fown, the feeds of thefe weed-plants would often fill the ground with a full crop ; but feeds can vegetate but once, confequently had this vegetation been brought on in the fallow, and the plants afterwards been ploughed under in due time, none could have appeared in the wheat-crop.

It is fuppofed, too, that the turnip-culture is peculiarly adapted to the deftruction of weeds, as for this fort of crop the ground muft of neceffity be in early and fine preparation, by which weeds of early growth are conveniently brought into vegetation, and deftroyed ; and thofe which remain in the living ftate in the foil may be exterminated by hoeing. It has been obferved by the writer, that wet weather is as neceffary as dry to give a fummer-fallow its whole effect ; for without a foaking of rain after the land is pretty well pulverifed, numbers of the feeds of weeds will not vegetate, but remain and grow amongft the crop ; the root-weeds are therefore to be deftroyed in dry weather, and the feedling ones after rain ; and though the land fhould, after a dry feafon, be apparently in excellent order for fowing, it will be better to wait the effect of rain, and even give time for the feedling weeds to vegetate, before the feed for the crop be actually fown.

It is, therefore, fuggefted, that the deftruction of root weeds, and thofe of the feedling kind, on corn-land, muft be effected upon different principles, and in different manners ; the former, by working them out of the foil in dry weather only ; the latter, by pulverifing and reducing the particles of the foil, fo as to induce the feed to germinate and fpring up fully after rain, and afterwards ploughing under the young plants : alfo that frequent ploughings and harrowings are neceffary, to expofe all the feedlings contained in the foil to the powers of vegetation. But it is conceived, that the ploughings and harrowings of fallow ground fhould not, however, immediately fucceed each other ; time fhould be given for the confolidation of the foil, which, after well harrowing, will undergo a flight fermentation, and fettle, as it were, into a mafs ; after which it will turn up mellow, and the deftruction of weeds will go on apace. It is thought, that the frequent ploughings, which have been recommended by fome, are not only unneceffary, but injurious. It has always been obferved, that one ploughing of a fallow too foon fucceeding another has no other effect, when ufed in this intention, than that of rooting about the clods, and preventing the general effect of confolidation and fermentation in the land. The fuffering of the weeds to fpread their leaves a little between the feveral ploughings of a fallow, for this purpofe, is not, it is fuppofed, injurious : care, however, muft be taken not to carry this notion too far, particularly in the cafe of fquitch or couch grafs, or fo as to fuffer any of the quick growing weeds to ripen their feeds, or the luxuriant ones to become too large for being buried with the plough. As thefe remarks are judicious, and perfectly practical, they deferve the particular attention and confideration of the farmer, wherever the weeding and proper cleaning of his ground is concerned.

It is ftated too, that in this view, if a fallow for turnips be crofs-ploughed and harrowed down in the month of March, it will generally lie very well to the beginning of May ; and that in general no fallow will want ploughing oftener, in fuch intention, than once in fix weeks, if fufficient harrowings be given between the ploughings. The particular time moft proper for thefe operations muft, however, be determined not by any general rule, but by local circumftances, experience, and obfervation.

In cafes where lands have not undergone proper improvement, or been under a bad ftate of management, weeds cannot be deftroyed without much labour and expence. (See Weed.) But where lands are already improved, and have been for fome length of time under a good fyftem of management, the bufinefs is in part performed, and the evil much leffened ; as in fuch cafes, as well as all others, every rotation or courfe of cropping fhould render the land cleaner and freer from weeds, which will certainly be the cafe, where there is a proper and correct attention beftowed on the bufinefs. The means which are neceffary to be ufed in this intention are commonly, it is faid, thefe : complete and well-managed fallows, as above, when fallows are neceffary or proper ; the ufe of manures, which are free from the feeds or quick roots of weeds ; the careful choice of fuch feed grain as is clean ; the practice of fhort tillages, or that of not taking too many crops in rotation ; the having recourfe to attentive weeding and a fpirited ufe of the hoe, in which view the drill hufbandry doubtlefsly, it is fuppofed, affords fuperior advantages to the broad-caft, in keeping land clean from weeds ; but that land muft be well cleaned before the drill hufbandry is applicable ; the plentiful ufe of the clean feeds of the beft graffes and trefoils at the end of the tillage, in each cafe ; the weeding of the land, when in or at grafs, fo as not to fuffer the feeds of any noxious or injurious plants to fpread themfelves ; and that when upon again breaking up the land, to purfue fuch a fyftem or plan of cropping as will not increafe or encourage weeds. But though much might be faid on each of thefe points, it is thought unneceffary, as the intelligent farmer will readily

adopt

adopt every neceſſary regulation and precaution from his own obſervation and experience. It will, therefore, only be needful to ſlightly touch upon the different particulars or objects. As the ſubject of fallows has been already conſidered and explained, it is unneceſſary to be further noticed in this place. In regard to fold-yard manure, it ſhould always, it is ſuppoſed, in this intention, undergo a fermentation before it is laid upon the land, ſufficient to prevent the future vegetation of any ſeeds that may be contained in it: but it ſhould likewiſe be kept as free as poſſible from the ſeeds of weeds; and perhaps it is beſt laid on graſs-land, applying only lime, or other manures certain of being clean, to fallows; or if dung not certainly clean from ſeeds be laid on fallows, it ſhould be applied on them early enough to give time to have the ſeeds to vegetate and ſpend themſelves before ſowing for the crop. It is ſaid, that every one knows the neceſſity of clean ſeed-corn to the producing of a clean crop, but ſometimes neglects to apply ſuch knowledge; and indeed clean ſeed-grain is not always to be procured. If weed-ſeeds be ſuſpected, they ſhould, as often as poſſible and practicable, be dreſſed out before ſowing the corn. The weeding of crops is generally imperfectly performed, and is likely to continue ſo, it is thought, in many places, on account of the difficulty of procuring hands enough for work which is only ſo temporary in its nature. Thiſtles are generally only cut off, but they ſhould always, it is ſaid, by drawn up by tongs, or other tools for the purpoſe, and the other ſorts of weeds by the hand. The hoe has yet been only of general uſe in turnip crops, nor is it likely to extend further, unleſs the drill huſbandry ſhould be more eſtabliſhed; nor even, in its preſent application, can proper hands enough be always, it is ſaid, procured at ſufficiently reaſonable rates. As much, however, ſhould conſtantly be done in all theſe ways as circumſtances will allow. In the laying down of land to graſs, the importance of clean graſs-feed is well underſtood; yet the ſeeds of docks are not unfrequently ſown with clover, and thoſe of other pernicious weed-plants with ray-graſs. In all caſes, the utmoſt attention ſhould be paid to the ſowing of clean ſeed of this ſmall kind. And in the weeding of graſs-land, docks and thiſtles are often mown, or only cut off, but they ſhould always be rooted up; for which purpoſe, docking irons formed upon ſufficiently good principles are moſtly had recourſe to. They are, it is ſuppoſed, every where well underſtood, conſiſting ſimply of a forked or clefted ſpike of iron, which is jogged within the cleft, and fixed to the end of a wooden lever: this being forced down by the hand or foot, ſo as to incloſe the root of a dock, or large thiſtle, will eaſily bring it up, particularly after rain; but mowing them off, being done with more expedition, is often practiſed; and they are ſometimes left undiſturbed, and ſuffered to ſcatter their ſeeds without any effort being made to prevent it, which is very injurious, and always to be avoided as much as poſſible. It is ſtated too, that upon breaking up a turf or ſward, it is underſtood in the writer's neighbourhood, that unleſs a wheat fallow or a turnip crop compoſe a part of the tillage, the land will be injured, and rendered fouler, and more addicted to produce weeds: this notion is, it is believed, a juſt one, though often deviated from in practice, for the ſake of preſent profit, and under the deluſive idea of cleaning the land again next tillage. It is, however, well aſcertained, that land well cleaned by former good management will beſt bear this deviation; for the fewer weeds it contains at breaking up, the leſs will be the increaſe of them during the tillage or after-culture of the ground.

The writer of the Elements of Agriculture noticed above has obſerved, that it is not enough to attend to weeding in the time of tillage-culture only: it is proper that graſs-fields and lands ſhould likewiſe be kept free of all noxious, hurtful, and unprofitable herbage. The negligence which may be ſeen in this reſpect, in many diſtricts and places, is, it is ſaid, ſhameful. Paſtures and other graſs-lands are ſometimes ſo cloſe covered with large weeds, that the paſturing animals have ſcarcely room to pick up a mouthful; and thus the vegetable food and other matters, which ſhould nouriſh good and wholeſome paſture and other graſs-land herbage, is conſumed by uſeleſs weeds. And ſpeaking of different coarſe and diſguſting weed-plants, ſuch as the dock, ragweed, bur, corn, and ſow-thiſtles, and ſome others, it is remarked, that the two laſt are of the ſort which extend their vivacious roots below the reach of the plough, when the land is in tillage. It is not, it is ſaid, uncommon with thoſe who affect to pay a little more attention than ordinary to their paſtures and graſs-lands, to cut down theſe plants in the flower. If this be done in a rainy time, or if ſuch rain falls ſoon after, the water deſcending into the freſh cut wound of the ſtem, debilitates the roots, and diſcourages the growth of the plants for a time, though they are ſeldom wholly deſtroyed by it; but that if ſuch critical rains do not occur, freſh leaves immediately ariſe to ſupport the roots, and the cutting over has very little or no effect. They ſhould conſequently be annually pulled up by the roots as ſoon as poſſible, after the flower begins to form and ſhew itſelf, taking advantage of the firſt ſhower which happens to fall, to ſoften the ground and make them draw up more freely. By purſuing this practice regularly and ſteadily for a number of years, the deep lying perennial roots are, it is ſaid, gradually weakened, and fall into decay. Nor is cutting down the ragweed of much avail. Some of the plants die, but many ſurvive, and branch out more copiouſly the enſuing year. But this plant not being deep-rooted, is eaſily pulled up when in flower, if the ground be ſoft at the time. The bur-thiſtle being a biennial plant, may be killed at any time by cutting it under the firſt leaves. The common dock is the moſt troubleſome plant in graſs-land, eſpecially in clayey ſoils, where it is always the moſt frequent. Every bit of its long tap-root left in the ground will continue to vegetate and grow, and at length form a new ſtem and plant. It ſhould, in all caſes, be fully turned out with the dock-iron, in the manner already noticed, as ſoon as the flowering-ſtem is formed; and as the plants of this kind riſe at two ſeaſons, the paſture or graſs fields ſhould be weeded twice in the ſummer, that no ſeeds may be allowed to ripen. The roots ſhould be fully expoſed to the heat and drought; for if they be in a moiſt place, they will continue to vegetate on the ſurface, as they lie and ſtrike out ſide-roots into the ground. All other ineſculent herbage on paſtures and other ſorts of graſs grounds, and all weeds bearing ſeeds by the ſides of roads, ditches, brooks, and other ſuch places, ſhould be cut down too, when they begin to flower, in order to prevent their increaſe by their ſeeds being diſperſed over the graſs fields and grounds.

The writer of the Glouceſterſhire Report on Agriculture, in reprobating the practice of confining the buſineſs of weeding almoſt ſolely to the tillage-lands, while the meadows and paſtures are almoſt wholly neglected, and overrun with docks, thiſtles, nettles, hemlock, and many other ſuch weed-plants, remarks, that it is ſuppoſed by the farmers, that the ſcythe will be early enough to cut them off: the ſeeds, however, are generally ripened and diſperſed before mowing time; and if not, they are carried with the hay to the ſtall, and mixed with the dung, or into the paſture

ture for fodder during the winter; in either of which cafes they cannot fail, it is fuppofed, of increafing greatly. Befides, the mere cutting off this kind of weeds rather improves than diminifhes their growth, by forcing them to throw out new fhoots from the roots, and that in greater abundance than before. Thus, a thiftle, which rifes at firft with a fingle ftem, if cut off above the furface of the ground, fpreads with feveral lateral branches, and covers a large fpace of ground. The moft likely method of deftroying them is to draw them up by the roots, as already feen, which may eafily be done when the ground is moift, and is done by thofe farmers there, it is faid, who are anxious for their credit, nice in their herbage, and proud of feeing their paftures rivalling the neatnefs of a lawn. The negligence, indeed, of a neighbour often operates as a difcouragement, and it is an evil not eafily to be prevented: it is, however, furprifing in another inftance, it is faid, to obferve an almoft unanimous encouragement given to the multiplication of noxious weeds. In the highways they are left to grow to maturity, and their feeds are difperfed in immenfe quantities in every direction, and all over the country, by the wind, or by being carried by birds. Under thefe circumftances, it is faid to be certainly of little ufe for one, or even all the occupiers of ground, to clear their lands of weeds, while this plentiful fource of them remains unmolefted. One fhould fuppofe, the writer obferves, that the evident mifchief refulting from this neglect would excite a general combination againft thefe deftructive enemies to the interefts of agriculture: that, however, not being the cafe, might it not, it is afked, be convenient to incorporate with the duty of the furveyors, or overlookers of the roads, the bufinefs of cutting up, and otherwife deftroying, fuch kinds of weeds within their diftricts or boundaries? Should the fact of the thoufand-fold increafe of fuch felf-fown feeds be doubted or difputed, let, it is faid, any one but obferve a patch on a common, from which the turf or fward has been pared, how completely it will be covered with thiftles in the following fummer; and the arable fields adjoining are not much better, where this negligence prevails.

And the writer of the paper on the fubject of weeding ftates, that there is another caufe of the increafe and propagation of weeds, which may be termed a *public* caufe, and which it is not in the power of any individual to prevent; but which a flovenly, neglectful, or ill-difpofed perfon may promote and increafe, and which can only be effectually prevented by a *political* regulation, and for which, it is believed, no provifion has yet been made in our political code: thus are the numbers of vigorous and luxuriant weeds which are fuffered to ripen their feeds in our hedges, paftures, woods, and other lands, and the feeds of which being provided with feathery matters, are difperfed over the whole territory of the kingdom, and propagate themfelves far and near, growing in whatever places they alight and fettle, and producing a moft abundant crop: the moft common and pernicious of which are fuppofed to be the different forts of fow-thiftles, fow-worts, common thiftles, colt's-foot, groundfels, knap-weeds, &c. For as the feeding and fcattering of the feeds of all thefe forts of plants is clearly a public nuifance, and as they are fubject to be carried to a great diftance by the above means, and to do harm to the lands of all occupiers indifcriminately, they fhould, it is thought, be under the controul of our political regulations. This would be the effectual means of preventing much labour and expence to the farmer and the occupier, in the weeding of different kinds of lands and crops, and at the fame time go a great way in rendering the territory of the country ultimately clear of a great proportion of its moft noxious and hurtful weeds. Befides, regulations of the above kind have been applied in different countries and places to weed-plants, which are much lefs injurious and hurtful than thefe. See WEED, and the above paper in the fifth volume of Communications to the Board of Agriculture.

In fome cafes and parts of the country, the weeds in the lefs heavy tillage-lands are deftroyed, by an entire and perfect fummer-fallow every third year, which is an effectual but expenfive method of proceeding; but on the ftrong loams and other heavy foils by good hoeing and hand-weeding the drilled or fet crops of beans, peas, and fome other kinds. On the fandy and other light loams, by well hoeing and weeding by hand the crops of peas, potatoes, turnips, and fome others. As foon as the peas or tares are off the land, the ground is ploughed and well harrowed, and the root-weeds picked or raked together, and burned or otherwife difpofed of, as noticed above; which is moftly repeated after the crofs-ploughing and harrowing have been performed. The ground being then in a great meafure free from root-weeds, the turnips are fown, and the feed-weeds that may arife deftroyed by twice or oftener hand-hoeing and weeding. This fort of practice being repeated or put in execution once in three or four years, is capable of keeping light land tolerably clean and free from weeds. However, in the cafe of a hot dry fummer, the labour and expence of raking, collecting, picking, and burning the weeds, may not unfrequently be faved, and the roots deftroyed, by only harrowing them to the furface after every ploughing; and by that means expofing them well to the heat of the fun for a fufficient length of time to kill them, which is fometimes effectually done in the courfe of a week. Care muft, however, always be taken that they are fully and completely deftroyed, otherwife much mifchief may be the confequence, as they are extremely tenacious of life.

In all cafes, where the ftaple or vegetable mould of the foil is of a fufficient depth to admit of trench-ploughing, that fort of ploughing, with the affiftance of heavy rolling, and other proper means, will in fome circumftances completely deftroy root-weeds. In fome cafes, it is even more effectual for that purpofe, it is faid, than any greater number of ploughings, and is an excellent method, where it can be accomplifhed without turning up a poor barren fubfoil. The great utility and importance of it in cleaning garden-grounds have been already feen, and it is fuppofed to be equally beneficial in deftroying weeds, and preferving the foil moift in the moft drying weather of the fummer feafon. See TRENCH-*Ploughing*, and TRENCHING. Alfo RIDGING-*up*.

The work of weeding in all cafes fhould be begun fufficiently early in the fpring, that the weeds may not be in too forward a ftate, and the bufinefs, in whatever way it is undertaken, be effectually and completely performed, without any fort of omiffion or neglect. In the meadows and pafture-lands it fhould be equally attended to as in the corn-fields, as in all fituations weeds are a very great drawback upon the farmer's profit, and of vaft inconvenience in many different ways.

It is prefumed by the writer of the paper on weeding, that if the above propofed regulations, precautions, and methods of deftroying injurious plants were generally adopted in practice, they would render the Britifh empire as free from weeds as thofe of China and Japan.

It may be concluded that, on the whole, by great, unremitted, and proper attention, with fome fuch regulations as the above, to the extermination and deftruction of all forts of ufelefs and hurtful weeds in cultivated grounds, and from meadows and paftures, the growth of injurious and worthlefs plants may be prevented, and the arable crops be rendered

dered much more abundant and productive than they uſually are, and thoſe of the graſs kind be provided with a better and more uſeful herbage for the ſupport of live-ſtock of all kinds, which would greatly contribute to the farmer's profit and advantage.

Weeding-*Chiſel*, in *Agriculture*, an uſeful tool with a divided chiſel point for cutting the roots of large weeds within the ground. See Weed-*Hook*.

Weeding *Dock-Spit*, the tool uſed in extirpating weeds of the dock, thiſtle, and other ſuch large kinds which are to be got up by the roots. It is a ſort of crow or lever, with a claw at the bottom end of it, a little curved forward, and divided into two ſide parts, in ſomewhat the manner of the thin end of a common hammer uſed for drawing nails: it has an arm or tread which projects at about eight or ten inches from the lower end, for the foot to reſt firmly upon in forcing it into the ground, and at a little diſtance above it, on the back ſide, a curve of iron, projecting about three inches; on the upper or top end, a handle is fixed, and faſtened as in the common ſpade: in uſing it the claw ſeizes the root of the plant, and, by a gentle preſſure of the handle end downwards, in the manner of the lever, eaſily and readily draws or forces it out of the ground: by means of this ſimple implement or contrivance, many hundreds of ſuch weed-plants may be eradicated or drawn out in the courſe of a day. It has ſometimes the names of weeding-ſpud or ſpade, and dock-ſpit or ſpud given it. See Weeding.

Weeding-*Forceps*, or *Tongs*, the tool of the nipper kind, which is made uſe of for taking up ſome ſorts of plants in weeding corn and other crops, ſuch as ſmall thiſtles of different kinds, ſmall docks, and various other ſuch weeds. It ſeizes them by the mouth part, which is fixed upon them by means of the long handles in uſing it, and readily forces them up. See Thistle-*Drawer*.

Weeding-*Fork*, a ſtrong three-pronged fork of the fork ſort employed for working root-weeds in tillage-lands, and forking out the weeds of the ſame kind in garden-grounds; in both which caſes it is a very uſeful and effective tool. It is ſometimes made with flat prongs, and termed a ſpud in plantation-grounds. See Fork.

Weeding-*Shim*, an implement which is conſtructed differently to ſuit different purpoſes, but that which is made with a frame ſomewhat like that of the common wheel-barrow, is conſidered the beſt in the county of Kent, where tools of this ſort are much uſed in the plantation-grounds for different crops. It is a very uſeful and convenient tool for the purpoſe of tearing up weeds on ſummer-fallows, and in many other caſes. Its cheapneſs too is a great recommendation of it, as it is capable of being well conſtructed for about two pounds. See Harrow, &c.

Weeding-*Spud*. See Weeding *Dock-Spit ſupra*.

WEEDS, in *Mining*, a term uſed by our Engliſh diggers to expreſs any ſort of unprofitable ſubſtance found among the ores of metals. They ſeem to have borrowed the phraſe from the gardeners; and as every thing with them is a weed, except what they have planted, and expect to gather, ſo every thing is a weed with the miners, except the thing they are ſinking for. See Digging.

The principal ſubſtances known in our mines under the name of weeds, are mundic or marcaſite; this is of three ſorts, white, yellow, and green; daze, a kind of glittering talcky ſtone, of the telaugium kind, which endures the fire, and is of various colours and hardneſſes; iron-moulds, or pyritæ; caul, which is browniſh and ſpongy; and gliſter, which is a ſort of talc. Phil. Tranſ. N° 69.

Weeds alſo denote a peculiar habit, worn by the relicts of perſons deceaſed, by way of mourning. See Mourning.

WEEK, *Septimana*, *hebdomada*, in *Chronology*, a diviſion of time, compriſing ſeven days.

The origin of this diviſion of weeks, or of computing time by ſevenths, is greatly controverted. Some will have it to take its riſe from the four quarters or intervals of the moon, between her changes of phaſes, which, being about ſeven days diſtant, gave occaſion to the diviſion. Be this as it will, the diviſion is certainly very ancient. The Syrians, Egyptians, and moſt of the oriental nations, appear to have uſed it from all antiquity: though it did not get footing in the Weſt till Chriſtianity brought it in: the Romans reckoned their days not by ſevenths, but by ninths; and the ancient Greeks by decads, or tenths.

Indeed, the Jews divided their time by weeks, but it was upon a different principle from the other eaſtern nations. God himſelf having appointed them to work ſix days, and to reſt the ſeventh, in order to keep up the ſenſe and remembrance of the creation; which, being effected in ſix days, he reſted the ſeventh.

Some authors will even have the uſe of weeks, among the other eaſtern nations, to have proceeded from the Jews; but with little appearance of probability. It is with better reaſon that others ſuppoſe the uſe of weeks, among the heathens of the Eaſt, to be a remain of the tradition of the creation, which they had ſtill retained with divers others.

This is the opinion of Grotius, De Veritat. Relig. Chriſt. lib. i., who likewiſe proves, that not only throughout the Eaſt, but even among the Greeks, Italians, Celtæ, Sclavi, and even the Romans themſelves, the days were divided into weeks; and that the ſeventh day was in extraordinary veneration. This appears from Joſeph. adv. Apion. II. Philo. de Creatione. Clem. Alexand. Strom. lib. v. Though Helmoldus, lib. i. cap. 84. Philoſtratus, lib. iii. cap. 13. Dion. lib. xxxviii. Tibullus, Lucian, Homer, Callimachus, Suetonius, Herodotus, &c. who mention the ſeptenary diviſion of days as very ancient, ſuppoſe it to have been derived from the Egyptians.

The *days of the week* were denominated by the Jews, from the order of their ſucceſſion from the ſabbath. Thus, the day next after the ſabbath, they called the *firſt* of the ſabbath; the next, the *ſecond* of the ſabbath; and ſo of the reſt; except the ſixth, which they call *paraſceve*, or preparation of the ſabbath.

The like method is ſtill kept up by the Chriſtian Arabs, Perſians, Ethiopians, &c. The ancient heathens denominated the days of the week from the ſeven planets; which names are ſtill generally retained among the Chriſtians of the Weſt. Thus the firſt day was called *Sun-day*, *dies ſolis*; the ſecond *Moon-day*, *dies lunæ*, &c. a practice the more natural on Dion's principle, who ſays, the Egyptians took the diviſion of the week itſelf from the ſeven planets.

In effect, the true reaſon of theſe denominations ſeems to be founded in aſtrology. For the aſtrologers diſtributing the government and direction of all the hours in the week among the ſeven planets, ♄ ♃ ♂ ☉ ♀ ☿ ☽, ſo as that the government of the firſt hour of the firſt day fell to Saturn, that of the ſecond day to Jupiter, &c. they gave each day the name of the planet, which, according to their doctrine, preſided over the firſt hour thereof; and that, according to the order ſpecified above; and which is included in the following technical verſe.

Poſt SIM SUM *ſequitur, pallida* Luna *ſubeſt.*

Wherein, the capital letters SIM SUM, and L, are the initial letters of the planets. So that the order of the planets

planets in the week, bears little relation to that in which they follow in the heavens: the former being founded on an imaginary power each planet has, in its turn, on the firſt hour of each day.

Dion. Caſſius gives another reaſon of the denomination, fetched from the celeſtial harmony. For it being obſerved that the harmony of the diateſſaron, which conſiſts in the ratio of 4 to 3, is of great force and effect in muſic; it was judged meet to proceed directly from Saturn to the Sun; becauſe, according to the old ſyſtem, there are three planets between Saturn and the Sun, and four from the Sun to the Moon.

Our anceſtors the Saxons, before their converſion to the Chriſtian faith, named the ſeven days of the week from the Sun and Moon and ſome of their deified heroes, to whom they were peculiarly conſecrated, which names we received and ſtill retain: thus Sunday was devoted to the Sun; Monday to the Moon; Tueſday, according to ſome, to Tuiſto or Tuiſco, mentioned by Tacitus; but, according to others, to Thyſa or Dyſa, the wife of Thor, and the goddeſs of juſtice; or, according to others, to Tyr; Wedneſday to Woden, the god of war; Thurſday to Thor, who preſided over the air, and was ſuppoſed to govern the winds and clouds; this is the ſame with Lucan's Taranis, ſimilar to the Welſh word for thunder; Friday to Friga or Fræa, the wife of Thor, and the goddeſs of peace and plenty; and Saturday to Seater, called alſo Orodo, to whom they prayed for protection, freedom, and concord, and for the fruits of the earth. The origin of the laſt appellation, however, is doubtful; as ſome have obſerved, that the name *Seater* is not mentioned by any writer before Verſtegan. See Verſtegan's Reſtitution of decayed Intelligence, p. 68. Junii Etym. Angl. and Mallet's North. Ant. vol. i. p. 91, &c.

To find the accompliſhment of Daniel's prophecy of the Meſſiah, the deſtruction, rebuilding, &c. of the temple, chap. ix. ver. 24, &c. the critics generally agree to underſtand *weeks of years*, inſtead of *weeks of days*.

Accordingly, Dr. Prideaux, fixing the end of theſe weeks at the death of Chriſt, in the year of the Julian period 4746, and in the Jewiſh month Niſan, dates their commencement in the month Niſan, in the year of the Julian period 4256, which was the very year and month in which Ezra had his commiſſion from Artaxerxes Longimanus, king of Perſia, for his return to Jeruſalem, there to reſtore the church and ſtate of the Jews. And thus he finds, that from the one period to the other, there were exactly 70 weeks of years, or 490 years. Connect. vol. ii. p. 381, &c.

WEEKS, *Ember*. See EMBER.

WEEKS, *Feaſt of*. See PENTECOST.

WEEK, *Paſſion*, or the *Holy Week*, is the laſt week in Lent, in which the church celebrates the myſtery of our Saviour's death and paſſion.

This is alſo ſometimes called the *great week*. Its inſtitution is generally referred, both by Proteſtants and Papiſts, to the times of the apoſtles. All the days of that week were held as faſts: no work was done on them; no juſtice was diſtributed; but the priſoners were ordinarily ſet at liberty, &c. even pleaſures, otherwiſe allowed, were at this time prohibited. The oſculum charitatis was now forborn: and divers mortifications practiſed by all ſorts of people, and even the emperors themſelves.

WEEK, *Rogation*. See ROGATION.

WEEK, or *Wick of a Candle*, &c. the cotton match in a candle or lamp. See CANDLE, LAMP, &c.

WEEK-*Fiſh*, in *Ichthyology*, a name given by ſome to a very delicate fiſh, caught on the Eaſt Indian ſhores, and called by the Dutch there the *wit-viſch*. See WIT-*Fiſh*.

WEEKLY *Markets and Fairs*, in *Agriculture*, are of conſiderable uſe and convenience to the farmer and land-owner, as affording the ready means of purchaſing, providing, and furniſhing them with the different articles they are continually in need of, as well as the various ſorts and deſcriptions of cattle and other live-ſtock, which are always wanted in ſuch caſes; as they are common in moſt large towns, the former once or oftener in the courſe of the week, and the latter in ſome inſtances in that time, and at more diſtant periods. They give the means, too, of readily diſpoſing of all ſorts of produce and ſtock of the farm kind, which is often a very great accommodation and advantage to the farmer and ſtore-maſter, as is fully ſeen in the weekly market of Smithfield in the metropolis, as well as in many particular markets and fairs in the country, as at Liverpool, Lancaſter, Garſtang, and many other towns in the north; and at Uxbridge, Reading, Chelmsford, Petworth, and a variety of other towns in the ſouth. See Owen's Book of Fairs, &c.

WEELING, ANSELM, in *Biography*, born at Bois-le-Duc in 1675, was an imitator of Godfrey Schalken and Adrian Vanderwerf; but particularly of the former; and many of his productions have been taken for pictures by that maſter. He died in 1749.

WEELS, in *Geography*, a river of Germany, which riſes in the duchy of Oldenburg, and joining the Ochte, in the county of Delmenhorſt, falls into the Weſer, 8 miles N.W. of Bremen.

WEEN. See HWEN.

WEENINX, JOHN BAPTIST, in *Biography*, an excellent artiſt, was born at Amſterdam in 1621, the ſon of John Weeninx, an artiſt of conſiderable celebrity. He loſt his father when he was very young, and was placed by his mother with a bookſeller; but his taſte for painting manifeſting itſelf decidedly, he was allowed to indulge it, and was placed as a diſciple with John Micker, and afterwards with Ab. Bloemart. He made a rapid progreſs, and drew with ſuperior power the principal buildings in Amſterdam and its vicinity. Animals, birds, huntings, &c. he was ſkilled in repreſenting, and he ſoon began to paint his ſubjects with ſucceſs. He left Bloemart, and ſtudied a ſhort time with Moojaert; but when he was 18, he found himſelf ſufficiently eſtabliſhed to truſt to himſelf, and his pictures were favourably received.

A deſire to improve led him to Rome, where his talents recommended him to many of the principal perſonages; among others, the cardinal Pamphili gave him a penſion, and honoured him with many commiſſions: he would fain, indeed, have retained him at Rome, but the ſolicitations of his family, and his natural deſire of exhibiting his power among his countrymen, induced him to return to Holland, after an abſence of four years. On his return, he found abundant admiration and employment, which, indeed, he very well merited, as his extraordinary facility in painting a vaſt variety of ſubjects has rarely been equalled. He painted hiſtory, portraits, landſcapes, ſea-ports, animals, and dead-game; but he particularly excelled in Italian ſea-ports, enriched with noble architecture, and decorated with figures. There is a very beautiful ſpecimen of his power in the gallery of Cleveland-houſe, which in Britton's Catalogue is numbered 243. He unfortunately died very young, in 1660, being only 39 years old.

WEENINX, JOHN, ſon of Baptiſt, mentioned above, was born at Amſterdam in 1644, and was inſtructed in painting by his father until he was 16 years of age, when he he had the misfortune to lofe that able inftructor. His talent was not of fo general a nature as that of his father; but in birds, flowers, animals, and fruit, he has feldom been furpaffed for the boldnefs, animation, and correctnefs of touch, or the brilliancy and clearnefs of colour, as well as of chiaro-ofcuro. The elector John William invited him to his court, and many of his moft confiderable productions are at the gallery of Duffeldorf. He decorated a hunting feat of the electors, the chateau of Benfberg, with a feries of hunting of the boar and the ftag, in which he difplayed his fkill and tafte with brilliant effect. His fmaller works are exquifitely finifhed, yet with great breadth, and defervedly efteemed. He died in 1719, at the age of 75.

WEEPER, in *Zoology*. See Simia *Capucina*.

WEEPING, in *Phyfiology*. See Lungs and Tears.

Weeping-*Rock*, in *Agriculture*, that fort of laminated, or porous, open rock, through which water paffes in a flow, gradual, weeping manner. Strata of this kind are not unfrequently very troublefome in the practice of draining. See Wall-*Spring* and Spring-*Draining*.

Weeping-*Spring*, that fort of difcharge of water from the internal parts of the earth which is produced in a very flow weeping manner. The draining of fprings of this fort is fometimes not attended with much difficulty, while in other cafes they are often very troublefome. See Spring and Spring-*Draining*.

WEER. See Weir.

WEERAWAU, in *Geography*, a town of Hindooftan, on the borders of the defert of Cutch; 40 miles W. of Buddakano.

WEERDT, or Werdt, a town of Germany, in the bifhopric of Munfter, on the Old Iffel; 40 miles W. of Munfter. N. lat. 51° 52′. E. long. 6° 33′.

WEERT, or Wert, a town of France, in the department of the Lower Meufe; 10 miles W. of Ruremond. N. lat. 51° 17′. E. long. 5° 43′.

Weert, *Nieder*, a town of France, in the department of the Lower Meufe; 10 miles S.W. of Venlo.

WEESDALE, a town of the ifland of Shetland; 6 miles N.W. of Lerwick.

WEESENSTEIN, or Wesenstein, a town of Saxony, in the margraviate of Meiffen; 5 miles S.W. of Pirna.

WEEVER. See Wever.

Weever, in *Ichthyology*, the Englifh name for the fifh called by Willughby and other authors the *draco-marinus*, or fea-dragon.

Belon fays, that this name is a corruption of the French *la vive*, becaufe this fifh is capable of living long out of the water.

Mr. Pennant defcribes another fpecies, under the name of the *great weever*, the *draco major*, or *araneus* of Salvian, which inhabits the fea near Scarborough. Brit. Zool. vol. iii. p. 171.

WEEVIL, in *Natural Hiftory*, the name of a fmall infect which does great damage in magazines of corn, by eating into the feveral grains, and deftroying their whole fubftance.

This creature is fomewhat bigger than a large loufe, and is of the fcarab or beetle kind, having two pretty, jointed, tufted horns, and a trunk or piercer, projecting from the fore part of its head: at the end of this trunk, which is very long in proportion to its body, there is a fort of forceps or fharp teeth, with which it gnaws its way into the heart of the grain, either to feek its food, or to depofit its eggs there.

By keeping thefe creatures alive in glafs tubes, with a few grains of wheat, their copulation and manner of generation have been difcovered. The female perforates a grain of wheat, and in it depofits a fingle egg, or, at the utmoft, two eggs; and this fhe does to five or fix grains every day, for feveral days together. Thefe eggs, which are not larger than a grain of fand, in about a week produce as odd a fort of white maggot, which wriggles its body very much about, but is very little able to move from place to place: this, in about a fortnight, turns to an aurelia, from which is produced the perfect *weevil*. This deftructive creature is itfelf very fubject to be deftroyed, and when in the egg or aurelia ftate, it is very fubject to be eaten by mites. Baker's Microf. p. 221. Leewenhoeck, tom. iv. ep. 76.

It is ftated in a feries of communications which contain different interefting particulars, inferted in the appendix to the Corrected Report on the Agriculture of the County of Middlefex, that J. L. Banger, efq. of the ifland of Madeira, has found that fteaming fuch grain as is infefted with the weevil has the effect of preferving it. In comparing the method ufed by another perfon with his, on portions of the fame cargo of grain, the quantity or weight was greater in the latter; but the moft effential difference was in the quality, which in the former was almoft unfaleable, while in the latter, or that of fteaming, it was better and fweeter than when firft received. The produce of grain from the ifland of St. Michael it is found cannot be preferved fo long a time as that which is imported from any other country, though the manner of keeping it there, which might throw fome light upon the fubject, is not known: of this the writer has recently obtained fufficient experience, it is faid, by having ordered a part of a cargo of grain to be placed in a ftore which had lately been ufed with that ifland wheat; and from this caufe, in a very fhort time, had become badly infected with the weevil. Another purchafer of a part of the fame cargo, too, is, from a fimilar caufe, a fufferer. The writer has not, however, much anxiety about it, as the grain he purchafed and fteamed once on the firft of January, and again on the firft of June, is now, (the time of writing,) in perfect prefervation, and free from the weevil. The Indian corn too, that was purchafed then in March laft, at which time it was very full of the infect, is at prefent free and perfect, it is faid, without a fecond heating. It is intended paffing it again through the fteam, however, it is faid, as foon as the apparatus is properly fixed, when no doubt is made of its keeping through the year. In examining the particular tendency that the grain lately arrived has to the generation of the infect, the writer has imagined it in fome meafure to proceed from the embargo laid upon American veffels having obliged the merchants in the different fea-ports to keep their granaries fo full as to have heated the grain; though he has fome reafon to think that the months of March and September are attended with peculiar circumftances refpecting the increafe of the weevil.

It is found that by the confumption of one hundred pounds weight of coals in a kitchen portable fteam apparatus, three *moys*, or feventy-two Englifh bufhels of grain can be fteamed in the common hours of work of one day.

The writer had then lately fteamed a granary of fixty moys, or one thoufand four hundred and forty Englifh bufhels, in about three weeks. The wafte of grain, not badly infected with the weevil, is found to be one *per cent.* in weight in one month, and the increafe fo rapid, that if proper precautions be not taken, in lefs than fix it will be rendered totally unfit for ufe; and that in the Weft Indies the writer is fatisfied from his own experience, that three months will be equal, in deftruction to the grain, to that

that of fix months in the temperate climate in which he writes. Perhaps, it is faid, no part of the globe would experience fo much benefit from the ufe of fteam as a rice country.

The writer having, by fubftituting copper tubes for thofe of tin, which were at firft employed, but tinned to prevent mifchief, at laft fucceeded in getting them fufficiently tight, proceeded better in his trials: the fteamed rice remained free from duft, and it is fuppofed that fteam may be rendered very ferviceable in feparating the hufk from the grain in that cafe, as well as in barley, &c.; nay, that it may be extended to flax, and many other articles.

The attention of the writer more lately has been particularly attracted, by finding fome grain that had been fteamed to grow, when fown, in repeated trials; and from the very flourifhing ftate of what is come up, and his own obfervations, he is led to think that the blight in wheat might be materially prevented by having it fteamed before it is fown. It was afterwards difcovered that the flourifhing condition of the wheat fown after fteaming furprifed every one who faw it; and it is thought to be an object worthy of confideration.

It was found, on taking a certain quantity of wheat that had been fteamed, and of fuch as had not, and fending them to the mill, that there was an increafe of nearly five *per cent.* in the bread produced from the wheat that was fteamed: but it is not certainly known if this difference would have arifen, if the latter had been dried in the fun or an oven, as fometimes practifed there, but which is troublefome. The beft bread made there is, it is faid, from a mixture of fine American flour and ifland wheat; and the writer has no doubt, that if a baker was to make ufe of fteam, he might, in the proportion of wheat in the quartern loaf, fave from five to ten *per cent.*

The writer intends to try the advantages to be gained by fteaming feeds to be fent to foreign countries. Bifcuit, he is convinced, may be kept any length of time by it; but from its fize, the operation of fteaming it is confiderably more difficult than grain. Wheat provided in any way, in general, it is faid, gets better and more free from the weevil by fteaming. See the Paper.

The weevil, too, is faid to be very injurious and deftructive to the wheat and Indian corn in America, fo that the means of preventing it muft be of great utility and confequence.

WEFERLINGEN, in *Geography*, a town of Weftphalia, in the principality of Halberftadt, infulated in the duchy of Magdeburg; 25 miles N. of Halberftadt.

WEFT, a kind of web, or thing woven; as, a *weft* or trefs of hair. See WEB, HAIR, TISSUE, &c.

WEIDENBACH, a town of Germany, in the marggravate of Anfpach; 5 miles S.S.E. of Anfpach.

WEIDENBERG, a town of Germany, in the principality of Culmbach; 7 miles E.S.E. of Bayreuth. N. lat. 49° 55′. E. long. 11° 46′.

WEIDERAU, a town of Saxony, in the lordfhip of Schonburg; 4 miles N.E. of Penig.

WEIERN, a town of Bavaria; 23 miles S.S.E. of Munich.

WEIF. See WAIF.

WEIGEL, ERHARD, in *Biography*, a German mathematician, was born at Weida, in Nordgau, in 1625, and educated at Wenfiedel, whither his parents were obliged to remove, on account of perfecution, when he was three years old; and afterwards at the Gymnafium of Halle, where he enjoyed the advantage of being inftructed in mathematics by Bartho-

Bartholomew Schimpfer, a celebrated aftronomer. The circumftances of his parents obliging him to return to Wenfiedel, he there purfued his ftudies under an able tutor. Afterwards, encouraged by Schimpfer, he fettled at Halle, where his reputation drew to him many pupils, by whom he was enabled to remove to Leipfic for farther improvement; fo that in 1653 he was invited to be profeffor of mathematics at Jena. By favour of William, duke of Saxony, he was appointed mathematician to the court, and chief director of buildings; and thus the latter years of his life were chiefly employed in travelling. In the progrefs of his years he made many improvements in globes, and other inftruments for facilitating the ftudy of aftronomy. This ingenious mathematician died in 1699. For a lift of his works, which were many, we refer to his article in Gen. Biog.

WEIGELIA, in *Botany*, a Japanefe genus, dedicated by Thunberg to the honour of Dr. Chriftian Ehrenfried Weigel, profeffor of Chemiftry in the univerfity of Gripfwald, in Upper Saxony, who publifhed at Berlin, in 1769, when he was only 21 years of age, a *Flora Pomerano-Rugica;* but whofe fame, as a deep and learned practical botanift, chiefly refts on his *Obfervationes Botanicæ*, publifhed as an inaugural differtation, under his prefidency, in 1772, in quarto, with three plates. This work, from its rarity, is not fo well known as it deferves to be. The author correfponded with Linnæus, and communicated fpecimens of his new or doubtful plants.—Thunb. Jap. 6. Nov. Gen. 5. Schreb. Gen. 113. Willd. Sp. Pl. v. 1. 836. Mart. Mill. Dict. v. 4. Juff. 421. Lamarck Illuftr. t. 105.—Clafs and order, *Pentandria Monogynia*. Nat. Ord. uncertain. Juffieu fufpects it may belong to his *Apocineæ*, the *Contortæ* of Linnæus; an opinion which the infertion of the ftyle at the bafe of the germen feems to favour; but the ferrated leaves are a great, perhaps infuperable, objection. If we might fufpect an error as to the fituation of the germen, the genus would readily range itfelf among Juffieu's *Caprifolia;* but the fecond fpecies has more the character of his *Bignoniæ*, and renders it probable that Thunberg is merely miftaken in his idea of the fimple nature of the germen.

Gen. Ch. *Cal.* Perianth fuperior, of five awl-fhaped, erect, equal leaves. *Cor.* of one petal, funnel-fhaped; tube the length of the calyx, internally hairy: limb bell-fhaped, cloven half way down into five ovate, obtufe, flightly fpreading fegments. *Stam.* Filaments five, inferted into the tube, thread-fhaped, erect, nearly as long as the corolla; anthers erect, linear, obtufe, cloven at the bafe. *Pift.* Germen fuperior, quadrangular, abrupt, fmooth; ftyle from the bafe of the germen, thread-fhaped, rather longer than the corolla; ftigma peltate, flat. *Fruit* unknown. Thunberg fufpected there was a folitary naked *feed*.

Eff. Ch. Corolla funnel-fhaped. Style from the bafe of the germen. Stigma peltate. Calyx fuperior, of five leaves.

1. W. *japonica*. Seffile-leaved Weigelia. Willd. n. 1. Thunb. Jap. 90. t. 16. Tr. of Linn. Soc. v. 2. 331. (Nippon Utfúgi; Kæmpf. Am. Exot. 855.)—Leaves feffile, ovato-lanceolate.—Native of hilly fituations in Japan, flowering in April and May. The *ftem* is fhrubby, with oppofite, round, fmooth branches, flightly quadrangular when young. *Leaves* oppofite, feffile, pointed, copioufly ferrated, an inch, or rather more, in length, veiny, fmooth on both fides, except the veins, which are hairy; paler beneath. *Flower-ftalks* axillary, compreffed, three-flowered, longer than the leaves, with two awl-fhaped *bracteas* at the bafe of each partial ftalk, and two more about half way up. *Flowers* about an inch long, reddifh-purple. Thunberg's defcription, in the *Flora Japonica*, confounds both fpecies together, and is therefore here neceffarily corrected.

2. W. *coræenfis*. Large-flowered Weigelia. Thunb. Tr. of Linn. Soc. v. 2. 331. Willd. n. 2. (Koreï Utfúgi; Kæmpf. Amoen. Exot. 855. Ic. Select. t. 45.)—Leaves ftalked, obovate.—Native of Corea, from whence Kæmpfer fuppofes it was brought to Japan. He defcribes it as a *fhrub* with beautiful *flowers*, fmelling like cloves, and changeable in colour, being fnow-white, flefh-coloured, and red, on the fame plant. His excellent drawing, among thofe engraved and diftributed through the munificence of fir Jofeph Banks, throws more light upon this fpecies, and indeed upon its genus, than any thing elfe we have met with. It appears to be a climbing or trailing *fhrub*, with round branches, and oppofite ftalked *leaves*, very like thofe of the *Hydrangea hortenfis* in fize and figure, being thrice the length of the firft fpecies, and obovate with a point. *Flower-ftalks* axillary and terminal, three-flowered, an inch and a half long, with awl-fhaped *bracteas*. *Tube* of the *corolla* flender, above half an inch long, twice the length of the *calyx;* limb bell-fhaped, twice the length of its tube, divided half way down into five broad, obtufe, horizontally fpreading fegments. *Stamens* projecting beyond the mouth. *Anthers* incumbent. *Stigma* large, peltate, flat. Nothing appears refpecting the *germen*, or its fituation. We do not clearly underftand the fecond of Kæmpfer's feparate figures, which is perhaps an under view of the *corolla*.

WEIGELSDORF, in *Geography*, a town of Bohemia, in the circle of Konigingratz; 2 miles W. of Trautenau.

WEIGELSHAUSEN, a town of the duchy of Wurzburg; 5 miles W.S.W. of Schweinfurt.

WEIGENHEIM, a town of Germany, in the lordfhip of Schwarzenburg; 10 miles S.S.W. of Schainfeld.

WEIGERSTORFF, a town of Auftria; 6 miles S. of Wells.

WEIGH, Way, or Wey, *Waga*, a weight of cheefe, wool, &c. containing two hundred and fifty-fix pounds avoirdupois. Of corn, the weigh contains forty bufhels; of barley or malt, fix quarters.

In fome places, as Effex, the weigh of cheefe is three hundred pounds. See Measure.

"Et decimam cafei fui de Herting, præter unam peifam, quæ pertinet ad ecclefiam de A. Mon. Angl." where *peifa* feems to be ufed for a weigh.

Coke alfo fpeaks of weighs of bay-falt.

Weigh-*Beams* are fteel-yards for the weighing of goods upon wharfs, &c.

WEIGHER, an officer in divers cities, appointed to weigh the commodities bought and fold, in a public balance, &c. Thefe weighers are generally obliged by oath to do juftice to both parties; and to keep a regifter of the things they weigh.

In Amfterdam there are twelve weighers, eftablifhed into a kind of office. As it was formerly allowed them to touch the ftrings of the balance in weighing, it was eafy for them to favour either the buyer or feller, according as the one gave them more money than the other. To prevent which abufe, it was charged on them, by an ordinance of the burgomafters in 1719, not to touch the balance in any manner whatever.

WEIGHGATT, in *Geography*, a name given to the ftrait called Waygatt, (which fee,) from the wind which blows through this ftrait (*waikan*, to blow,) becaufe a ftrong S.W. wind blows out of it. It is alfo called Hindelopen. See Martens's Voyage, p. 27.

WEIGHING,

WEIGHING, the act of examining a body in the balance, to find its weight.

The diftillers in London weigh their veffels when full; and for a half hogfhead, which is thirty-one gallons and a half, allow two hundred one quarter and eleven pounds for the cafk and liquor. For a puncheon, they allow fix hundred one quarter and two pounds; for a Canary pipe, eight hundred a half and feventeen pounds.

Weighing-*Cage*, in *Agriculture*, a fort of machine or contrivance which is made in fomewhat the form or manner of an open box or cage, by means of which any fmall animal, fuch as a pig, fheep, calf, or any other of a fimilar kind, may be very eafily and expeditioufly weighed, and with fufficient accuracy and correctnefs for the purpofes of the farmer, ftore-mafter, and grazier. It is conftructed on the principle of the common fteel-yard. It has a ftrong wooden frame, on which there are fteel centres, in which the pivots of the lever are hung. Upon the fhort fide of the lever is fufpended a fort of coop, furrounded by ftrong net-work, in which the animal intended to be weighed is put and fecured; the point of fufpenfion is connected with the coop by means of two curved iron-rods, which at the fame time form the head of it. A common fcale, in which the weights are to be put, is hung on the longer fide of the lever. See Steel-*Yard*.

Weighing-*Chair*, a machine contrived by Sanctorius, to determine the quantity of matter carried off from the body, and that of food taken at a meal; and to warn the feeder when he had eat his quantum.

That ingenious author, having obferved, with many others, that a great part of our diforders arifes from the excefs in the quantity of our foods, more than in the quality thereof; as alfo how much a fixed portion, once well adjufted, would, if kept to regularly, contribute to health; bethought himfelf of an expedient to that purpofe. The refult was the weighing-chair: which was a chair fixed at one arm of a fort of balance, wherein a perfon being feated at meat, as foon as he had ate his allowance, the increafe of weight made his feat preponderate: fo that, defcending to the ground, he left his table, victuals, and all, out of reach.

Weighing-*Houfe*, a building furnifhed with a dock, and conveniences for gauging or afcertaining the tonnage of boats that are to be ufed on a canal.

Weighing-*Machine for Turnpike Roads*, in *Mechanics*, a machine for weighing heavy bodies, and particularly wheel-carriages. This is commonly done in order to afcertain if a carriage is within the weight allowed by law to be carried by fuch carriage on the turnpike-roads; a weighing-machine, or weigh-bridge, being fixed at every turnpike-gate. See Turnpike.

Formerly immenfe machines were ufed for this purpofe: the machine was erected in an open building, beneath which the road paffed, fo that a cart, waggon, or other carriage, could be drawn under it; ftrong chains were then paffed beneath the body of the carriage, to attach it to the extremity of an immenfe fteel-yard. The fulcrum of the fteel-yard was fufpended by a lever, or by pulleys and crane-work, from the top of the building; and when the carriage was properly fecured, the fteel-yard was hoifted up by the crane-work, fo as to fufpend the waggon, and it could then be weighed by applying the fliding-weight of the fteel-yard to different parts of the divided bar. Several curious machines of this kind are defcribed by Leopold, in his Theatrum Staticum, 1724.

This method was tedious and dangerous; but when turnpike-roads became more common, a very fuperior machine was introduced, and we now find one at almoft every turnpike-gate. It is called a weigh-bridge, becaufe the carriage is drawn upon a wooden platform or bridge, which is placed over a pit, made in the line of the road, to contain the machinery. The pit is walled withinfide, and the platform is exactly fitted to the walls of the pit; but as it does not touch the walls, it is at liberty to move freely up and down. The platform is fupported by levers, placed beneath it, and is exactly level with the furface of the road, fo that the carriage is eafily drawn on to it. This is done without any difficulty or lofs of time, becaufe the platform is in the direct line of the road, and the carriage is only required to ftop for a minute whilft its wheels ftand fairly upon the platform, and the horfes ftand upon the folid ground beyond the platform. A few fmall weights put into a fcale, like that of a common balance, determine the weight of the carriage and its load. If the weight of the carriage is previoufly known, the weight of the load may be found, by deducting the weight of the carriage from the total.

This weigh-bridge is placed at the fide of a fmall houfe, which ufually ferves as a lodgement for the gate-keeper, and the fcale is fituated within the houfe. The platform is fupported by two double levers contained in the pit; the ends of thefe levers are borne up by a long horizontal lever, which paffes through one of the fide-walls of the pit, and enters into the houfe: from the end of this lever, a fmall iron rod is carried up to one end of a common fcale-beam or balance, from the other end of which the fcale is fufpended. All the levers are of the nature of fteel-yards, that is, the weight or load of the bridge is applied upon the levers which fupport it, at points very near to their refpective fulcrums, or centres of motion; whilft the ends of thefe levers are fupported, at a very confiderable diftance from their fulcrums, by the long lever, and they bear upon this lever at a point very near to its fulcrum; but the counterbalancing force, that is, the effort of the weights in the fcale, is applied to the extreme end of the long lever, very far diftant from the fulcrum. For this reafon, a fmall weight, as one pound for inftance, placed in the fcale, will bear up a large weight, for inftance, 60 pounds, or one hundred weight placed upon the platform, according as the machine is conftructed. This has an advantage, befides the convenience of fmall weights, *viz.* that the platform with the carriage does not fink down any perceptible quantity during the action of weighing; for when the weight in the fcale is brought to equilibrium with the load, any motion or fpace which the fmall weight paffes through, when the fcale-beam vibrates, muft be to the fpace which the platform and carriage pafs through at the fame inftant, in the ratio of the load to the weight. Sometimes, inftead of ufing a fcale-board and detached weights, a long fteel-yard is employed, with a weight to flide along upon it to different diftances from the centre, until it will counterbalance the load on the platform; in that cafe, the lever is graduated to fhew the weight upon the platform.

Salmon's Patent Weighing Machine.—This is very generally ufed in the vicinity of London; it points out the weight on a dial.

Plate II., *Engines*, contains figures of a weighing machine of the beft kind. *Fig.* 1. is a horizontal plan of the levers contained in the pit, the platform being taken off to expofe them. The under fide of the platform is fhewn at *fig.* 2, and *fig.* 3. is a vertical fection of the whole machine.

E E (*fig.* 3.) is the platform; its upper furface is exactly level with the ground, and the edge of the planking of the platform is fitted into a border or frame which furmounts the fide walls of the pit, leaving a fmall crevice all round its edges, fo that the platform does not touch the fixed frame,

 although

although it is very near to it. The platform is compofed of a ftrong frame of wood (as fhewn in *fig.* 2.), and the upper fide is covered with wood planking. It is likewife defended from wear, by iron-bars and large-headed nails, which are faftened on the upper fide. Near each of the four angles of the platform a piece of iron is fixed, as fhewn by *b*; and it is on thefe four points that the platform is borne. When the platform is put in its place, thefe pieces of iron apply to the pins *b b* (*fig.* 1.), which are fixed in four ftrong iron levers, marked A A, B B. Each of thefe levers is fupported at the extreme end *c*, on a fulcrum or centre-pin refting on a metal fupport, as fhewn in *fig.* 4, which is borne by a piece of timber *o o*, worked into the walls of the pit at the angle. At the oppofite ends the levers A A are brought together, and B B the fame, fo that all four meet in two points *a a*, and by means of links, fhewn in *fig.* 5, are all connected with a long lever C C. This refts on a fupport or fulcrum D, borne by a pillar erected from the bottom of the pit. The end of the lever at I is received between two uprights to guide it, but do not any way confine its motion. In the common machine, it is from the extreme end of the lever C D that the iron rod before mentioned is carried up to the fcale-beam, or fteel-yard, as before defcribed; but the patent machine in the figure is differently conftructed in that part.

The fixed centres *c*, of the levers A A and B B, are at the ends of thofe levers, and the points *b b*, on which the platform bears, are very near to the centre *c*; but the diftance of the points *a* from *c* is nine times as great as from *c* to *b*, confequently a force of one pound applied to lift up the levers at the point *a* would balance nine pounds laid upon the platform. In like manner the diftance from the point *a* to the fulcrum D is only one-feventh part of the diftance from the fulcrum to the end of the lever C; hence, one pound applied to lift up the end of the lever C would raife feven pounds applied at the point *a*, and feven pounds applied at *a* would balance fixty-three pounds placed on the platform. To weigh with a machine of this kind, if we ufe a fcale and balance connected with the end of the long lever, we muft ufe weights which are only one fixty-third part of the marks which they bear.

Mr. Salmon's machine operates in a much more perfect manner, by the help of a felf-adjufting balance-wheel, which will weigh every different body, without employing any loofe weights; and it fhews the weight by means of an index and dial, like that of a clock. To effect this, another lever or fteel-yard F G is applied, whereof F is the fulcrum, and *f* the point from which a link C defcends to the end of the long lever C D. At the extreme end G, a ftrap is attached to afcend to the balance-wheel *i i*.

Now, as the diftance F *f* is only one-tenth of the diftance F G, one pound applied to lift up the end G would raife ten pounds at *f*, or $10 \times 63 = 630$ pounds placed on the platform.

To draw the end G of the lever upwards, a thin leather ftrap *g* is attached to it, and the upper end of this is coiled round a fmall roller *h*, which is fixed upon an horizontal axis, as is fhewn on a larger fcale in *fig.* 7, where the axis is marked *b b*. This is reduced to fmall pivots at the extremities, which are borne by friction-wheels *a a*, to render its motion as free as poffible. On the fame axis *b* is fixed a wheel *i i*, (fee alfo *fig.* 6.), and againft the arms of this wheel a fpiral ledge is fixed, with a fufficient projection to admit a fine filk line to wind upon the fpiral, when the wheel is turned round. A weight *k*, which is fufpended to the line, forms the counterbalance to the load placed upon the weigh-bridge (fee *fig.* 3.), and the weight of the load is determined by the diftance which the roller and wheel *i* are turned round. This diftance is fhewn by an index *c* fixed on the extreme end of the axis *b*, and pointing to different divifions engraved round a dial, as fhewn in *fig.* 6.

This fingle weight *k* can counterbalance all the different weights which may be placed on the platform, becaufe the line by which the weight *k* is fufpended, when it winds upon the circumference of the fpiral, continually applies itfelf at a different diftance from the centre of the axis, fo as to operate with greater force. Hence, when any weight is placed upon the platform E, it preffes down the levers A A and B B; thefe deprefs the long lever C D, and this again actuates the lever F G, and draws down the ftrap *g*, which unwinds from the roller on the axis *b b*, fo as to turn it round, together with the wheel and fpiral. The weight *k* winds upon the fpiral, but the fufpending line foon arrives at that part of the fpiral where its radius is fufficiently increafed, to enable the weight *k* to counterbalance the load upon the platform; the balance-wheel being then come to an equilibrium, will move no farther, and the index points out upon the dial the weight of the load upon the platform.

The fpiral originates in the central part, at a circle which is of the fame diameter as the roller, upon which the ftrap *g*, *fig.* 3. winds; and the weight *k* muft be equal to the fix-hundred-and-thirtieth part of the weight of the platform and levers A A, B B, when there is no weight upon it. When the weight *k* hangs from this commencement of the fpiral, the index *c* ftands at zero, as fhewn in *fig.* 6. The fpiral is fo made, that to turn it round fixty degrees will require one ton weight to be laid on the platform, and every additional ton will turn the wheel and index round another fixty degrees, fo that the machine will bear fix tons before the index makes a complete revolution. Each fpace of fixty degrees is divided into twenty parts, which reprefent hundred weights; and each one is fubdivided into halves or quarters, which divifions are very apparent on a large dial.

In conftructing a machine of this kind, every attention muft be paid to accuracy in the centres of motion of the different levers; all thefe points fhould be made of fteel, and hardened. The form of the centres fhould be that of a fharp edge, like a blunt knife, with the edge refting on a furface of hard fteel, made rather concave, (fee *fig.* 4.) Centres, or bearing points of this kind, made fharp, will move with very little friction; and if the fteel is good, and perfectly hard, the edges will not become blunt in many years' ufe. In all cafes, the bearing-pins with the fharp edges muft be fixed in the levers; becaufe if the levers were made with plain furfaces, and to have fharp pins to bear upon them, there would be no certainty as to the effective lengths of the different levers, and they would vary in their power whenever the fharp edge changed its place upon the fupporting furface.

The four principal levers, A A, B B, are made double, or with open loops at the ends, as fhewn in *figs.* 1 and 4; two fteel pins are put through the double part, one of them marked *c*, being made with a fharp edge at the lower fide, but the other, *b*, is fharpened on the upper fide. The former bears upon a fixed fupport faced with hard fteel, and the other receives the metal ftems, *b*, *fig.* 2. which are fixed to the underfide of the platform. The two levers, A A, are joined together at the point *a*; and the two levers, B B, are alfo joined in a fimilar manner. Each pair of levers are connected by a crofs-bar, as fhewn in *fig.* 1, fo as to make two triangles.

The ends *p* or *s*, *fig.* 5. of the compound levers A A or B B, where they join together, have a fcrew fitted through them, as fhewn in *fig.* 5; the ends of thefe fcrews are made

of

of ſteel, and ſharp-pointed, in order to reſt in a cup or ſocket, *r*, of ſteel, formed in the lower part of a loop or link I. The upper end of the loop is ſuſpended upon a ſharp-edged pin fixed in the lever C D, *fig.* 1, which lever is marked K and H in *fig.* 5. The link belonging to the lever A A is ſuſpended on one end of this pin, and the other loop upon the other end of the ſame pin. The lever F G is made juſt the ſame as a common ſteel-yard.

The ſpiral, *fig.* 6, muſt be made very correctly in braſs, and the line which winds upon it ſhould be very flexible, and of equal thickneſs. After every care has been taken to make all parts of the machine very accurately, they muſt be put together; and known weights being laid upon the platform, the diviſions on the dial ſhould be laid down from the poſitions of the index. If the dial is thus divided by actual experiment, the machine will weigh very accurately; but its ſenſibility will depend upon the ſharpneſs of the centres of the levers, and the hardneſs of the ſteel. When it is in good order, the addition of a quarter of a hundred weight to three or four tons, on the weigh-bridge, ought to produce a motion of the index. In an average ſtate of the machine, it may be depended upon to within half a hundred weight.

Mr. Salmon had a patent for this machine in 1796, but his invention is confined to the balance-wheel and ſpiral, as ſhewn in *figs.* 6. and 7. Theſe parts, ſeparated from the great machine, make a very accurate and complete weighing machine by themſelves, when incloſed in a box; a common ſcale, to contain the goods which are to be weighed, being ſuſpended from the lower end of the ſtrap which winds round the roller.

The introduction of theſe index weighing-machines for turnpike-roads is of great utility, to diminiſh thoſe inceſſant diſputes between the gate-keeper and the carriers reſpecting the weight of their loads. In the common weighing-machines, the weights, being looſe and of an arbitrary weight, may be changed or diminiſhed by the gate-keeper to make the loads appear greater; and the carrier has no means of detecting this fraud, except by unloading and weighing his cargo in ſmall quantities, which is ſcarcely practicable; neither can he be aſſured of the manner of weighing, even if the weights are juſt. Another ſource of uncertainty is, whether the machine be in exact balance when there is no load on the platform; for as the wood imbibes wet and becomes dirty, it makes conſiderable variations in the balance of the machine. To put the machine in equilibrio, a heavy weight is hung on the end of the lever C D, *fig.* 3, and can be placed nearer to or farther from the centre. This ſhould always be adjuſted, but is frequently neglected, and is difficult of detection.

With the index-machine all theſe difficulties are avoided: it is conſtructed by a maker whoſe character is at ſtake, and when once truly made will continue in the ſame ſtate, for the whole is locked up, ſo that the gate-keeper cannot have acceſs to the index. The only defect ariſing from age and wear is, that the index becomes leſs ſenſible, and moves ſluggiſhly and by ſtarts. This the carrier can try at any time by preſſing his foot upon the platform; and he can always ſee if the index returns to zero when the load is removed; and if it does not, he can ſee how much the machine is out of balance.

The law reſpecting weighing carriages is an inducement to fraud in the gate-keepers; a certain weight is allowed by act of parliament to be carried by each deſcription of carriage, which weight is regulated according to the width of the carriage-wheels, the number of horſes, and the ſeaſon of the year, whether winter or ſummer.

If the load does not exceed the allowed weight, a certain toll is charged for the carriage; but for all exceſs of weight, a very heavy toll is charged on each hundred-weight as a penalty, the amount of which is increaſed in proportion to the quantity of over-weight. (See Turnpike.) It is a valuable prize for a gate-keeper to find a carriage overloaded.

Weighing-*Machines for ſmall Weights*. Theſe are of different conſtructions, according to the uſe for which they are intended.

In ſome the weight of any body is determined by putting looſe weights into an oppoſite ſcale, and theſe weights may be either equal weights to thoſe which they are to denote, as in the caſe of a balance with equal arms, or the weights may be ſmaller and applied to the longer arm of an unequal balance, as in the ſteel-yard. The former is by far the moſt accurate, and from the facility of proving its accuracy by placing the weights in either of the ſcales, it has become the legal mode of weighing. Steel-yards are accurate if carefully uſed, but afford many opportunities of fraud in the hands of diſhoneſt perſons.

Mr. Medhurſt's patent weighing-machine is very uſeful in ſhops and warehouſes, being more convenient than the common balance and ſcales, and having the ſame property of equal arms to the lever. The ſcale-boards, inſtead of being ſuſpended from the arms of the balance, are ſecurely poiſed between the arms of a double balance-beam, and are placed at ſuch a height as is moſt convenient to receive the goods which are to be weighed. The weights are to be put into the oppoſite ſcale, but can be put in either; and the load on the oppoſite one, if there is any doubt of the accuracy of the balance.

When more conſiderable weights are to be weighed, equal weights are ſo inconvenient, that ſmall machines, ſuch as are uſed for carriages, are to be preferred for convenience, as they require only ſmall weights in the ſcale.

There is another kind of weighing-machines which requires no looſe weights, but ſhews the weight by a pointer or index upon a divided arch, or on a dial-plate.

The index and balance-wheel of Mr. Salmon's machine, when detached, make a very complete weighing inſtrument of this kind, as before deſcribed.

Other index machines act with a pendulum: thus, the ſcale to receive the goods is ſuſpended from a lever, to which a pendulous arm is attached with a heavy weight at the extremity to form a pendulum. The application of any weight in the ſcale tends to remove the pendulum from its vertical poſition; and it is a property of a pendulum to increaſe in its effort to return to the perpendicular, in proportion to the diſtance which it is removed from it. The quantity of deviation from the perpendicular is indicated by an index or pointer to the diviſions on an arch, and theſe diviſions are numbered to denote the weight. The machine uſed for weighing hanks of cotton is of this kind, and apothecaries ſometimes uſe a ſimilar inſtrument.

Many of the index machines are made with ſprings, which are bent by the application of the weight; and the degree of their flexure, as determined by ſome indexes, is an indication of the weight applied. Several machines of this kind are deſcribed in our article Dynanometer; and although they are rather differently conſtructed, to fit them for meaſuring the ſtrength of horſes, &c. all of them may be converted to weighing-machines, by applying a proper ſuſpending hook, with a ſcale to receive the matter to be weighed.

A curious machine of this kind was made many years ago by M. Hanin of Paris, and preſented to the Society of Arts. The weight is determined by the degree to which a ſemia femicircular fteel fpring will be bent, when the weight is applied to force the ends of the fpring to recede from each other. The quantity is fhewn by an index, which turns round over a circular dial-plate, like a clock-hand. The principal curiofity of this machine is, that the dial contains thirteen concentric circles, each divided to fhew the weight in the denominations of different countries; *viz.* on the two external circles are divifions to fhew troy and avoirdupois weight in pounds; within this is a circle to fhew the correfponding number of Paris livres; next Portuguefe arrobas, and Spanifh arrobas; then Dutch, Swedifh, Danifh, and German pounds; fo that the inftrument becomes an univerfal table for the ratios of thefe different weights.

Weighing-*Machine*, in *Agriculture* and *Rural Economy*, a fort of machine or contrivance made ufe of for the purpofe of weighing neat cattle and fome other kinds of animals alive, as well as different other ufes. It is a machine which is perfectly fimple and eafy in its manner of conftruction. It has a beam of the fteel-yard kind, at the top of which is a pin, on which the fufpenfion of the beam is made. There is a counterpoife which is moveable along the beam by means of a fliding focket, on which is raifed an iron arm, fupporting a wooden box or fcale to receive the counterbalancing weights in the operation of weighing. There are different levers, which are hung on a projecting pin of the beam by one end, the other refting on an iron fupport. There is a lid or platform, on which is placed the fubject to be weighed; to the under fide of this, at each corner, are attached blocks, from which proceed iron pieces, fimilar in form to the fupporting piece, but reverfed in pofition: by means of thefe four pieces the lid or platform ftands with its whole weight entirely on the lever; other pieces applying themfelves to the levers at a fmall diftance nearer to the centre of the machine than to the fupporting piece.

In the operation of weighing, the fubject to be weighed being placed on the lid or platform, preffed by the different pieces on the levers, which by their fufpenfion on the beam determine it from its even pofition by a quantity proportioned to the weight of the fubject, which is expreffed by the counterbalancing weights required to be placed in the box or fcale. See Steel-*Yard*.

A machine of this nature is of vaft utility and importance in the different fyftems of grazing, feeding, and fattening various forts of live-ftock and domeftic animals, efpecially where they are carried on to any confiderable extent, not only in afcertaining and marking the progrefs which is made by the different animals, and in fhewing how they pay for the ufe of any particular kind of food, or what power and property it may have in promoting the fattening procefs, but in many other ways.

Weighing-machines, conftructed upon the fame plan as thofe ufed on the public roads, are applicable, too, in the above cafes, and many others of the rural kind, being ready and convenient for fuch ufes.

Weighing *of the Air*. See Weight *of Air*.

Weighing *Anchor*, in *Sea Language*. See Anchor.

WEIGHT, in *Phyfics*, a quality in bodies by which they tend towards the centre of the earth, or in a line perpendicular to its furface. Or, weight may be defined, more generally, a property inherent in all bodies, by which they tend to fome common point, called the centre of gravity; and that with a velocity in proportion as they are more or lefs denfe, or as the medium through which they pafs is more or lefs rare.

Weight and gravity are generally confidered as one and the fame thing. Some philofophers, however, diftinguifh gravity as the quality inherent in the body, and weight as the fame quality exerting itfelf according to its natural tendency. See Gravity, Gravitation, and Density.

Sir Ifaac Newton demonftrates, 1ft, That the weights of all bodies at equal diftances from the centre of the earth, are directly proportional to the quantity of matter that each contains: whence it follows, that the weights of bodies have no dependence on their fhapes or textures; and that all fpaces are not equally full of matter.

2dly, On different parts of the earth's furface, the weight of the fame body is different, owing to the fpheroidical figure of the earth, which caufes the body on the furface to be nearer the centre in going from the equator toward the poles: and the increafe in the weight is nearly in proportion to the verfed fine of double the latitude; or, which is the fame thing, to the fquare of the right fine of the latitude; the weight at the equator to that at the pole being as 229 to 230; or, the whole increafe of weight from the equator to the pole, is the 229th part of the former.

3dly, That the weights of the fame body at different diftances above the earth, are inverfely as the fquares of the diftances from the centre, fo that a body at the diftance of the moon, which is fixty femi-diameters from the earth's centre, would weigh only the 3600th part of what it weighs at the earth's furface.

4thly, That at different diftances within the earth or below the furface, the weights of the fame body are directly as the diftances from the earth's centre: fo that, at half way toward the centre, a body would weigh but half as much, and at the very centre it would have no weight at all.

5thly, A body immerfed in a fluid, which is fpecifically lighter than itfelf, lofes fo much of its weight, as is equal to the weight of a quantity of the fluid of the fame bulk with itfelf. Hence, a body lofes more of its weight in a heavier fluid than in a lighter one, and therefore it weighs more in a lighter fluid than in a heavier one.

The foregoing principles laid down by Newton are univerfally admitted as correct, with the exception of the proportional weight of bodies on different parts of the earth's furface; for it is important to obferve, that he founded his calculation of the earth's ellipticity on the hypothefis of its being homogeneous, which is not the cafe; and hence he makes the equatorial diameter greater than the polar axis, as 230 to 229. But from the numerous experiments fince made on the pendulum in different parts of the world, the ellipticity is found to be not fo great.

By the inveftigations on this fubject by the marquis de Laplace, (Mecanique Celefte, vol. ii.) the ellipticity is found to be $\frac{1}{336}$; and the calculations and experiments of other aftronomers concur nearly in this refult, making it on an average about $\frac{1}{308}$. In our article Standard, we have given tables of thofe determinations, and likewife of the principal experiments made on the pendulum in different latitudes; and we fhall here add fome further inveftigations and new calculations, as effentially connected with our fubject Weight, and of peculiar intereft at the prefent time.

The chevalier Delambre, in his "Aftronomie," vol. iii. p. 585, gives the following fimple and elegant expofition of the pendulum, with other ufeful formulæ for finding the earth's ellipticity, &c.

Let h be the height of the place of obfervation above the level of the fea; R, the radius of the earth; then the length of the pendulum is to be multiplied by

$$\left(\frac{R + h}{R}\right)^2 = \left(1 + \frac{2\,R\,h + h^2}{R^2}\right) = 1 + \frac{2\,h}{R}.$$

Let

Let L be the length of the pendulum at the equator; for another latitude, it will be $L + a$ fin.^{2} H, fo that a is the excefs of the polar pendulum above the equatorial pendulum, H being the latitude of the place.

Let m and n be the two pendulums obferved in two very different latitudes.

$$m = L + a \text{ fin.}^2 H,$$
$$n = L + a \text{ fin.}^2 H',$$

$m - n = a\,(\text{fin.}^2 H - \text{fin.}^2 H') = a \text{ fin. } (H - H') \text{ fin. } (H + H')$: hence $a = \dfrac{m - n}{\text{fin. } (H - H') \text{ fin. } (H + H')}$.

If there be a greater number of fimilar equations, put in each the numerical value of fin.^{2} H, and determine the two conftant quantities, L and a, by the fum of the obfervations, employing, if you think proper, the method of the fmaller fquares.

Now the ellipticity is proved to be $0.00865 - \dfrac{a}{L}$. We have then a value of the ellipticity, which may be compared with that of the degrees. It was in this manner that M. Mathieu found the ellipticity to be $\dfrac{1}{298.2}$, by the fix actual meafurements of the pendulum made on the meridian from Dunkirk to Formentera. So far Delambre.

From the above equations and formulæ it is manifeft, that if L, the length of the equatorial pendulum, and a, the difference between it and the polar pendulum, be known, all other queftions connected with the fubject may be accurately determined; and hence it is, that the important problem of meafuring the pendulum has long engaged, and ftill continues to command the attention of the firft aftronomers in Europe.

Laplace, in the Mecanique Celefte, gives the following values of L and a; *viz.* $0^m.990631631 + 0^m.005637$ fin.^{2} latitude, from which formula the lengths of the pendulum may be computed in all latitudes; but the fame learned author has recently publifhed another formula in the Connoiffance des Tems (1820, page 442), which is thus given.

" Mathieu, by a new difcuffion of all the obfervations of the pendulum, in ufing the refults of Borda's experiments reduced to the level of the fea, finds the following expreffion of the length of the pendulum,

$$0^m.990787 + 0^m.0053982 \text{ fin.}^2 \text{ latitude.}$$

" In this expreffion I have diminifhed by the two-thoufandth of a millimetre the refult of Borda upon this length, for the correction of the radius of the cylinder, which formed the knife edge; a radius which I value at eight thoufandths of a millimetre.

" The experiments now about to be made with particular care, in the two hemifpheres, will fhed new light on the coefficient of the fquare of the fine of the latitude, or on the variation of weight on the furface of the earth.".

From the above formula we have computed the following table, and have found the earth's ellipticity to be $\frac{1}{313}$. By this alfo the increafe of the weight of a body from the equator to the poles is $\frac{1}{180}$ of the whole, whereas that deduced from the Mecanique Celefte is $\frac{1}{178}$, which proportion has been adopted by Poiffon, Biot, and other writers on the fubject.

TABLE fhewing the comparative Weight of Bodies on different Parts of the Earth's Surface, with the proportional Length of the Seconds Pendulum, and alfo its daily Number of Vibrations in each Latitude: fuppofing it correct at the Greenwich Obfervatory, that is vibrating 86400 Seconds in 24 Hours.

In

In computing the foregoing table we have, as on former occafions in this work, reckoned the French metre at 39.371 Englifh inches, and the correctnefs of this meafure is of the greateft importance to fcience. It was that originally determined by M. Pictet, in the National Inftitute, by comparing the platina metre with the brafs yard made by Mr. Troughton, which was agreed upon by the Royal Society of London, as the beft medium among our different ftandards, and the moft accurate in its divifions. In making the neceffary deductions for the effects of temperature on the different metals, Borda's tables of expanfion were ufed; but from other tables and ftandards different lengths of the metre have been determined; particularly by Dr. Mafkelyne, who made it 39.370226, and lately by Capt. Kater, who comes ftill nearer to Pictet, making it 39.37071. But unlefs fuch meafurements are made from the fame ftandard yard, and with the fame tables of expanfion, perfect agreement cannot be expected; and then it will be neceffary to determine the important queftion, whether fuch tables and ftandards are quite correct? In fhort, an approximation to perfect accuracy is as much as can be hoped for. It is, however, fatisfactory to obferve, that the difference between the determinations of M. Pictet and Capt. Kater is fcarcely difcernible, even in the moft delicate operations of an obfervatory, as it does not amount, when applied in meafuring the pendulum, to more than one-third of a fecond in twenty-four hours. But for all general purpofes the difference is wholly imperceptible.

This near agreement, therefore, confirms the propriety of our continuing Pictet's meafure, which is fanctioned by general ufage both in England and France, and has the additional advantage of numerical fimplicity, which, for commercial purpofes, is no flight recommendation.

Before we enter upon the fubject of commercial weight, fome general view ought to be given of the operations now about to take place on the pendulum in the two hemifpheres, as alluded to in our quotation from Laplace.

The experiments intended by the French, in a voyage of difcovery to the fouthern hemifphere, are to be made with pendulums of an extremely fimple conftruction, the aftronomical rates of which are previoufly afcertained at the Paris obfervatory. In thefe pendulums no maintaining power is applied, nor any compenfation for temperature. The thermometer, therefore, and the magnitude of the arc of vibration, muft be continually obferved, and the neceffary corrections applied, as in the experiment of Borda explained in Delambre's Aftronomie, vol. iii. p. 579. Pendulums of a fimilar conftruction were employed by the French aftronomers, M. Biot and M. Arago, at the royal obfervatory of Greenwich, and in other parts of Great Britain during the laft year (1817); but the refult of their experiments has not yet reached us.

A very correct and beautiful apparatus has lately been erected at our royal obfervatory, for the purpofe of meafuring the length of the pendulum; and alfo with a view of determining, with extreme exactnefs, the difference of the force of gravity at Greenwich and Paris, or, in other words, the comparative weight of bodies in thefe two latitudes.

This apparatus does not very effentially differ from that of Borda, except that a cylindrical rod of a given length is affumed as a ftandard, and the difference between this cylinder and the whole vibrating fyftem is determined by a micrometer motion given to the fteel table. In the French apparatus the fteel table remains fixed, and the meafuring-rod is lengthened by means of a fcrew, till the lower furface comes in contact with the plane of the table.

We have likewife obferved, that in Mr. Pond's apparatus, the pendulum of the clock is, by an ingenious contrivance, brought almoft into contact with the experimental pendulum, by which the coincidences can be diftinctly obferved with a high optical power.

In the expedition which has been lately fent by the Britifh government to explore the arctic regions, experiments are to be made for fimilar purpofes, but with different apparatus. Two famous clocks, by Shelton, which were ufed by captain Cook, are fent. Each is furnifhed with a new brafs pendulum of an entire piece, which can only vary in length by change of temperature, and this is to be allowed for from conftant obfervation of the thermometer. The rates of the clocks in London have been accurately determined; and if the fame can be afcertained at or near the pole, the refult will be very important.

In concluding our view of the philofophy of weight, its varieties on the furfaces of the planets fhould be noticed; which are determined on the fame principles as on the furface of the earth. See PLANET, and SYSTEM.

The weight of bodies on the furface of the fun is computed by Laplace to be about twenty-five times greater than on that of the earth; without, however, allowing for the diminution of gravity by centrifugal force, which he calculates to be about $\frac{1}{7}$. See CENTRIFUGAL *Force*.

WEIGHT, in *Commerce*, denotes the quantity of any commodity or fubftance, which is determined by being placed in a fcale againft fome known ftandard or weight. The art of weighing is therefore of the utmoft importance, as it furnifhes the beft practical means of afcertaining the quantity of matter in any given body, and thence the value of moft of the neceffaries of life.

Weights are generally made of ftone, iron, lead, brafs, or mixed metal; and they are moftly ftamped by proper authorities, denoting that they have been fized or compared with fome known or legal ftandard. See STANDARD, and alfo MEASURE.

The weights of all nations differ from each other, and frequently in the fame country a great diverfity prevails. The common denomination is the pound, of which there are moftly two forts, one for weighing the precious metals, and the other for common articles; fuch are the troy and avoirdupois weights in England. The former is generally divided into twelve ounces, and the latter into fixteen. But their divifion and multiples, as well as relative proportions, are extremely various. We fhall confider them here under two diftinct heads, *viz.* *Ancient Weights*, and *Modern Weights*.

Ancient Weights. — From the great importance of weights and meafures, their adjuftments muft have been coeval with the firft regulations of civil fociety; and hence their origin is too remote to be traced by any authentic hiftory. The only ancient weights that are known with any degree of certainty are thofe of the Jews, Greeks, and Romans.

The ancient Jews, having no ftamped coin, weighed all their gold and filver in the following fimple manner, dividing their talent into 50 maneh, and their maneh into 60 fhekels.

TABLE I.—Jewifh Weights reduced to Englifh Troy Weight (from Arbuthnot).

			lb.	oz.	pwt.	gr.
Shekel			0	0	9	$2\frac{4}{7}$
60	Maneh		2	3	6	$10\frac{2}{7}$
3000	50	Talent	113	10	1	$10\frac{2}{7}$

Note.—In reckoning money, 50 fhekels made a maneh; but in weight, 60 fhekels.

The weight of the Roman denarius, ounce, and pound, is otherwife ftated as follows :

		English Grains.
By Arbuthnot,	the Denarius, (7th part of the Ounce)	62,4
	the Ounce	437,2
	the Pound	5246,4
By Chriftiani,	the Denarius, (8th part of the Ounce)	51,9
	the Ounce	415,1
	the Pound	4981,2

See DENARIUS.

Modern Weights, or rather weights ufed in modern times, are in general very remote in their origin. We fhall begin with Britifh weights, and follow with thofe of France, making accurate comparifons between both; after which the divifions of the weights of the principal trading places in Europe, and other parts of the world, will be given; with tables of their relative proportions, extracted, by permiffion, from the Univerfal Cambift.

Englifh Weights.—By the twenty-feventh chapter of *Magna Charta*, the weights are to be the fame all over England; but for different commodities there are two forts, *viz.* troy weight, and avoirdupois weight.

The origin from which they are both raifed is the grain of wheat, gathered in the middle of the ear: 32 of thefe well dried make one penny-weight, 20 penny-weights 1 oz., and 12 oz. 1 lb. troy. Stat. 51 Hen. III. 31 Edw. I. 12 Hen. VII.

By the laws of affife, from the reign of William the Conqueror to the reign of Henry VII., the legal pound weight contained a pound of 12 ounces, raifed from 32 grains of wheat; and the legal gallon meafure invariably contained 8 of thofe pounds of wheat, 8 gallons made a bufhel, and 8 bufhels a quarter.

Henry VII. altered the old Englifh weight, and introduced a pound, under the name of troy, which exceeded the old Saxon pound by $\frac{3}{4}$ of an ounce: in proof of this it is alleged, that Henry VIII. when he abolifhed the old pound in the eighteenth of his reign, and eftablifhed the troy, declares that the troy pound exceeded the old pound by $\frac{3}{4}$ of an ounce.

This troy pound now in ufe, confifting of 12 ounces, contains 5760 troy grains, and the ounce therefore contains 480 grains; confequently 360 grains, equal to $\frac{3}{4}$ of the ounce, deducted from 5760, leave 5400 troy grains, equal to the weight of the old Saxon pound which he abolifhed. It appears, therefore, that the old Saxon pound was $\frac{540}{576}$ of the prefent troy pound; and as the avoirdupois pound of 16 ounces contains 7000 troy grains, the old Saxon pound was $\frac{54}{70}$ of the prefent avoirdupois pound.

Although formerly 32 grains made a penny-weight, it has in later times been thought fufficient to divide the penny-weights into 24 equal parts called grains, being the leaft weights now in common ufe.

The firft ftatute that directs the ufe of the avoirdupois weight is that of 24 Henry VIII., which plainly implies that it was no legal weight till that ftatute gave it a legal fanction; and the particular ufe to which the faid weight is thus directed, is fimply for weighing butcher's meat in the market. How or when it came into private ufe is not clearly known. Phil. Tranf. vol. lxv. part i. art. 3.

TABLE V.—Of Troy Weight, as ufed by the Goldfmiths, &c.

Grains.			
24	Penny-weight.		
480	20	Ounce.	
5760	240	12	Pound.

The grain troy is divided into 20 mites, the mite into 24 doits,

doits, the doit into 20 periots, and the periot into 24 blanks. Thefe divifions are imaginary, but there are real weights of decimal divifions to the thoufandth part of a grain.

TABLE VI.—Of Troy Weight, as ufed by the Apothecaries.

Grains.				
20	Scruple. ℈			
60	3	Drachm. ʒ		
480	24	8	Ounce. ℥	
5760	288	96	12	Pound.

This weight is effentially the fame as troy weight, but differently divided. It is chiefly ufed for medical prefcriptions: but drugs are moftly bought and fold by avoirdupois weight.

TABLE VII.—Diamond Weight.

Diamonds and other precious ftones are weighed by carats, the carat being divided into 4 grains, and the grain into 16 parts. The diamond carat weighs $3\frac{1}{5}$ grains troy: thus,

Diamond Weight.				Troy Weight.
16 Parts	=	1 Grain	=	$0\frac{8}{10}$ Grain.
4 Grains	=	1 Carat	=	$3\frac{1}{5}$ Grains.

TABLE VIII.—Of Avoirdupois Weight.

Drachms.					
16	Ounce.				
256	16	Pound.			
7168	448	28	Quarter.		
28672	1792	112	4	Hundred.	
573440	35840	2240	80	20	Ton.

The drachm is fubdivided into three fcruples, and each fcruple into ten grains; the pound or 7680 grains avoirdupois = 7000 grains troy, and hence 1 grain troy = 1097 grains avoirdupois.

Hence alfo	-	144 lb. avoirdupois	=	175 lb. troy.
And	-	192 oz. ditto	-	175 oz. do.

The ftone is generally 14 lb. avoirdupois weight, but for butcher's meat or fifh it is 8 lb. Hence the hundred equals 8 ftone of 14 lb. or 14 ftone of 8 lb.

A ftone of glafs is 5 lb. A feam of glafs 24 ftone, or 120 lb.

The fother of lead is generally $19\frac{1}{2}$ cwt.
at Newcaftle, 21 cwt.
at Stockton, 22 cwt.

Hay and ftraw are fold by the load of 36 truffes.

The trufs of hay weighs 56 lb. and of ftraw 36 lb. The trufs of new hay is 60 lb. until the 1ft of September.

A view of local varieties of Englifh weights will follow the prefent article.

TABLE IX.—Wool Weight.

Wool, like other common articles, is weighed by the avoirdupois, but the divifions differ from the above table: thus,

7	Pounds	- -	=	1 Clove
2	Cloves	- -	-	1 Stone
2	Stone	- -	-	1 Tod
$6\frac{1}{2}$	Tods	- -	-	1 Wey
2	Weys	- -	-	1 Sack
12	Sacks	- -	-	1 Laft.

The Weights of Ireland are the fame as thofe of England; and they are ufed for corn inftead of meafures, which feems to be the moft correct method of dealing.

Weights of Scotland.—By the act of union paffed in 1707, the weights and meafures of England were to be adopted in Scotland, but their introduction there is by no means general.

The Englifh troy weight and apothecaries' weight, however, are ufed throughout Scotland, in the fame manner as in England, with the exception that the Scotch jewellers divide the troy ounce into 16 drops, each drop being 30 troy grains; whereas the Englifh divide it into 20 penny-weights, and a penny-weight into 24 grains, as before ftated.

The Englifh avoirdupois weight is ufed for the fale of leather, foap, fugar, tea, flour, candles, and other groceries; alfo for felling rofin, wax, pitch, wrought metals, fome Baltic goods, and all goods brought from England.

Scotch troy weight, alfo called *Amfterdam* and *French Weight*, is ufed for weighing iron, hemp, flax, Baltic and Dutch goods, meal, butcher's meat, unwrought pewter and lead, and likewife for fome more articles. The pound, 16 of which compofe a ftone, contains 7616 troy grains: it is confequently nearly 9 *per cent.* heavier than avoirdupois, or 100 lbs. are equal to $108\frac{4}{5}$ lbs. avoirdupois.

Trone Weight.—This weight was abolifhed by act in 1618. Its name is ftill retained in felling butter, cheefe, tallow, wool, lint, hemp, hay, and fome other home commodities; but the trone ftone and pound are generally denominated by avoirdupois pounds and ounces. The trone pound always contains the fame number of ounces avoirdupois, as the ftone contains pounds. The weight of the ftone, however, is variable. It appears from a recent publication (Kelly's Metrology), that there are about thirty different fyftems of weights and meafures in Scotland.

Weights of France.—In order fully to explain this important part of our article, three different weights muft be noticed; *viz.* the ancient fyftem, called the "Poids de Marc;" the "Metrical Syftem," begun in 1795; and the "Syfteme Ufuel," fanctioned by an Imperial decree of 1812.

The old French weight (poids de marc), the pound or livre, contains 2 marcs, 16 ounces, 128 gros, 384 deniers, and 9216 grains, and equals 7556 grains troy. The new or metrical fyftem, alfo called the decimal fyftem, has been already explained under our article STANDARD. The following are its divifions, with its proportion to the poids de marc and Englifh troy weight. The gramme is the element of all weights, and it is multiplied and divided by tens in the following terms:

The word *Deca* prefixed means	-	10 times.
Hecto - -	-	100 times.
Kilo - -	-	1000 times.
Myria - -	-	10000 times.

On the contrary, for divifors,

the word *Deci* expreffes the	10th part,
Centi - -	100th part, and
Milli -	1000th part.

TABLE

TABLE X.

	Poids de Marc.					Eng. Troy Weight.			
	livres.	on.	gros.	grs.		lb.	oz.	dwt.	grs.
Bar or Cubic Metre of Water.	2042	14	0	14	-	2681	3	6	2
Myriagramme	20	6	6	63.5	-	26	9	15	1.46
Kilogramme	-	2	0	5 35.15	-	2	8	3	12.146
Hectogramme	-	-	3	2 10.715	-		3	4	8.414
Decagramme	-	-		2 44.2715			-	6	10.441
Gramme	-	-		18.82715			-		15.4441
Decigramme	-	-		1.882715			-		1.54441
Centigramme	-	-		0.1882715				-	0.15444

The gramme weighs 5.648 drachms avoirdupois, and the kilogramme 35.3 oz. or 2 lb. 3 oz. 4.8 drachms avoirdupois. The *Quintal Metrique*, therefore, weighs 1 cwt. 3 qrs. 24 lb. avoirdupois.

The pound of the *Syſteme Uſuel*, is the half kilogramme; but the diviſions are binary, according to the ancient ſyſtem.

Weights of Spain.—The Caſtilian mark is uſed for the precious metals. In weighing gold, it is divided into 50 caſtellanos, 400 tomines, or 4800 grains; but for ſilver, the ſame mark is divided into eight ounces, 64 ochavos, 128 adarmes, 384 tomines, or 4608 grains. The commercial weight is alſo Caſtilian. The pound is divided into 2 marks, 16 ounces, 128 drachms, or 9216 grains.—25 pounds = 1 arroba; 4 arrobas = 1 quintal.

Weights of Portugal.—Gold and ſilver are weighed by the mark of 8 ounces; the ounce being ſubdivided into 8 outavas, 24 eſcrupulos, or 576 grains. The commercial pound is divided into 2 marks or 16 ounces, the ounce into 8 outavas or 576 grains.—32 lb. = 1 arroba; 4 arrobas = 1 quintal.

Weights of Holland.—Gold and ſilver are weighed by the mark of 8 ounces. The ounce is divided into 20 engels or eſterlins; the engel into 32 aas. Thus the mark weighs 5120 aas. The commercial pound is 40 aas heavier than the above pound troy. It is divided into 2 marks, 16 ounces, 32 loots, or 128 drachms.—8 lb. = 1 ſtone; 15 lb. = 1 liſpond; 100 lb. = 1 centner; and 300 lb. = 1 ſhippond.

A new ſyſtem of monies, weights, and meaſures, ſimilar to the decimal ſyſtem of France, has been lately decreed for Holland, Brabant, and Flanders, by the king of the Netherlands.

Weights of Germany.—The weight for gold and ſilver is not the ſame in all parts of Germany, but the Cologne mark is every where the ſtandard weight for coins. It is divided into 8 ounces, 16 loths, 256 pfenings, 512 hellers, 4352 eſchen, or 65536 richt-pfenings. The pound or pfund commercial weight is generally divided into 2 marks, 16 ounces, 32 loths, 128 quentins, 512 pfenings, 1024 hellers. The larger weights are the ſhippond, the centner or quintal, the liſpond, and the ſtein; but they do not in all places contain the ſame number of pounds, and their diviſions as well as relative proportions are extremely various throughout the empire.

Weights of Italy.—The weights of Italy are various both in their diviſions and relative proportions. Thus, at Rome, the pound for weighing gold and ſilver is divided into 12 ounces, the ounce into 12 drachms, 24 denari or ſcrupoli, 48 oboli, 144 ſilique or 576 grani. At Naples, the pound or libra is divided into 12 ounces, the ounce into 30 trapeſi, and the trapeſo into 20 acini. At Genoa, Florence, Leghorn, and Milan, it is divided into eight ounces, the ounce into 24 denari or 576 grani. At Venice, the marc is divided into 8 oncie, 32 quarti, 192 denari, 1152 carati, or 4608 grani. The commercial weight in moſt of the above places is the ſame for light goods as for gold and ſilver, and is called peſo ſottile; but a heavier weight is uſed for coarſe commodities, and is called peſo groſſo. Their cantaro or quintal varies from 100 to 250 lb., and in ſome places the great cantaro is 1000 lb.

Weights of Denmark.—The pound for gold and ſilver contains 2 marks, 16 ounces, 32 lots, 128 quentins, or 512 orts or pfenings. The pound commercial weight is divided like that for the precious metals. The ſhippond contains 320 lbs. 20 liſponds, or $3\frac{1}{5}$ centners.

Weights of Sweden.—The marck for the precious metals contains 4384 aas; but for commercial purpoſes there are four other weights, *viz.* the victualie-wigt, divided into 32 lods or 128 quentins; the bergs-wigt or miner's weight, the landſtads-wigt, and the metal-wigt. The pound of each of the three latter is divided into 16 lods, or 64 quintals.

Weights of Ruſſia.—The pound in Ruſſia uſed for all commodities is divided into 32 loths, or 96 ſolotnicks.—40 lb. = 1 pood, and 10 poods = 1 berquet.

Weights of Aſia.—The weights of Aſia are far too numerous and various in their diviſions for our limits; but it may be obſerved, that decimal diviſions are more general there than in Europe.

Weights of Africa.—Upon the Barbary coaſt and in Egypt, the weights are ſimilar to each other in their diviſions, but very different in their relative proportions. The principal weight is the cantaro, divided into 100 rottoli, which is likewiſe uſed in Italy, Conſtantinople, and ſeveral places in the Levant.

Weights of America.—The weights and meaſures generally uſed in America, are thoſe of the countries by which the different ſettlements were originally colonized. Thus the Spaniſh weights are retained in all parts of South America except Brazil, where thoſe of Portugal are uſed. In the United States of North America, the Engliſh ſyſtem of weights and meaſures is ſtill continued, although ſeveral plans have been propoſed for changing them.

Compariſon of Weights.—The following Tables ſhew the relation between Engliſh and foreign weights. Alſo the proportion of the latter to each other, which is found by a ſingle ſtating in the Rule of Three, as in the following examples:

Example 1.—How many marks of Berlin weight are equal to 560 kilogrammes of France?

Becauſe 159.29 marks of Berlin = 100 lb. Engliſh Troy (*per* Table XI.), and 37.31 kilogrammes, by the ſame Table, = 100 lb. Engliſh Troy; it follows that 37.31 kilogrammes = 159.26 marks of Berlin; therefore, ſay,

As 37.31 kilog. : 159.29 marks :: 560 kilog. : 2390.84 marks.

Example 2.—How many pounds commercial weight of Amſterdam are equal to 276 pounds of Leghorn?

Here, by Table XII., 91.81 lb. of Amſterdam = 133.56 lb. of Leghorn, both being equal to 100 lb. Avoirdupois; therefore,

As 133.56 lb. of Leghorn : 91.81 lb. of Amſterdam :: 276 lb. of Leghorn : 189.7 lb. of Amſterdam.

Plan for the Reviſion of foreign Weights, &c.—The commercial world will learn with ſatisfaction that a plan has lately been commenced, under the auſpices of the Britiſh government, for reviſing the tables of compariſon between foreign weights and meaſures; as it is well known that many of the tables in uſe abound in contradictory ſtatements; and even where they agree, they are frequently found to differ from mercantile experience.

The origin of thoſe tables of compariſon cannot be traced. It is probable that they have been gradually formed through a long courſe of ages, from the caſual reports of individuals in different countries. When, therefore, it is conſidered, how uncertain ſuch reports muſt have been, and alſo to what changes weights and meaſures are expoſed from decay, accident, or deſign, it is not ſurpriſing that ſo much confuſion ſhould be experienced, eſpecially in tables where no general reviſion has ever taken place.

The only compariſon of the kind upon record is that made in 1767, by M. Tillet, at the Paris Mint, by order of the French government. His operations, however, were confined to money weights, and theſe only of a limited number of places. His tables, as far as they extend, have been generally uſed, although their accuracy is, in many inſtances, diſputed, eſpecially by Kruſe, and other German writers. Nelkenbrecker, in his elaborate work on monies, weights, and meaſures, publiſhed at Berlin in 1810, gives a long ſtatement (page 508.) of diſcrepances between Tillet's reports and thoſe of other aſſay maſters.

But the moſt numerous and important errors are in the tables of commercial weights and meaſures; and therefore with a view of remedying an evil ſo perplexing to merchants, our government has recently iſſued an order to the Britiſh conſuls abroad, to ſend home well-atteſted copies of foreign ſtandard weights, that they may be accurately compared with thoſe of England at his majeſty's mint. Correct ſtatements are likewiſe required of the mathematical dimenſions of meaſures of capacity, and of their comparative contents, as eſtimated and acted upon by merchants.

We have authority further to ſtate, that the plan was examined and approved by the Board of Trade, on the 14th of January 1818; and, by their lordſhips' recommendation, the order to the conſuls has been iſſued from the foreign-office, by Viſcount Caſtlereagh.

The copies of ſtandards thus tranſmitted to London are to be weighed and compared by Robert Bingley, eſq. F.R.S., the king's aſſay-maſter of the Mint; and the reſults of thoſe important compariſons are to be publiſhed by Dr. Kelly, who projected the plan, and who will perform the calculations. The reviſed tables are expected to be brought out in the ſecond edition of his Cambiſt; and ſhould they be printed before our Cyclopædia is finiſhed, we hope for the author's permiſſion to inſert them in our *Addenda.*

WEIGHTS

WEIGHTS *and Meaſures*, in *Agriculture* and *Rural Economy*, are of great conſequence to the land-owner and the farmer, as being the proportions or quantities by which various ſorts of produce, of the agricultural and other ſuch kinds, are diſpoſed of and ſold. They are found to vary very greatly in different diſtricts and parts of the country, as well as in different places and towns of the ſame diſtrict or county, and even in the markets of the ſame town. Conſequently, the confuſion, uncertainty, inconvenience, and loſs which are thus produced, are often very great and troubleſome. We have already, in the preceding article, obſerved, that the two principal weights eſtabliſhed in Great Britain are the troy and avoirdupois weights, and by theſe moſt of the articles of farm produce, and thoſe of many other kinds, are ſold in this country.

There are ſome, however, that are diſpoſed of in other ways, as will be ſeen below.

However, as the diverſity of weights and meaſures (in different places) creates much perplexity and uncertainty in the purchaſe as well as diſpoſal of different ſorts of produce, it would not only be highly deſirable, but convenient and advantageous, to have one univerſal ſtandard or ſyſtem of weights and meaſures. For an account of the attempts that have been made to obtain ſuch a ſtandard, ſee STANDARD.

Different Weights and Meaſures for Farm and other produce by Troy Weight.

24 Grains	make	1 Pennyweight
20 Pennyweights	-	1 Ounce
12 Ounces	- -	1 Pound.

By this weight are weighed gold, ſilver, amber, bread, corn, and all liquors.—14 oz. 11 dwts. $15\frac{1}{2}$ grains, or 292 dwts. nearly, are equal to a pound avoirdupois.

By Avoirdupois Weight.

16 Drams	make	1 Ounce
16 Ounces	- - -	1 Pound
28 Pounds	- - -	1 Quarter
4 Quarters	- - -	1 Hund. weight
20 Hund. weight	- - -	1 Ton.

By this weight are weighed all the farm produce, ſuch as butter, cheeſe, and many other articles; and all metals, except thoſe of the finer kinds. In other caſes,

$7\frac{1}{2}$ Pounds	make	1 Gallon of train-oil
8 Pounds	- -	1 Stone of butcher's meat
14 Pounds	- -	1 Stone of horſeman's weight
$19\frac{1}{2}$ Hundreds	-	1 Fodder of lead.

In Wool Weight.

$7\frac{1}{2}$ Pounds	make	1 Clove
2 Cloves	- - -	1 Stone
2 Stone	- - -	1 Todd
$6\frac{1}{2}$ Todds	- - -	1 Weigh or Wey
2 Weys	- - -	1 Sack
12 Sacks	- - -	1 Laſt.

In Hay Weight.

56 Pounds of old hay, or 60 Pounds of new ditto	make	1 Truſs
36 Truſſes	- - - -	1 Load.

In Bread Weight.

	lb.	oz.	dr.
A peck loaf weighs - -	17	6	$0\frac{1}{2}$
A half ditto - - - -	8	11	0
A quartern ditto - - -	4	5	8

By Dry Meaſure.

2 Pints	make	1 Quart
2 Quarts	- - - -	1 Pottle
2 Pottles	- - - -	1 Gallon
2 Gallons	- - - -	1 Peck
4 Pecks	- - - -	1 Buſhel
4 Buſhels	- - - -	1 Coomb
2 Coombs, or eight buſhels	-	1 Quarter
4 Quarters, or 32 buſhels in the country, and 36 in London		1 Chaldron
5 Quarters	- - - -	1 Weigh or Wey
2 Weys, or 10 quarters	- -	1 Laſt.

By this meaſure are meaſured corn, ſalt, lead, ore, oyſters, different other ſuch matters, and all dry goods. The ſtandard Winchester buſhel is a cylinder $18\frac{1}{2}$ inches diameter, and 8 inches deep.

By Long Meaſure.

3 Barleycorns	make	1 Inch
12 Inches	- - - -	1 Foot
3 Feet	- - - -	1 Yard
6 Feet	- - - -	1 Fathom
$5\frac{1}{2}$ Yards	- - - -	1 Pole, rod, or perch
40 Poles	- - - -	1 Furlong
8 Furlongs	- - - -	1 Mile
3 Miles	- - - -	1 League
60 Geographical, or $69\frac{1}{2}$ Engliſh miles	-	1 Degree
360 Degrees	- - - -	The circumference of the Globe.

This comprehends length only, as in the above caſes.

By Square Meaſure.

144 Square inches	make	1 Square foot
9 Square feet	- - -	1 Square yard
100 Square feet	- - -	1 Sq. of flooring
$272\frac{1}{4}$ Square feet	- - -	1 Square rod
40 Square rods	- - -	1 Square rood
4 Square roods	- - -	1 Square acre
30 Square acres	- - -	1 Square yard of land
100 Square acres	- - -	1 Square hide
640 Square acres	- - -	1 Square mile.

Square meaſure comprehends length and breadth, and is uſed in meaſuring land, in paving, flooring, painting, glazing, plaiſtering, roofing, ſlating, tyling, and for ſeveral other rural purpoſes.

In land meaſuring is uſed Gunter's chain, which is 4 poles or 22 yards, or 66 feet long, and contains 100 links, each link being 7.92 inches long.

And 43560 ſquare feet or 4840 ſquare yards, or 160 ſquare poles, that is, 160 poles in length and 1 pole in breadth, or 4 ſquare roods, or 10 ſquare chains, that is, 10 chains in length and 1 chain in breadth, make an acre of land.

By Cubic or Solid Meaſure.

1728 Cubic inches	make	1 Cubic foot
27 Cubic feet	- - -	1 Cubic yard
40 Feet of rough timber 50 Feet of hewn ditto	-	1 Load

This comprehends length, breadth, and thickneſs.

And

And 108 folid feet, that is, 12 feet in length, 3 feet in breadth, and 3 deep, or commonly 14 feet long, 3 feet 1 inch broad, and 3 feet 1 inch deep, are a ftack of wood.

And 128 folid feet, that is, 8 feet long, 4 feet broad, and 4 feet deep, are a cord of wood.

In Coal Meafure.

4 Pecks	make	1 Bufhel
3 Bufhels	- - - -	1 Sack
12 Sacks, or 36 bufhels	- -	1 Chaldron
21 Chaldrons	- - - -	1 Score

In Corn Meafure.

1 Load of corn	makes	5 Bufhels
1 Laft of ditto	- - -	43 Do.

It is enacted by 31 George III., that a Winchefter bufhel of corn fhould weigh as follows:

	lb.			lb.	
Wheat	57	avoirdupois,	Wheat meal	56	Flour, 45lb. of which fhould be equal to a Winchefter bufhel unground.
Barley	49	- -	Flour	48	
Bigg	42	- -	Ditto	41	
Oats	38	- -	——	32	
Rye	55	- -	——	53	

After thefe ftatements of the different weights and meafures which are in common ufe for different forts of produce, it may not be improper to notice fome of the differences of weights and meafures, as they exift in different diftricts, towns, and parts of the kingdom, according to the account which has been given of them, and as they are injurious to the farmer.

In the counties or diftricts near the metropolis, the ftatute meafures are pretty commonly employed, though there are many irregularities and deviations; but in thofe at fome diftance there are more frequent and remarkable variations and differences.

In the county of Middlefex, the weights and meafures made ufe of are moftly thofe of the ftandard legal kind, and confequently the variations in them are but little.

Wood is fold by the ftack, as packed three feet by three, and twelve feet long, containing in this manner 108 cubical feet.

Effex is now pretty much in the fame ftate as above, in regard to its weights and meafures, though formerly they varied very greatly, wheat being fold either by weight or meafure, as agreed upon. The meafure then eight gallons and a half the bufhel; and the weight, that ufually termed the peck weight, or the medium of what eight and a half of good wheat would weigh.

Then all other forts of grain were fold by meafure, but by that which was very different in different places, and for different forts, the bufhel of barley, malt, oats, &c. being often nine gallons; others eight and a half, and eight and three pints, &c. There are ftill fome remains of thefe meafures in the county. Various articles, too, are ftill fold there by the tale, the dozen, the fcore, and the hundred of fix fcore, fuch as hop-poles, faggots, &c.

The writer of the Berkfhire Agricultural Report remarks, that, notwithftanding the fines and forfeitures attached to felling corn by any other than the ftandard bufhel, and the obvious ill confequences refulting from the practice without one counterbalancing advantage, that county, like moft others, has its diverfity of meafures, which only encourages jobbers, to the prejudice of the grower of corn; who, influenced by habit, does not always take into confideration, that if he fhould fell nine gallons inftead of eight to the bufhel, he is giving a bufhel in every quarter of grain more than the laws allow, or juftice requires, and that the dealer is probably making that proportion of profit, out of his ignorance or obftinacy.

The owners of land cannot, therefore, more effectually ferve their tenants, it is fuppofed, than by exerting themfelves to introduce an uniformity of meafure in their refpective neighbourhoods.

The nine-gallon bufhel prevails in fome parts of the county, but in others the ftandard. At Faringdon and Wantage, the former is almoft exclufively ufed; but at Abingdon both it and the ftandard bufhel are employed. The former is the cuftom of the market, however, unlefs the contrary be fpecified; but malt fold out of the town is only eight gallons meafure.

Corn is commonly fold by the load of five quarters. In building, hedging, and ditching, the perch or pole of eighteen feet is the ufual meafure.

Wood is fold by the foot, and load-underwood by the cord, in fome places abfurdly called a load, and by the proper load.

Befides the ftatute acre, there are alfo common field acres, which are fometimes more, and fometimes lefs, than the ftatute.

In weights the diverfity is great in moft places.

In the county of Suffex, the weights and meafures moft commonly ufed are, the pound, ftone, acre, load, bufhel, &c. There are feveral forts of acres, which are a great fource of perplexity and confufion—the fhort acre, the ftatute acre, the foreft acre, and various others: the foreft acre is nine fcore rods; the ftatute, eight fcore; and the fhort acre, fix fcore in fome places, in others five fcore. The ftranger, unaware of the variations that prevail in the weights and meafures, is, it is faid, liable to fall into miftakes in every ftep he takes; and that until a radical reform is brought to bear, the prefent confufion in buying and felling muft prevail, and the honeft and unfufpecting will be taken in by the crafty and defigning.

In the other fouthern diftricts or counties, the variations in their weights and meafures are much the fame, though lefs than in thofe of the north.

It is ftated in the Gloucefter Report on Agriculture, that in the market of that town, the bufhel varies from nine to ten gallons; in the foreft diftrict it is nearly ten gallons; on the Cotfwolds about nine; in the vale nine and a half; and in the lower vale, and at Cirencefter, nine and a quart, of all forts of grain.

Near Briftol, potatoes, green peas, &c. are fold by the double peck, containing two common ones ftruck level with the top; while at Gloucefter, and higher up the vale, it is a common peck heaped up. Wool is generally fold by the ftone weight of $12\frac{1}{2}$lbs., or the tod of $28\frac{1}{2}$lbs. Butter often by the pound of 18 oz.; and the quart of about 3lbs.

In Herefordfhire the peculiar weights and meafures which are at prefent in ufe are thefe, according to the Survey on Agriculture for that diftrict.

1 Pound of frefh butter	-	18 Ounces
1 Stone	- - - -	12 Pounds
1 Cuftomary acre	- -	$\frac{2}{3}$ Of a ftatute acre
1 Hop acre	- - -	That fpace of ground which contains 1000 plants; *viz.* about $\frac{1}{2}$ a ftatute acre
1 Lugg	- - -	49 Square yards of coppice-wood

Wood

1 Wood acre - -	$\frac{3}{5}$ Larger than a ftatute, *i. e.* as 8 are to 5
1 Day's math - -	About a ftatute acre of meadow or grafs land, being the quantity ufually mown by one man in one day
1 Perch of fencing -	7 Yards
1 Perch of walling -	$16\frac{1}{2}$ Feet
1 Perch of land - -	$5\frac{1}{2}$ Yards (as ftatute)
1 Bufhel of grain - -	10 Gallons
1 Bufhel of malt - -	$8\frac{1}{2}$ Gallons.

In the Report on Agriculture for Shropfhire, it is ftated, that wheat, barley, and peas, are fold by the ftrike or bufhel, which, in Shrewfbury market, is 38 quarts, but in fome other markets it is 40 quarts. That the 38 quarts of wheat fhould weigh 75lbs., the 40 quarts 80lb. In other markets in the county, the bufhel of wheat does not weigh more than 70lbs.: this is chiefly applicable to the eaftern diftrict of the county. The bufhel of flour is every where 56lbs. That 38 quarts of barley weigh about 65lbs. That a bufhel of oats means three half bufhels of the cuftomary meafure at Shrewfbury, and fhould weigh better than 93lbs. But that in other markets it means $2\frac{1}{2}$ bufhels, fometimes heaped, fometimes ftricken, and fometimes a medium between both. That a bag of wheat means three bufhels cuftomary meafure. The quarter bufhel is called a hoop or peck; and the fourth of that is called a quarter. Butter, when frefh, weighs 17 oz. to the pound; when falted, 16 oz. The laft is reckoned by the gawn, which fignifies 12lbs. of 16 oz. in Shrewfbury, and 16lbs. of 16 oz. at Bridgnorth. Cheefe is fold by the cwt., which, at Shrewfbury, means 121lbs., and 113lbs at Bridgnorth. Coals are fold by the ton, which is 20 cwt. of 112lbs. at fome pits, and 120lbs. at others: the ftack is now rarely ufed; it was a meafure of four feet fquare, and would fometimes weigh 25 cwt. Hay is fold by the ton, of 20 cwt. of 112lbs. Home-made linen cloth is fold by the ell, which meafures a yard and a half; and it is added, that the acre is the ftatute acre. That the workman's rood in digging is eight yards fquare; but in hedging eight yards in length.

It is fuggefted, too, that there is an error in the ftandard meafure, that in the Exchequer not agreeing with the requifitions of the 13 Will. III. c. 5. By which ftatute, the bufhel is ordered to be $18\frac{1}{4}$ inches round, and 8 deep; it would confequently contain

Cubic inches - - - - - -	2150
That in the Exchequer contains - -	2124
Eight of the ftandard gallons - -	2168
Thirty-two ditto quarts - - -	2240
Sixty-four ditto pints - - -	2027

That the difference between the bufhel and 32 of the quarts is, therefore, 116 cubic inches, or nearly three pints and a half.

It is ftated, too, that in the northern part of the North Riding of Yorkfhire, the cuftomary bufhel exceeds that of the Winchefter, by full two quarts; but nearer to the fouthern extremity, feldom by more than one: the bufhel of fome individuals in the Riding is ftill larger, meafuring about 10 *per cent.* more than the ftatute requires.

And further, that a ftone of wool in York market is fixteen pounds, and four ounces in each ftone are allowed for draught; that is, for the draught of each fleece, the wool-buyers being empowered by act of parliament to weigh each fleece *feparately*, if they like. That at Ripon market, a ftone of wool is 16 pounds 12 ounces. And a ftone of wool in the Weftern Moorlands is $17\frac{1}{2}$ pounds; the half pound, the writer apprehends, is for draught, as in York market.

But that at Darlington, where the wool grown about Richmond in that diftrict is chiefly fold, the ftone is 18 pounds. And that in the Eaftern Moorlands, the weights ufed by individuals vary up to 19 pounds to the ftone.

That the pound of butter in the Riding varies from 16 to 24 ounces. But that a ftone of all other commodities throughout the whole of it is 14 pounds.

In Chefhire, though the variety in the weights and meafures is very confiderable, it is lefs on the whole than in fome other parts of the country.

The weights in this diftrict are ufually the avoirdupois 112lbs. to the hundred weight. Some articles are fold by what is called the long hundred of 120lbs. Cheefe is one of thefe. Hay, too, is generally there fold by the cwt. of 120lbs.

Butter, in moft parts of the county, is difpofed of by the pound weighing 18 ounces. In fome places it is fold in lumps, made up in moulds of different forms, called difhes, or half difhes. Thefe weigh 24 or 12 ounces each.

Potatoes are ufually difpofed of by the bufhel weighing 90 pounds.

Wheat by the bufhel weighing either 70 or 75 pounds.

Oats by the bufhel weighing from 45 to 50 pounds, as the price and bargain may be.

Oatmeal by the load weighing 240 pounds.

Barley is fometimes fold by the bufhel of 60 pounds, and fometimes by the meafure of 38 quarts.

Malt by the meafure of 32 or 36 quarts.

Land was formerly very generally meafured there by what is called the Chefhire acre, containing 10,240 fquare yards; and this meafure ftill continues to be ufed to a certain extent, particularly in the northern part of the county. The ftatute acre is now, however, it is faid, in much more general ufe.

A rood of land is 64 yards. A rood of hedging, ditching, and other fuch operations, eight yards in length. And a rood of marl is 62 cubic yards.

In the Lancafhire Report on Agriculture, it is obferved, that the rod is of no lefs than fix different lengths in different parts of the county; namely, the ftatute, or $5\frac{1}{2}$ yards, 6, $6\frac{1}{2}$, 7, $7\frac{1}{2}$, and 8 yards, to the rod, pole, or perch: and that the meafures are equally variable. At Lancafter a load of wheat, beans, and peas, is four and a half bufhels (Winchefter); barley, fix Winchefter bufhels; oats, feven and a half Winchefter bufhels: they have alfo a meafure called a *windle*, which is equal to three Winchefter bufhels. But that wheat has been fold lately by the weight of 280lbs.

That at Ulverftone, a load of wheat is four and a half Winchefter bufhels; oats, fix Winchefter bufhels. And that at Manchefter, a load of wheat is fixteen fcore; a load of oats, nine Winchefter bufhels; a load of beans, five Winchefter bufhels; a load of potatoes, twelve fcore and twelve pounds, wafhed; unwafhed, thirteen fcore. That Liverpool town's bufhel is $34\frac{1}{2}$ quarts for oats, barley, and beans, making exactly 36 quarts Winchefter, or one-eighth more than a Winchefter bufhel, and by the cuftom of trade, one given in at every fcore, or twenty-one bufhels; of late, wheat, barley, and oats, have been fold by weight, but never yet beans; wheat, 70lbs. to the bufhel; barley, 60lbs.; and oats, 45lbs.: and probably this mode by weight is the faireft for both a buyer and feller; for, befides the difficulty of getting a true ftandard bufhel or meafure, the dexterity

 of

of corn-meters is ſuch, that it is aſſerted they can gain either to the buyer or ſeller from 10 to 20 *per cent.* in different modes of meaſurement; that 5 *per cent.* can be obtained by this practice, by even bunglers in the buſineſs: this is an enormous profit, and the unfairneſs of ſuch practices merits the ſevereſt reprehenſion.

That at Preſton the windle of wheat, beans, and barley, is three and a half Wincheſter buſhels; but of late 220lbs. have been reckoned a windle of wheat: they have alſo a meaſure there called a peck, which is twenty-eight quarts, four of which are called a windle.

In reſpect to weights, there are three different ones expreſſed under the general term hundred weight; namely, 100lbs., 112lbs., and 120lbs. The ſtone, too, varies. In Liverpool, 20lbs. are the weight allowed for the ſeveral articles under that denomination, as beef, hay, ſtraw, &c.; and probably all the articles produced from land. And butter is required to weigh 18 ounces avoirdupois, or it may be ſeized by the magiſtrates.

At Lancaſter, and the neighbourhood, they have ſeveral different weights, as the Lancaſter peck, of twenty-four quarts; the common peck, of ſixteen quarts; the half Wincheſter; the windle, of three and a half buſhels; the met, of fifty-ſix quarts; the ackendale, or ackentyde, the eighth part of the above, or ſeven quarts, and the meaſure of four quarts. The load of malt is ſix buſhels.

Butter eighteen ounces to the pound; other articles ſixteen.

There are alſo different local variations in many articles.

In Weſtmoreland, the pound conſiſts of twelve, ſixteen, eighteen, or twenty-one ounces; and the ſtone of fourteen, ſixteen, or twenty pounds. There is alſo a Wincheſter buſhel, a cuſtomary buſhel equal to three of theſe, a buſhel of two buſhels for the ſale of potatoes near Appleby, and one of two and a half for that of barley. Rye is ſold by the boll of two buſhels, and potatoes by the load of four buſhels and a half heaped; or more generally a bag, which holds ſeven and a half buſhels, is filled and ſold for a load of potatoes.

There is the ſtatute acre, too, of 4840 ſquare yards, the cuſtomary acre of 6760 raiſed from the perch of ſix and a half yards, and a third acre on the borders of Lancaſhire, raiſed from the perch of ſeven yards, containing 7840, being the ſame as the Iriſh plantation acre.

It is remarked, likewiſe, in the Cumberland Report on Agriculture, that the ſame confuſion in weights and meaſures prevails there, as in many other parts of the kingdom.

That a Wincheſter buſhel is thirty-two quarts; a Carliſle buſhel, ninety-ſix quarts; and a Penrith buſhel, ſixty-four quarts, for wheat and rye; and eighty quarts, for barley, oats, and potatoes.

That a ſtone of tallow, wool, yarn, or hay, is 16lbs.; and a ſtone of butcher's meat 14lbs., but in many places 16lbs.

That the pound is ſixteen ounces, by which butter and various other articles are weighed.

The writers of the Account of Agriculture for Northumberland, ſtate that their weights and meaſures are in a ſad ſtate of confuſion; a pound, a ſtone, a buſhel, and a boll, are rarely the ſame in different markets, and frequently vary in the ſame market for different articles.

At Newcaſtle.

4 Beatments	make	1 Peck

3 Pecks		1 Buſhel
6 Buſhels		1 Boll.

That a ſtone of wool in ſome parts is 24lbs.; in others, 18lbs.; and a ſtone of every other article is 14lbs.

As the weights and meaſures made uſe of in Scotland differ very materially from thoſe employed in England, it may, of courſe, not be uſeleſs to give a curſory view of them under the preſent head. It has been obſerved by Mr. Somerville, in his Account of the Agriculture of Eaſt Lothian, that land is meaſured by the Scotch acre, which is to the Engliſh acre very nearly in the proportion of five to four.

That the boll is the denomination of corn meaſure always uſed, but the contents vary according to the ſpecies of grain meaſured. But that there are uniformly four firlots in the boll of all grain; but the firlot differs in ſize in the proportion of 21, 25, to 31. Wheat, rye, beans, and peas, are ſold by the ſmall firlot; malt, barley, and oats, are ſold by the large one. Four ſmall firlots are 4.087276 Wincheſter buſhels; four large ones are 5.96263 buſhels Wincheſter. The boll of wheat then is a ſmall fraction more than half a quarter; and the boll of barley, a fraction leſs than three-fourths of a quarter. But this calculation applies, it muſt be remembered, to the Linlithgow boll, which is accounted the ſtandard meaſure of Scotland: the meaſure actually uſed in Eaſt Lothian is ſomewhat larger.

In the Mid-Lothian Report on Agriculture, it is ſtated, that flour, pot-barley, groceries, iron, and ropes, are bought and ſold there, by what is termed Engliſh weight, being 16 oz. to the pound, and 16lbs. to the ſtone. But that butcher's meat, oatmeal, and flax, are bought and ſold by what is called Dutch weight, of which the proportion to the Engliſh is as $17\frac{1}{2}$ to 16.

That wool, hay, and butter, are bought and ſold by trone weight, of which the proportion is to the Engliſh, as 22 to 16. That other articles are bought and ſold by either of theſe weights, as it may happen.

But that in long meaſure the inch is the root, of which 12 go to the foot, and 37 to the Scotch yard.

And that land is meaſured by a chain 24 yards in length, or 74 feet, divided into 100 links, of 8.888 inches each in length; 10 ſquare chains make an acre, or 5760 ſquare yards Scotch, equal to 6084.444 Engliſh; and as

the

the Engliſh acre conſiſts of 4840 ſquare yards, hence the proportion that the Scotch acre bears to the Engliſh is, with a ſmall fraction more, as 5 to 4, as ſeen above.

That in liquid meaſure the *pint* is the root, containing 103.404 cubic inches; the half and quarter in proportion.

That the Linlithgow wheat firlot, the only ſtandard meaſure for that grain in Scotland, contains $21\frac{1}{4}$ pints; hence in cubic inches 2197.34. The Wincheſter buſhel, in like manner the Engliſh ſtandard, contains 2150.42 cubic inches; hence the Scotch wheat firlot is about $2\frac{1}{7}$ *per cent.* greater than the Engliſh buſhel.

And the Linlithgow barley meaſure, which is likewiſe the ſtandard, contains 31 pints, or 3205.54 cubic inches; hence $5\frac{23}{24}$ buſhels are very nearly equal to the Scotch boll of 4 firlots.

That ſtraw is ſold by tale, 40 windlens to a kemple, generally from 14 to 16 ſtone trone weight.

It is noticed, that in Eaſt Lothian, meal is ſold by the peck of eight pounds Amſterdam weight; and that the boll of meal contains ſixteen pecks or eight ſtones.

It is ſtated in the Clydeſdale Report on Agriculture, that in the dry meaſure, uſed in the ſale of grain of all kinds, a boll contains four firlots, a firlot four pecks, and a peck four forpits or lippies; 16 bolls make a chalder. The firlot uſed to meaſure barley and oats, is almoſt one-half larger than the firlot for meaſuring wheat, beans, peas, &c. That both theſe meaſures are about one-ſixteenth larger than the Linlithgow ſtandards of the ſame denominations. But for more than thirty years paſt, wheat has been bought and ſold by the Linlithgow ſtandard, which is now attempted to be introduced for other grains.

That in the lower parts of the county potatoes have been meaſured, for theſe forty years, with a diſh of the ſhape of a caſk, the peck meaſure holding fifteen Scotch pints; its weight, full of potatoes recently dug, is 43lbs. avoirdupois. In the higher parts of the county potatoes are ſold by the barley meaſure.

That the peck, or *ſleek*, for meaſuring pears and apples, holds about eighteen pints. The confuſion occaſioned by the irregularity of weights and meaſures, is too obvious, the writer ſays, to require any comment.

In the Argyleſhire Agricultural Report, it is ſaid that at Inverary the boll of meal is eight ſtone Scotch troy, or Dutch $17\frac{1}{2}$lbs. avoirdupois to the ſtone. At Campbelton it is ten ſtone, of the ſame weight; or ſixteen pecks of 10lbs. Scotch troy, or 10lbs. 15 oz. avoirdupois each.

That in ſome parts of the Knapdale and Lorn, the boll is nine ſtone. That in the firſt of the above places, oats, barley, and malt, are meaſured by a firlot of 3438.183 cubic inches; equal to one firlot, two pints, one mutchkin, Scotch ſtandard meaſure, which makes the boll (of four firlots) 7.258 *per cent.* better than the Scotch ſtandard meaſure, and equal to ſix buſhels, one peck, nine pints, 10.2 cubic inches, Engliſh ſtandard meaſure.

And that in Kintyre, oats, barley, or bear and malt, were, for time immemorial, ſold by a heaped peck, of which the ſtandard lay with the dean of Guild in Campbelton. Of this meaſure, ſeventeen pecks made, and ſtill make, the Kintyre boll from Auguſt to Patrickmas, and only ſixteen from that date to the new crop; and the diviſions of the boll are regulated by the ſame proportions. But from the inconvenience of meaſuring by the heaped peck, it has been converted into the ſtriked one containing the ſame quantity; and this new ſtriked peck committed to the dean of Guild, has been ſince the ſtandard of the diſtrict. The dimenſions of it are twelve Engliſh inches diameter, equally wide throughout, and ten and a tenth Engliſh inches deep. The contents of it in cubic inches are 1142.28576, equal to eleven Scotch pints, and a very little more than two-thirds of a gill, which makes the Kintyre boll 19418.85792 cubic inches, before Patrickmas, and 18276.57216 after it. A lippie more, or $\frac{1}{64}$th of a boll, for town dues, is given with every boll delivered in Campbelton. The firſt is equal to nine Wincheſter buſhels, and 65.03112 cubic inches, (about $\frac{1}{33}$ of a buſhel) and equal to one boll eight pecks, 1.61788 lippie, Linlithgow ſtandard meaſure. The latter is equal to eight and a half Wincheſter buſhels, excepting 2.0394 cubic inches, and to one boll ſix pecks, $3\frac{46}{250}$ lippies Linlithgow. The Wincheſter buſhel contains 2150.42 cubic inches. The Linlithgow boll ſtandard meaſure 12822.096.

That at Inverary, the peck of potatoes contains fourteen pints and one mutchkin, ale meaſure. At Campbelton, it contains about nine Engliſh wine gallons, and is given heaped; and generally weighs about 56lbs. avoirdupois.

But that beans and peas are ſold in Kintyre by the old peck ſtriked, or by a meaſure one-third leſs than that for oats and bear. Lineal and liquid meaſures are the ſame with the Scotch ſtandards. Butter, cheeſe, tallow, hay, wool, and lint, are ſold by the ſtone of 24lbs. avoirdupois. Butcher's meat by the pound of twenty-four ounces avoirdupois at Inverary, and of ſixteen ounces at Campbelton. The herring-barrel contains thirty-two Engliſh gallons of wine meaſure, or 67.28 cuſtomary ale pints of 109.866 cubic inches each.

Theſe facts and ſtatements ſufficiently ſhew the neceſſity of ſome regulation being ſpeedily adopted of adjuſting weights and meaſures to ſome ſimple ſtandard, both in this and the northern parts of the kingdom.

The table of weights conſtructed by lord Somerville, and introduced below, may be uſeful to the ſtock-farmer and grazier in moſt ſituations.

WEIGHT,

Weight, *Pondus*, in *Mechanics*, is any thing to be raiſed, ſuſtained, or moved by a machine; or any thing that in any manner reſiſts the motion to be produced. See Motion, &c.

In all machines, there is a natural ratio between the weight and the moving power. If the weight be increaſed, the power muſt be ſo too; that is, the wheels, &c. are to be multiplied, and ſo the time increaſed, or the velocity diminiſhed.

"The centre of gravity F, (*Plate* XL. *Mechanics*, *fig*. 6.) of a body I H, together with the weight of the body, being given; to determine the point M, in which, lying on a horizontal plane, a given weight G, hung in L, cannot remove the body I H out of its horizontal ſituation."

Conceive a weight hung in the centre of gravity F, equal to the weight of the whole body I H, and find the common centre of gravity M, of that and the given weight G. If the point M be laid on the horizontal plane, the weight G will not be able to move the body H I out of its place.

"The centre of gravity C (*fig*. 7.) of a body A B, together with its weight G, being given; to determine the points L and M, wherein props M N and L O are to be placed, that each may bear any given proportion of the weight."

In the horizontal line A B, paſſing through the centre of gravity C, aſſume the right lines M C and C L in the given ratio. Props, then, M N, L O, placed in theſe points, will be preſſed in the given ratio.

Hence, if in the points M, L, in lieu of props, you place the ſhoulders or arms of porters, &c. they will be able to bear the burden alike; if their ſhares be proportioned to their ſtrengths. Thus we have a way of diſtributing a burden in any given ratio.

Weights, *Groſs*, *Neat*, *Penny*, *Aſſay of*, *Ancel*. See the ſeveral articles.

Weight *of the Atmoſphere*. See Atmosphere.

Weight *of the Air*, is equal to the elaſticity thereof.

To find the Weight of a Cubic Inch of Air.—Weigh a round glaſs veſſel full of common air, very accurately; then exhauſt the air out of it; weigh the exhauſted veſſel, and ſubtract the latter weight from the former, the remainder is the weight of the air exhauſted.

Find, then, the content of the veſſel by the laws of meaſuring; and the ratio of the remaining air to the primitive air. This done, the bulk of the remaining air is found by the rule of three; which being ſubtracted from the capacity of the veſſel, the remainder will be the bulk of air extracted. Or, if the air-pump be very tight, and the exhauſtion continued as long as any air is got out, the remaining air will be ſo ſmall, that it may be very ſafely neglected, and the content of the veſſel taken for the bulk of the exhauſted air.

Having, therefore, the weight and bulk of the whole exhauſted air, the weight of one cubic inch is eaſily had by the rule of three.

This method was firſt uſed by Otto Guericke, and afterwards by Burcher de Volder, who gives us the following particulars in his experiment. 1. That the weight of the glaſs ſpherical veſſel he made uſe of, full of common air, was 7 lbs. 1 oz. 2 drs. 48 grs.; when exhauſted of air, 7 lbs. 1 oz. 1 dr. 31 grs.; and when full of water, 16 lbs. 12 oz. 7 drs. 14 grs. The weight of the air, therefore, was 1 dr. 17 grs. or 77 grs.; the weight of the water 9 lbs. 11 oz. 5 drs. 43 grs. or 74743 grs. Conſequently, the ratio of the ſpecific gravity between water and air is 74743 : 77 :: $970\frac{53}{77}$: 1. Now, De Volder having found a cubic foot of water to weigh 64 lbs., by inferring, as 970 is to 1, ſo is 64 lbs. to a fourth proportional, deduced by the rule of three, the weight of a cubic foot of air, *viz*. 1 oz. 27 grs. or 507 grs. nearly. Wolfii Elem. tom. ii. p. 291.

From other later experiments accurately made with the hydroſtatical balance, a cubic inch of air appears to be equal to two-ſevenths of a grain, and therefore a cubic foot equal to $493\frac{5}{7}$ troy grains. There are various ways of eſtimating the weight of the air; for which, ſee Air, Atmosphere, Barometer, *Specific* Gravity, &c.

It may be eaſily determined by fitting a braſs cap, with a valve tied over it, to the mouth of a thin bottle or Florence flaſk, whoſe contents are exactly known, and ſcrewing the neck of this cap into the hole of the plate of the air-pump; then, having exhauſted the flaſk of its air and taken it off from the pump, ſuſpend it at one end of a balance, and nicely counterpoiſe it by weights in the ſcale at the other end: when this is done, raiſe up the valve with a pin, and the air will ruſh into the flaſk, and cauſe it to deſcend. When it is full of air, put grains into the ſcale at the other end to reſtore the equilibrium; and if the flaſk holds exactly a quart, it will be found, that 17 grs. will be ſufficient for this purpoſe, when the quickſilver ſtands at $29\frac{1}{2}$ inches in the barometer; and this ſhews, that when the air is at a mean ratio of denſity, a quart of it weighs 17 grs.; and conſequently a gallon weighs 68 grs.: *i. e*. 231 cubic inches of air are equal in weight to 68 grs., and 1728 cubic inches, or a cubic foot of air, weighs $509\frac{156}{231}$ grs.; and as a cubic foot of water weighs about 437702 troy grains, the ſpecific gravity of water will appear to be more than 850 times that of air. See Air.

The weight of *ſea-water* is different in different climates. Mr. Boyle having furniſhed a learned phyſician, going on a voyage to America, with an hydroſtatical balance, and recommended him to obſerve, from time to time, the difference of weight he might meet withal; this account was returned him: that the ſea-water increaſed in weight, the nearer he came to the line, till he arrived at a certain degree of latitude, as he remembers, about the 30th; beyond which, it retained the ſame ſpecific weight, till he came to Barbadoes. Philoſ. Tranſ. N° 18.

The weight of a cubical inch of good brandy, rum, or other proof ſpirits, is 235.7 grs.; therefore, if a true inch cube of any metal weighs 235.7 grs. leſs in ſpirits than in air, it ſhews the ſpirits are proof; if it loſes leſs of its aerial weight in ſpirits, they are above proof; if it loſes more, they are under: for the better the ſpirits are, they are the lighter; and the worſe, the heavier.

As all bodies expand with heat and contract with cold, in different degrees, the ſpecific gravities of bodies are not preciſely the ſame in ſummer as in winter. It has been found, that a cubic inch of good brandy is 10 grs. heavier in winter than in ſummer; as much ſpirit of nitre, 20 grs.; vinegar, 6 grs.; and ſpring-water, 3 grs. Hence it is moſt profitable to buy ſpirits in winter, and ſell them in ſummer, ſince they are always bought and ſold by meaſure. It has been found, that 32 gallons of ſpirits in winter will make 33 in ſummer. Ferguſon's Lect. p. 98. 4to. See *Specific* Gravity, and Hydrometer.

Weight *of the Human Body*. It is to be obſerved, that the heat and dryneſs of the air both leſſen the weight of the body, and the cold and moiſture of the air both increaſe this weight. See Moisture.

Much ſleep, much food, and little exerciſe, are the principal things which increaſe the weight of the body, and make animals grow fat. Conſequently, if the weight of the body be too great for good and uninterrupted health, it may be leſſened by diminiſhing ſleep and food, and by increaſing creafing exercife. On the contrary, if the weight of the body be too little for good health, it may be increafed by adding to food and fleep, and by leffening exercife; and the food muft be increafed chiefly by increafing drink and liquid nourifhment. For the difcharges are commonly lefs from drink and liquid nourifhment, than from dry and folid food.

There is but one weight under which a body can enjoy the beft and uninterrupted health, and that weight muft be fuch, that perfpiration and urine may be nearly equal at all feafons of the year; for by this means the body will be uniformly drained of its moifture: the inward parts by urine, and the more fuperficial parts by perfpiration, without any irregular and unnatural difcharges, and its moving weight will continue nearly the fame at all feafons of the year. Dr. Bryan Robinfon thinks this weight may be fettled by his obfervations in his Treatife on Food and Difcharges of Human Bodies.

A quick increafe of weight in human bodies often produces diftempers; the beft way to prevent this increafe is either by fafting or exercife. But amidft a variety of difturbing caufes, nothing fo effectually prevents fuch an increafe of weight as a very exact and regular diet, which may prevent the difcharges from running into irregularities and difproportions to one another. See Dr. Bryan Robinfon of the Food and Difcharges of Human Bodies, p. 82. feq.

Men, and other animals of extraordinary weight, are often recorded in the writings of the learned. See Phil. Tranf. N° 479, p. 102.

Weight, *Athletic*, in the *Animal Economy*, that weight of the body under which an animal has the greateft ftrength and activity. Dr. Robinfon thinks this happens when the weight of the heart, and the proportion of the weight of the heart to the weight of the body, are greateft. For the ftrength of an animal is meafured by the ftrength of its mufcles, and the ftrength of the mufcles is meafured by the ftrength of the heart. Alfo the activity of an animal is meafured by the weight of the heart, in proportion to the weight of the body.

If the weight of the body of an animal be greater than its athletic weight, it may be reduced to that weight by evacuations, dry food, and exercife. Thefe leffen the weight of the body by wafting its fat, and leffening its liver, and they increafe the weight of the heart, by increafing the quantity and motion of the blood; fo that by leffening the weight of the body, and by increafing that of the heart, they will foon reduce the animal to its athletic weight. Thus a game cock, in ten days, is reduced to its athletic weight, and prepared for fighting. If the food which, with the evacuations and exercife, reduced the cock to its athletic weight in ten days, be continued any longer, the cock will lofe his ftrength and activity.

It is known by experience, that a cock cannot ftand above twenty-four hours at his athletic weight, and that he has even changed for the worfe in twelve hours. When he is in the beft condition, his head is of a glowing red colour, his neck thick, and his thigh thick and firm; the day after, his complexion is lefs glowing, his neck thinner, and his thigh fofter; and the third day his thigh will be very foft and flaccid. Four game cocks, reduced to their athletic weight, were killed, and found to be very full of blood, with large hearts, large mufcles, and no fat.

It is to be obferved, that the athletic weight of an animal is a very dangerous weight. Fevers and apoplexies are the diforders which commonly happen to animals under or near the athletic weights. Hence, horfes fed upon dry food are much more fubject to fevers and apoplexies than horfes fed upon grafs. Robinfon's Differtation, p. 117, &c.

Weights, *Seffions for*. See Sessions.

Weight, *Live and Dead, of Animals*, in *Agriculture* and *Rural Economy*, the differences between their living and dead weights as affecting their goodnefs and value for the purpofe of the breeder and feeder or fattener. But few correct trials have yet been made in the view of determining this very important point or particular. It would feem, however, from the little that has been done on the fubject, that thofe forts of live-ftock that have the beft forms, and the leaft weight in the different offal parts, are the moft valuable and beneficial to the ftock mafter and farmer.

In neat cattle ftock the difference or lofs in this way is fomewhere about a fourth, but the moft in thofe breeds which are the leaft correct in their forms or fhapes. In fome unimproved breeds it has been found a good deal more, while in thofe which have been greatly improved rather lefs. In calves it will moftly be from a third to a fourth.

In the good Herefords, and fome of the beft long horn or Lancafhire forts, thefe proportions have been found on trial to be very nearly correct, both in the grown beafts and the calves.

In fheep ftock, too, the fame principle, for the moft part, holds good, thofe having the leaft difference or lofs in this way that are the beft in their forms.

In trials with the South Down breed of fheep, as ftated in the Corrected Report on the Agriculture of the County of Suffex, the proportions of the live and dead weight are thefe:

	lbs.
Live weight of the fheep - -	192
Dead weight next day of carcafe -	125

Weight of Offal.

	lbs.	oz.
Blood - - - - - -	6	0
Entrails - - - - - -	11	0
Caul - - - - - -	16	4
Gut fat - - - - - -	5	0
Head and pluck - - -	8	12
Pelt - - - - - -	15	12

In an average fpecimen of a wether of the fame breed:

	lbs.
Live weight of the fheep - -	133
Dead weight the day after - -	73

Weight of Offal.

	lbs.
Blood - - - - - -	4
Tallow - - - - - -	10
Entrails - - - - - -	14
Skin and feet - - - -	16
Head and pluck - - - -	9

In one of general Murray's breed of the fame kind:

	lbs.
Live weight - - - - -	129
Dead weight - - - - -	62

Weight of Offal.

	lbs.
Tallow - - - - - -	6

It is remarked that the lightnefs of the offal, fuch as the head, horns, feet, entrails, pluck, blood, pelt, &c. is the circumftance which characterizes a good fheep; and it is faid, ſaid, that Diſhley wethers well fattened are in the proportion of one ounce of bone to a pound of fleſh.

That the offal, in the fat wether of the South Down breed firſt ſtated, was but a fifth part and a fraction of the live weight, as below:

	lbs.	oz.
Live weight - - - - -	192	0
Offal - - - - - -	42	0
Carcaſe - - - - -	125	0
Fat - - - - - -	21	4
Loſt by killing - - - -	3	12
	192	0

Some uſeful information, which has a tendency to elucidate the point concerning the proportion between the live and dead weight of ſome different breeds of ſheep, has been given under the head ſheep. See Sheep, Pelt, and Tallow.

In good pig ſtock the difference in the proportion between the live and dead weight of the animals, or the loſs of weight that is ſuſtained by the farmer, will be found probably to be rather leſs than a fourth in the better breeds, and rather more than that in thoſe which are inferior in their qualities. The beſt breeds of pigs have by much the leaſt loſs in this way, and they have advantages in other reſpects. See Swine.

Theſe facts and ſtatements tend to ſhew the advantages which the farmer has in keeping good live-ſtock of all kinds.

WEIGHTON, Market, in *Geography*, a ſmall market-town in the Holme-beacon diviſion of Harthill wapentake, Eaſt Riding of the county of York, England, is ſituated on a little river called Foulneſs, in the high road between York and Hull, at the diſtance of 19 miles E.S.E. from York, and 192 miles N. by W. from London. Some antiquaries conſidered this place the Roman ſtation, Dolgovitia, till Drake, with great appearance of probability, aſſigned that ſtation to the village of Londeſburgh, nearly three miles north of Weighton. This town conſiſts of one long ſtreet, interſected by a few ſmaller: till within the laſt thirty years, the houſes were in general low and mean, and covered with thatch; but ſince that period, a number of reſpectable buildings have been erected, and conſiderable improvements have been made. A weekly market is held on Wedneſdays, when a great quantity of corn is often ſold, though but little is expoſed, being chiefly diſpoſed of by ſample. Two fairs are held annually for horſes, cattle, and particularly for ſheep, and cheeſe. The trade of the town has been conſiderably increaſed by means of a canal from the Humber; whereby coals and other articles are brought hither, and the barges return laden with grain. By the population return of the year 1811, the inhabitants of this town are enumerated at 1508; the number of houſes as 239. The church is an ancient maſſive edifice; it formerly had a wooden ſpire, which has been recently taken down, and a conſiderable addition made to the height of the tower; the interior of the church has alſo been greatly improved, and furniſhed with an additional gallery. A meeting-houſe for Methodiſts has lately been erected. There is no endowed ſchool in the pariſh. About two miles eaſt of Weighton is the brow of the Yorkſhire wolds, whence very extenſive views are obtained.—Beauties of England and Wales, vol. xvi. Yorkſhire, by J. Bigland, 1812. Drake's Eboracum, or the Hiſtory and Antiquities of York, fol. 1736.

WEIGSDORF, a town of Bohemia, in the circle of Boleſlaw; 8 miles N.N.E. of Krottau.

WEIGSTOTTEN, a town of Auſtria; 6 miles N.W. of Steyr.

WEIKENDORFF, a town of Auſtria; 8 miles S. of Ziſterſdorf.

WEIKERSTORF, a town of Auſtria; 4 miles S.W. of Sonneberg.

WEIKERTSCHLAG, a town of Auſtria; 8 miles W. of Droſendorf.

WEIL, a town of Wurtemberg, on the Wirm. This was an imperial town, till in 1802 it was given to the duke of Wurtemberg, by whoſe dominions it was ſurrounded; 10 miles W.S.W. of Stuttgart. N. lat. 48° 48′. E. long. 8° 50′.

WEILACH, a river of Bavaria, which runs into the Par, near Schrobenhauſen.

WEILBACH, a river of Germany, which runs into the Lahn, 2 miles S. of Weilburg.

WEILBURG, a town of Germany, which gives name to a county belonging to the houſe of Naſſau, hence called Naſſau Weilburg, ſituated on an eminence on the Lahn, over which it has a bridge of ſtone. The prince's palace here contains ſome very elegant apartments; with a fine garden belonging to it, and a chapel anſwerable to the whole. All the roads near the town lie in a direct line, and are planted on each ſide with a row of trees. In the neighbourhood is a large menagerie; 9 miles W. of Wetzlar. N. lat. 50° 26′. E. long. 8° 18′.

WEILE, or Wedel, a ſea-port town of Denmark, in North Jutland, ſituated on a bay in the Little Belt; 38 miles N.E. of Ripen. N. lat. 55° 45′. E. long. 9° 30′.

WEILHAIM, or Weilheim, a town of Bavaria; 26 miles S.W. of Munich. N. lat. 47° 44′. E. long. 11° 4′.

WEILHEIM, a town of Wurtemberg, on the Lauter; 20 miles N.E. of Ulm. N. lat. 48° 33′. E. long. 9° 35′.

WEILKO Strzlcze. See Strelitz.

WEILMUNSTER, a town of the principality of Naſſau Weilburg; 5 miles S. of Weilburg.

WEILNAU, a town of Germany, in the principality of Naſſau Weilburg; 13 miles S. of Weilburg.

WEILTINGEN, a town of Wurtemberg, on the Warnitz; 40 miles S.W. of Nuremberg. N. lat. 49° 3′. E. long. 10° 30′.

WEIMAR, a principality and duchy of Saxony, ſituated in Thuringia, on the ſides of the Ilm; about 24 miles in length, and 20 in breadth, but conſiderable tracts are detached from the main body.—Alſo, a town of Saxony, and capital of a duchy of the ſame name, with a palace of the prince, in which the duke has a valuable library, a cabinet of medals, a muſeum, and a gallery of paintings; and where are kept the archives of the Erneſtine line of the dukes of Saxony; 94 miles W. of Dreſden. N. lat. 51° 2′. E. long. 11° 22′.

WEINBERG, a town of Auſtria; 4 miles S.E. of Freyſtadt.—Alſo, a town of the principality of Anſpach; 3 miles N.N.E. of Feuchtwang.

WEINFELDEN, a town of Switzerland, in the canton of Zurich, and principal place of a bailiwick, in the Thurgau; 4 miles S.W. of Conſtance.

WEINGARTEN, a town of the duchy of Baden; 13 miles S.S.E. of Spire. N. lat. 49° 3′. E. long. 8° 30′.

WEINGE, a town of Sweden, in the province of Halland; 12 miles S.E. of Halmſtadt.

WEINHAUSEN, a town of Weſtphalia, in the principality of Luneburg Zell; 6 miles from Zell.

WEINHEIM, a town of the duchy of Baden, fituated in the Bergftraffe, and famous for its wine. The Roman Catholics, the Lutherans, and the Calvinifts, have each a church; 9 miles N. of Heidelberg.

WEINITZ, or VINIZA, a town of the duchy of Carniola, on the Kulp; 10 miles E.N.E. of Gotfchee.

WEINMANNIA, in *Botany*, a name which feems to have originated with Dr. Patrick Browne, who, without due attention, called it *Windmannia.* The perfon whom he defigned to commemorate was John William Weinmann, an apothecary of Ratifbon, author of a huge botanical German work, entitled *Phytanthozaiconographia*, confifting of four thick folios, with 1025 large coloured engravings of plants. The firft volume appeared in 1737, the laft in 1745, after the author's deceafe. There is a preface to the latter by Haller. Dieterich and Bieler contributed part of the text, and there are ample indexes, in various languages. The plates are rude, and gloomily coloured. Trew, whofe candour neverthelefs is allowed by Haller, fays, "varieties are not diftinguifhed," in this work, "from fpecies, the ftructure of the flowers is fcarcely expreffed, nor was the author competent to refer his plants to their true genera." Burmann began a Dutch edition, with fome additions, in 1736. The book is neceffarily expenfive, on account of its bulk, and is rare in England. We have feldom had occafion to confult it, nor have we ever done fo without difappointment.—Linn. Gen. 195. Schreb. 263. Willd. Sp. Pl. v. 2. 436. Mart. Mill. Dict. v. 4. Juff. 309. Poiret in Lamarck Dict. v. 7. 578. Lamarck Illuftr. t. 313. (Windmannia; Browne Jam. 212.) —Clafs and order, *Octandria Digynia.* Nat. Ord. akin to *Saxifragæ*, Juff.; or rather, we fhould think, as he himfelf hints, to his *Rhododendra.*

Gen. Ch. *Cal.* Perianth inferior, of four ovate, fpreading, permanent leaves. *Cor.* Petals four, equal, undivided, larger than the calyx. Nectary glandular, furrounding the bafe of the germen. *Stam.* Filaments eight, erect, thread-fhaped, longer than the petals; anthers roundifh, of two cells. *Pift.* Germen fuperior, ovate, acute; ftyles two, fomewhat fpreading, the length of the ftamens, permanent; ftigmas obtufe. *Peric.* Capfule elliptic-oblong, with two points, two cells, and two valves, whofe inflexed margins form the double partitions. *Seeds* about eight in each cell, roundifh.

Eff. Ch. Calyx of four leaves. Petals four. Capfule fuperior, with two beaks, two cells, and two valves with inflexed margins. Seeds feveral.

A very handfome genus of extra-European fhrubs, with oppofite, compound or fimple leaves, accompanied by interfoliaceous deciduous ftipulas. The flowers are fmall, copious, racemofe, rarely panicled. *Capfules* permanent long after the feeds are fhed. CUNONIA, (fee that article,) appears to differ from this genus, merely by adding one-fifth to the parts of fructification, which in this cafe is of no avail whatever.

Sect. 1. *Leaves compound.*

1. W. *glabra.* Smooth Pinnate Weinmannia. Linn. Suppl. 228. Willd. n. 1. Swartz Obf. 151. (W. pinnata; Linn. Sp. Pl. 515, excluding the reference to Browne.) —Leaves pinnate; leaflets obovate, crenate, fmooth on both fides. Capfule roundifh-elliptical, bluntifh.—Native of the Weft Indies. The *ftem*, ufually fhrubby, fometimes becomes a *tree*, forty feet high, with round, rugged *branches*; when young angular, and coarfely downy. *Leaves* of fix pair, more or lefs, with an odd one, of obovate, abrupt *leaflets*, half an inch at moft in length, all nearly equal, furnifhed with one rib and feveral tranfverfe veins; entire and wedge-fhaped towards the bafe. *Common footftalk* jointed, each articulation, between the leaflets, winged with a leafy rhomboid expanfion, tapering moft downward, and hairy at each end. *Clufters* oppofite, at the end of each branch, on hairy axillary ftalks, denfe, about an inch long when in flower; twice as long, and much more lax, when in fruit. *Flowers* very fmall, white, on fafciculated, fhort, thick, hairy partial ftalks. *Capfules* about half the fize of hempfeed, brown; their *ftalks* elongated; their valves obtufe, tipped with the *ftyles*, and, as they ripen, turning their pale narrow edges, which had formed the partitions, outwards. Permanent *ftyles* moftly recurved, rather fhorter than the valves. We have not feen the *feeds*.

2. W. *tinctoria.* Red-tan Weinmannia. (Weinmannia; Lamarck t. 313. f. 1. Tan-rouge; Commerfon MSS.)— Leaves pinnate; leaflets elliptical, crenate, fmooth on both fides. Capfule ovato-lanceolate, taper-pointed. Seeds hairy. —Gathered by Commerfon in the ifle of Bourbon, where it is known by the name of *Tan-rouge*, becaufe the bark ferves to dye leather of a red colour. The flowers are fuppofed to furnifh the bees with much of their honey. French botanifts appear to have confounded this plant with the preceding. It is certainly what Lamarck has figured, and what Poiret has quoted, for *W. glabra*, the latter having taken *Tan-rouge* from hence, for his French generic name of the whole genus, though without adverting to its ufe in the ifle of Bourbon, or its being a native of that country. The *leaves* are full twice the fize of *W. glabra*, with elliptical, not obovate, leaflets: wings of their *footftalks* fimilar to the laft. *Clufters* of *flowers* much more lax, and lefs hairy, three or four inches long; the *flowers* twice as large. *Capfules* of a very different fhape, and paler redder hue, tapering into the ftraight erect *ftyles*, which are not a quarter fo long as the *valves*, nor are the edges of the latter ever turned outward, or flattened. The *clufters* of ripe *capfules* are cylindrical, denfe, four or five inches in length. *Seeds* clothed with a few long prominent hairs.

3. W. *hirta.* Hairy-leaved Weinmannia, or Baftard Brafiletto. Swartz Ind. Occ. 691. Willd. n. 2. Poiret in Lam. n. 3.—Leaves pinnate; leaflets elliptic-ovate, crenate, hairy at the back. Capfules oblong.—Native of lofty mountains in the fouth part of Jamaica, in St. Andrew's parifh, near Coldfpring, the refidence of Matthew Wallen, efq. (See WALLENIA.) This, according to Dr. Swartz, from whom we have a fpecimen, is a very rare fpecies. It is either a *fhrub*, or a handfome *tree*, from forty to fifty feet high, crowned at the very top of its fmooth *trunk* with lax, hairy, or fomewhat downy, rufty-coloured *branches.* The *leaves* moft refemble the laft in fhape, but are clothed beneath, fometimes on both fides, with coarfe, fcattered, prominent hairs. The leafy borders of each joint of the common *footftalk* are narrower, and lefs angular, than thofe of our firft or fecond fpecies, and their midrib is very hairy beneath. *Clufters* alfo very hairy, an inch or two in length, in pairs at the fummits of the branches. *Flowers* the fize of the laft, white. *Capfule*, according to Swartz, fmall, oblong, rather pointed, with feveral fmall roundifh *feeds*. This tree flowers in September and October. Some fpecimens, in the herbarium of the younger Linnæus, excite a doubt whether the hairinefs of the foliage may invariably be relied on. Still we have no doubt of the diftinctnefs of thefe three fpecies. The third is perhaps moft allied to the fecond, which appears to be what Dr. Swartz faw marked *W. arborea*, and which Commerfon was faid to have gathered in the ifle of Mauritius. We do not at all comprehend how the joints of the common *footftalk* can be termed "fomewhat heart-fhaped," in *W. hirta*; they are rather more truly obovate

vate than in either of the foregoing, being lefs angular, or deltoid.

4. W. *trichofperma*. Hairy-feeded Weinmannia. Cavan. Ic. v. 6. 45. t. 567. Poiret n. 2.—Leaves pinnate; leaflets elliptic-oblong, ferrated, fmooth on both fides. Capfule roundifh-elliptical. Seeds denfely hairy.—Gathered by Louis Née, at San Carlos, in Chili, bearing ripe capfules in February. *Cavanilles*. By the plate above quoted, this bears moft refemblance to the firft fpecies, efpecially in the acute angles of the deltoid articulations of the *footftalks*, which in all the other fpecies are rounded. But the *leaflets* are longer and more elliptical, ferrated rather than crenate; the *capfules* broadly elliptical, not obtufe, their inflexed edges, if the figure be accurate, much broader, and continuing inflexed. The *feeds* are roundifh-kidneyfhaped, clothed with long, copious, projecting hairs, of which no mention is made by any botanift who has defcribed the *feeds* of *W. glabra* or *W. hirta*, and therefore we muft prefume they do not exift in thofe fpecies. We find fuch hairs, very fparingly, on the globular *feeds* of *W. tinctoria*, but the *capfules* of that fpecies are abundantly different from the prefent.

5. W. *tomentofa*. Woolly Weinmannia. Linn. Suppl. 227. Willd. n. 3. Poiret n. 4.—Leaves pinnate; leaflets elliptical, revolute, entire, woolly beneath.—Gathered in New Granada, by Mutis. A very diftinct and remarkable fpecies. The *branches* are woody, round, denfely leafy, rough, fomewhat warty, of a dark brown; hoary and downy when young. *Leaves* hardly an inch and a half long; leaflets about five pair, with an odd one, each one-third of an inch in length, convex, flightly hairy, fingle-ribbed; the under fide clothed with copious, loofe, hoary, woolly hairs. The joints of the common *footftalk* are rather fhorter than the leaflets, obovate, not angular; their edges revolute, and the under fide woolly. *Stipulas* large, ovate, reflexed, coloured, hairy externally, deciduous. *Flowers* in very denfe *clufters*, rather above an inch long, on thick, fhort, woolly, axillary ftalks. *Calyx* hairy. *Capfules* wanting in our fpecimens.

6. W. *trifoliata*. Three-leaved Weinmannia. Linn. Suppl. 227. Thunb. Prodr. 77. Willd. n. 4. Poiret n. 5. Lamarck f. 2.—Leaves ternate; leaflets obovate, crenate, fmooth.—Gathered by Thunberg, at the Cape of Good Hope. The whole *fhrub* is faid to be very fmooth. *Leaflets* equal, about an inch long, being about two-thirds the length of their common *footftalk*, which is fimple and naked. *Clufters* cylindrical, denfe, two or three inches long, on axillary ftalks about half their own length. The *germen* in Lamarck's figure is roundifh and hairy. We have feen no fpecimen, nor is there any account of the *capfule* or *feeds*.

Sect. 2. *Leaves fimple.*

7. W. *racemofa*. Smooth-clustered Simple-leaved Weinmannia. Linn. Suppl. 227. Willd. n. 5. Forft. Prodr. 27. Poiret n. 580.—Leaves fimple, ftalked, ovate, with toothlike ferratures. Clufters axillary, folitary, nearly fmooth.—Gathered by Forfter, as well as by Menzies, in New Zealand. The *branches* are ftout, woody, repeatedly branched in an oppofite manner, round and rough. *Footftalks* ftout, fmooth, half an inch long, articulated at the fummit with the leaf, which is two, or two and a half, inches long, and one broad, pointed, coriaceous, quite fmooth, ftrongly veined, befet with blunt, inflexed, wavy teeth, or ferratures; paler beneath. *Clufters* about the tops of the branches, though axillary, ftalked, longer than the leaves, cylindrical, continuous; their general and partial *ftalks* either flightly downy, or quite fmooth. *Capfules* obovate, pointed, fomewhat downy; the inflexed edges of their valves finally expanded. We cannot find a *feed* in any of our fpecimens.

8. W. *parviflora*. Small-flowered Weinmannia. Forft. Prodr. 29. Willd. n. 6. Poiret n. 7.—"Leaves fimple, nearly feffile, ovate, pointed, with tooth-like ferratures. Clufters terminal, aggregate, hairy."—Native of Otaheite. *Forfter*. Willdenow, who had feen a dried fpecimen, defcribes the *branches* as hairy when young. *Leaves* on fhort ftalks, oblong, fmooth on both fides. *Clufters* downy, from three to fix at the top of each branch, forming a fort of panicle. *Flowers* but a quarter the fize of the preceding.

9. W. *ovata*. Ovate-Crenate Weinmannia. Cavan. Ic. v. 6. 45. t. 566. Poiret n. 9.—Leaves fimple, elliptical, crenate, acute at each end, on fhort ftalks. Clufters axillary, folitary, oppofite, fomewhat downy.—Native of Peru, in a large alluvial excavation, near the town of St. Buenaventura, flowering in June and July. This is a *tree* eighteen feet high, with furrowed, rather knotty *branches*, thickened at the infertion of the *leaves*, which feem very like thofe of *W. racemofa* in fhape, fize, veins, and fmoothnefs, but are more truly crenate, and ftand on fhorter *footftalks*. *Clufters* oppofite, at the tops of the branches, though axillary and folitary, each two or three inches long; their partial ftalks aggregate, and fomewhat villous. Nothing is known of the *capfule* or *feeds*. We could wifh for better materials than Cavanilles affords us, for diftinguifhing this fpecies from the *racemofa*, n. 7.

10. W. *paniculata*. Panicled Weinmannia. Cavan. Ic. v. 6. 44. t. 565. Poiret n. 8.—Leaves fimple, elliptic-lanceolate, fharply ferrated. Panicles axillary, compound.—Gathered by Louis Née, at the fea-fhore near Talcahuano, in Chili, flowering in February. A *tree* about the ftature of the laft, but the *leaves* are longer, more lanceolate, with parallel veins, and copious fharp ferratures, which give them fome refemblance to the fweet-chefnut leaf. They are fmooth, and ftand on ftout downy *footftalks*. The panicled *inflorefcence* is fingular among all the known fpecies. *Flowers* yellowifh-red. *Capfules* elliptical, acute, downy, beaked with the ftraight *ftyles*, which are as long as the valves. *Seeds* obovate, fmooth, on flender ftalks, pendulous. We have a fpecimen from the late abbé Cavanilles.

WEINSBERG, in *Geography*, a town of Wurtemburg; a part of which is built on a round hill, on which alfo ftands a ruined caftle: the other part lies in a valley. In it is a fpecial fuperintendency. The valley in which it lies is famous for wine; 5 miles N.E. of Heilbronn.

WEINSTEIG, a town of Auftria; 8 miles N. of Korn Neuburg.

WEINZIERL, a town of Auftria; 8 miles S.E. of Ips.

WEIPERSHOFEN, a town of the principality of Anfpach; 5 miles S.E. of Creilfheim.

WEIPERT, a town of Bohemia, in the circle of Saatz; 14 miles W. of Commotau.

WEIR, one of the fmaller Orkney iflands, containing about 65 inhabitants. It had formerly a church, which is now in ruins; 2 miles S. of Roufa.

WEIR, or WEAR, in *Rural Economy*, a fort of dam, bulwark, or ftrong erection, formed acrofs a brook, rivulet, ftream, river, main, or other fuch water-courfe, for the purpofe of diverting or turning the water, in watering land. It is occafionally made in different ways, as of timber alone, fometimes of bricks, or ftones, and timber, and of different other materials, as will be feen below, having from two to eight or ten thoroughs or openings for letting the water pafs through, according as the breadth of the

ftream

ſtream and other circumſtances may be. The height of it is always equal to the depth of the ſtream compared with the adjacent land.

The water of a very ſmall and gentle ſtream may often be diverted for this uſe, by means of a few ſods firmly put down, with ſome ſtones above them : but for lands of any conſiderable extent, the kinds directed below are neceſſary, according as the ſtrength of the reſpective ſtreams may happen to be.

Strong wooden beams or balks thrown acroſs the ſtream, and made cloſe by means of boards well ſecured, are, in many caſes, ſufficiently ſtrong, commodious, and convenient, in ſlow moving waters, of no great power or force.

A few cart-loads of ſtones thrown properly in acroſs the ſtream, forms alſo a bulwark, wide at the baſe, and narrowing towards the top, the whole being puddled with clay or gravelly earth, which ſometimes anſwers well. Over the top of this bulwark, the ſuperfluous waters paſs in a free manner, falling down the gentle ſlope, to which, if well conſtructed, they do no ſort of injury.

A weir ſuitable for a ſmall river may conſiſt too of ſeveral rows of ſtakes, firmly driven down and interlaced with the branches of fir-trees, the intervals of the rows being filled with ſtones. The ſand and mud that come down with the floods fill up this ſort of weir, and render it fit for effecting its purpoſe. In heavy rains the ſuperfluous water paſſes entirely over.

But for more powerful rivers, the weirs may be conſtructed of ſtrong frame-works of wood, firmly and ſtrongly joined together, and the different compartments all paved with large ſtones : the weir riſing very gradually againſt the ſtream, and being made to ſlope gradually away before it, as it flows over it. In this way the largeſt and moſt powerful rivers may moſtly be managed, if the weirs be well ſuited to them ; ſo that it is but in few caſes adviſeable to attempt the watering lands from rivers that cannot be diverted by one or other of theſe ſorts of weirs, as the expence and hazard taken together may greatly exceed the advantage to be derived. It may, however, in ſome caſes of large rivers, be neceſſary and proper to have recourſe to more expenſive weirs, ſuch as that deſcribed below.

In this weir, which was formed on a large, rapid, and ſtrong river, under the direction of the Rev. W. H. Coham, in Devonſhire, after the ſtream had been temporarily diverted, and every thing removed for a proper foundation, a double row of pits was dug into a rocky ſubſtratum, directly acroſs the bottom, or bed of the river, at about five feet aſunder lengthways, by four feet in breadth, and about two feet in depth ; and into theſe pits oak poſts of about ſix or ſeven inches ſquare were fixed. The maſon then raiſed a perpendicular wall, without any cement, about five feet and a half thick, entirely encloſing the poſts, the labourers being employed in the mean time in *backing up* the wall on the higher ſide with ſome of the *ſtiffeſt* clay to be had. This was, however, afterwards found to be wrong ; it ſhould have been done in the *puddle* manner, by means of mould and gravelly earth.

When the wall was raiſed to ſuch a height as was deemed neceſſary, in relation to the level required, and the preſervation of the lands adjacent, the upper parts of the oak poſts were ſawn off, in order to receive croſs-pieces and joiſts, the front poſts being then left to ſtand about ſix inches higher than the hinder ones ; and on theſe joiſts oak planks were pinned, about ſix feet and a half long by three inches thick. Theſe planks were brought forward to project about one foot and a half over the perpendicular of the wall, on the lower ſide, forming a ſort of lip, as it has been termed ; the clay, together with theſe planks, conſtituting an inclined plane, and terminating at the diſtance of about fifteen feet up the ſtream, on the common bed of the river.

The entrance for the *leat* was cut at about thirty feet above the *lip* of the weir, where, to regulate the quantity of water to be admitted, three ſtrong flood-hatches, to be lifted or let down by a lever and windlaſs, were placed ; and through which a column of water, of about eight feet in width by four feet in depth, may be introduced at any time. Between the leat and the river a ſtone wall, ſtrongly cemented, is erected, which is about eight feet in height, and carried from the head of the leat to about thirty feet below the weir, in a parallel line with the river, and at the end of which wall another flood-hatch is fixed on a level with the bed of the river. This latter hatch will always be of great advantage when any reparations may be wanting on the weir ; as on drawing it up when the water is low, the weir in a few hours will be left perfectly dry, and the workmen, with the greateſt convenience, may proceed in their operations. From the top of the ſide wall, above the weir, the ground is made ſloping to the river, and below it is covered with turf, and levelled as a foot-path.

Immediately below the weir, in this caſe, there is an outlet regulated by another flood-hatch, and conducted through a *ſhoot* formed of oak plank, from the leat, and contrived for the admiſſion of ſalmon, which are there ſometimes taken ; and below the lower flood-hatch, a trap, or *willey*, as it is there termed, is made for the catching of ſmaller fiſh : this part of the work does not, however, properly belong to this kind of weir, therefore it need not be more noticed.

The height of the weir is about four feet above the level of the river where it is fixed ; and its length, from bank to bank, directly acroſs, or at right angles with the ſtream, is about forty-eight feet ; forty feet of which is carried at a perfect level, and over which the water falls preciſely at the ſame depth, forming a beautiful caſcade. The remaining portions of the length of the weir, namely, four feet on each ſide, are raiſed, gradually aſcending to the banks for the purpoſe of warding off the torrent from them in time of floods, when the river, in this caſe, is very tumultuous.

The lip part of the weir is found to anſwer perfectly ; as in proportion to the force of the water behind, ſo is the diſtance which it is thrown over the weir from the foundation of the perpendicular wall.

If the writer had not been foiled, and had part of the work to perform over again, in conſequence of the uſe of clay, as already noticed, being under the neceſſity of driving on the weir in a direct line with the former work, into the ſide of the oppoſite bank, as before ; and after removing as much of the clay as could be got at, which will not unite completely with the ſoil, but become liable to be undermined by the water, by making a *puddle*, as uſed in canals of mould and gravel, in its ſtead, which ſucceeded in a complete manner ; the whole coſt of the weir would not have exceeded 75*l*.

This weir or wear, from its preſent appearances, may now, it is ſaid, ſeem to bid defiance to time ; and be ſafely recommended as a pattern to thoſe who may have occaſion to conſtruct any thing of a ſimilar kind, either for watering land, for machinery, or other uſes. See Watering *Land*.

In the weirs or wears which are thrown over large rivers for the purpoſe of raiſing the water for the uſe of mills, and in many other intentions, and which are moſtly conſtructed of of ftone, with ftrong framed wood-work, in fomewhat the above manner, there are many different contrivances calculated for different ufes, fuch as locks for fecuring large fifh, places for taking and preferving thofe of the fmaller forts, and different others. See Dr. Anderfon's Treatife on the Erection of Weirs, &c. where a full explanation of the principles and manner of conftructing them will be found.

WEIS SEE, in *Geography*, a lake of the duchy of Carinthia; 10 miles N.W. of Velach.

WEISA, a town of Saxony, in the circle of Erzgebirg; 3 miles S.S.W. of Wolkenftein.

WEISBRON. See VESPRIN.

WEISCHE OPPA, a river of Silefia, which runs N.E. into the Schwartze Oppa.

WEISCHENFELD, a town of Bavaria, in the bifhopric of Bamberg; 18 miles E.S.E. of Bamberg. N. lat. 49° 49′. E. long. 11° 19′.

WEISDORF, a town of Germany, in the principality of Culmbach; 3 miles E. of Munchberg.

WEISEN, a town of Pruffia, in the province of Oberland; 10 miles W.S.W. of Leibftadt.

WEISENBAD, a town of Saxony, in the circle of Erzgebirg; 3 miles S.S.E. of Wolkenftein.

WEISENBERG, a townfhip of Pennfylvania; 60 miles N. of Philadelphia.

WEISENBERG, or WOSSBERK, a town of Lufatia; 8 miles E. of Budiffen. N. lat. 51° 12′. E. long. 14° 40′.

WEISENBRUN, a town of Bavaria, in the bifhopric of Bamberg; 24 miles S. of Cronach.

WEISENBURG, a town of Auftria; 12 miles S.S.W. of St. Polten.

WEISENBURG. See WEISSEMBURG.

WEISENHORN, a town of the duchy of Baden, fituated in a county to which it gives name, on the Roth; 11 miles S.E. of Ulm. N. lat. 48° 17′. E. long. 10° 8′.

WEISENKIRCHEN, a town of Auftria; 11 miles S.W. of Tulln.

WEISFURT, a river of Silefia, which runs into the Oder, 3 miles below Beuthen.

WEISKIRCH, a town of Bohemia, in the circle of Boleflaw; 3 miles S.S.E. of Krottau.

WEISKIRCHEN, or HRANITZE, a town of Moravia, in the circle of Prerau; 15 miles E.N.E. of Prerau. N. lat. 49° 30′. E. long. 17° 43′.

WEISMAYN, a town of Bavaria, in the bifhopric of Bamberg; 20 miles N.E. of Bamberg. N. lat. 50° 6′. E. long. 11° 18′.

WEISSE, CHRISTIAN-FELIX, in *Biography*, a German poet, was born in 1726, at Annaberg, in Saxony, and educated, firft at the Gymnafium of Altenburg, and afterwards at Leipfic. The objects to which his tafte moft powerfully inclined him were poetry and the drama; and he and his friend Leffing concurred in tranflating for the ftage from French and Englifh works, and afterwards in furnifhing original compofitions. He alfo contended with his friend in lyric poetry. After completing his courfe of education, he became private tutor in a family of diftinction at Leipfic, purfuing his dramatic and poetical career, and gaining a great degree of popularity. He alfo edited the Bibliotheque of Belles Lettres, when Nicholai furrendered it. Although, in 1761, he obtained a place in the revenue at Leipfic, he profecuted his employment as a writer for the ftage; and when he became the father of a family, he directed his attention to education, and publifhed feveral pieces in this department: particularly, in 1772, a collection of fhort tales and moral maxims, which had a confiderable circulation; and in 1775 he revived a weekly publication, which Adelung had difcontinued, under the title of the "Children's Friend." This work became afterwards a quarterly publication, and between the years 1775 and 1782, paffed through five editions. From this popular work Berquin derived the idea of his "Ami des Enfans," and he was indebted to it for many of his materials. As Weiffe's children grew to maturity and fettled in the world, he altered the plan of his work, and continued it under the form of Letters; and Berquin alfo followed him in his "Ami des Adolefcentes." In 1790 the beautiful eftate of Stotteritz near Leipfic, which Weiffe inherited, placed his family in affluent circumftances, and furnifhed him with a pleafant refidence. Towards the latter part of his life he contributed fhort fables and poetical tales to journals and periodical publications, which were well received, and at length clofed his life with reputation, in December 1804. His dramatic works, which were continued to five volumes, are faid to have formed an epoch in the hiftory of the German ftage, and both his tranflations and original compofitions were well received. Gen. Biog.

WEISSE, in *Geography*, a river of Pruffia, which runs into the Rufs, 20 miles N.W. of Tilfit.

WEISSEBERG, a mountain of Bohemia, celebrated for the defeat of the elector-palatine, about 3 miles from Prague.

WEISSELBURG, a town of Pruffia, in the province of Oberland; 5 miles S. of Marienwerder.

WEISSELMUNDA. See WEICHSELMUNDE.

WEISSEMBURG, or KORN WEISSEMBURG, or *Wiffemburg*, a town of France, and principal place of a diftrict in the department of the Lower Rhine, fituated on the Lauter, at the foot of the Vofges. This town was formerly imperial, and was ceded to France by the peace of Ryfwick. The fortifications were deftroyed by Louis XIV.; but ftrong lines of defence are fixed from this town to the Rhine, a little to the eaft of Lauterburg, on the S. fide of the Lauter; 27 miles N. of Strafburg. N. lat. 49° 3′. E. long. 8°.

WEISSEMBURG, a town of Bavaria, called *Weiffemburg near the Nordgau*. It contains two churches and a medicinal fpring. Weiffemburg was an imperial town, till in 1802 it was given to the elector of Bavaria; 28 miles S.S.W. of Nuremberg. N. lat. 48° 58′. E. long. 10° 55′.

WEISSEMBURG, or *Alba Julia*, or *Carlfburg*, or *Fejervar*, a town of Tranfylvania, capital of a county, and fee of the bifhop of Tranfylvania, beautifully fituated on the Maros. It was a long time the metropolis of Dacia, and the feat of its monarchs, who had a palace here. It was likewife the feat of a Roman legion. The name Alba Julia it owes to Julia Augufta, mother of Marcus Aurelius. Charles VI. named it Carlfburg; 90 miles N.E. of Temefvar. N. lat. 46° 16′. E. long. 24° 10′.

WEISSEN SEE, a lake of Pruffia; 12 miles W. of Lick.—Alfo, a lake of Bavaria, in the territory of Augfburg; 2 miles S.W. of Fueffen.—Alfo, a lake of Carinthia; 6 miles S. of Saxenburg.

WEISSENAU, a princely abbey of Germany, in the circle of Swabia. In 1802 it was given to the elector of Bavaria; 2 miles S. of Ravenfburg.

WEISSENBACH, a town of the principality of Culmbach; 5 miles E. of Kirch Lamitz.—Alfo, a town of Auftria; 12 miles N. of Grein.—Alfo, a town of Auftria; 9 miles W. of Freyftatt.

WEISSENBERG, a townfhip of Pennfylvania, in the county of Northampton, containing 1046 inhabitants.

WEISSENBORN, a town of Saxony, in the circle of Erzgebirg; 3 miles S.S.E. of Freyberg.

WEISSENBURG, a town of Saxony, in the circle of Erzgebirg; 5 miles S.S.W. of Zwickau.—Alſo, a village of Switzerland, in the canton of Berne, celebrated for its medicinal baths; 18 miles S. of Berne.

WEISSENDORF, a town of Bavaria, in the biſhopric of Bamberg; 9 miles S.W. of Forcheim.

WEISSENFELS, a town of the duchy of Carniola; 28 miles W.N.W. of Crainburg.—Alſo, a town of Thuringia, on the Saal. It gives title to a branch of the houſe of Saxony, called Saxe Weiſſenfels, who ordinarily reſide in a citadel above the town, called Auguſtuſberg; 18 miles W.S.W. of Leipſic. N. lat. 51° 14′. E. long. 11° 59′.

WEISSENHORN, a town and citadel of Bavaria, which gives name to a county belonging to the lords of Fugger; 8 miles S.E. of Ulm.

WEISSENKIRCH, a town of Bavaria, in the principality of Aichſtatt; 3 miles S.S.E. of Aichſtatt.

WEISSENPACH, a town of Auſtria; 4 miles N.W. of Bohmiſch Waidhoven.

WEISSENSEE, a town of Thuringia, near what formerly conſtituted an inland lake, which was divided into the Great and Leſs, or into the Upper and Lower, between both which it lay; but the former being drained in the year 1705, and converted into arable and meadow grounds, a ſmall part of it only being then left; and this alſo has been ſince dried up; 14 miles N. of Erfurt. N. lat. 51° 10′. E. long. 11° 6′.

WEISSENSTADT, a town of Germany, in the principality of Bayreuth, on the Egra, where it forms a large pond or lake, abounding in fiſh; 6 miles N.N.W. of Wonſiedel.

WEISSENTHURN, a town of Sclavonia; 18 miles N.N.W. of Verovitza.—Alſo, a town of the duchy of Stiria; 3 miles E.S.E. of Judenburg.

WEISSESTEIN, a town and caſtle of Bavaria; 10 miles N.N.E. of Deckendorf.

WEISSIA, in *Botany*, an Hedwigian genus of Moſſes, is now, by nearly univerſal conſent, united to GRIMMIA, for reaſons given under that article. There is indeed no difference of habit, nor any certain character, however minute and obſcure, between them. This is the more to be regretted, as we have few more meritorious claimants for diſtinction in cryptogamic botany than Mr. Frederic William Weis, author of the *Plantæ Cryptogamicæ Floræ Gottingenſis*, an octavo volume, printed at Gottingen, in 1770. No ſtudent in that department of the ſcience can diſpenſe with this little book, in which the ſynonyms of the deſcriptions are treated with equal practical ſkill. *Fungi*, and neceſſarily Sea-weeds, are excluded from this *Flora*. We truſt ſome reſponſible author will reſtore a *Weiſia*, worthy of bearing the name. The double *ſs* is a blunder which requires correction.

WEISSLAREUT, in *Geography*, a town of Germany, in the principality of Culmbach; 4 miles S. of Hof.

WEISSNITZ, or WEISSERITZ, a river of Saxony, which riſes in two branches, the Wilde and Rothe, which unite two miles E. of Tharand, and afterwards run into the Elbe, near Dreſden.

WEISTHURN, a town of Bohemia, in the circle of Konigingratz; 6 miles W. of Schlan.

WEISTRA, a town of Auſtria; 5 miles E. of Steyr.

WEISTRITZ, a town of Sileſia, in the principality of Schweidnitz, on a river of the ſame name. Gold is found in the environs; 2 miles S. of Schweidnitz.

WEISTRITZ, a river of Sileſia, which runs into the Oder, near Schweidnitz.

WEISWASSER, a town of Bohemia, in the circle of Boleſlaw; 6 miles N.W. of Jung Buntzel.—Alſo, a town of Sileſia, in the principality of Neiſſe; 4 miles S.W. of Patſchkau.

WEISZBACH, a town of Saxony, in the circle of Erzgebirg; 5 miles N.N.W. of Wolkenſtein.

WEITENFELDS, a town of the duchy of Carinthia; 2 miles W.S.W. of Gurck.

WEITENHAGEN, a town of Anterior Pomerania; 2 miles S.S.W. of Griefswalde.

WEITENSTEIN, a town of the duchy of Stiria; 8 miles S.E. of Windiſch Gratz.

WEITRA, or WEITRACH, a town of Auſtria; 36 miles N.W. of Crems. N. lat. 48° 41′. E. long. 14° 59′.

WEITRASILD, a town of Auſtria; 2 miles S. of Hardegg.

WEITTENEG, a town of Auſtria, on the Danube; 18 miles above Crems.

WEITZ, a town of the duchy of Stiria; 11 miles N.E. of Gratz.

WEITZSBERG, a mountain of Stiria; 10 miles N.E. of Gratz.

WEIXEN, a river of Auſtria, which runs into the Danube, 3 miles below Grein.

WEIZLPACH, a town of Auſtria; 12 miles W.S.W. of St. Polten.

WEKLSDORF, a town of Bohemia, in the circle of Konigingratz; 7 miles N.W. of Branau.

WELACH. See VELACH.

WELANG, a ſmall iſland in the Eaſt Indian ſea. S. lat. 1° 25′. E. long. 130° 30′.

WELAU, a town of Pruſſia, in the province of Samland; 28 miles E.S.E. of Königſberg. N. lat. 54° 36′. E. long. 21° 23′.

WELCH MOUNTAINS, mountains of Pennſylvania; 30 miles W. of Philadelphia.

WELCHEIM, a town of Bavaria; 7 miles N.W. of Neuburg.

WELCKERSHAUSEN, a town of Germany, in the county of Henneberg; 3 miles N. of Meinungen.

WELCOME BAY, a bay on the weſt end of the iſland of Java. S. lat. 6° 35′. E. long. 105° 30′.

WELD, or WOLD, *reſeda luteola* of Linnæus, a plant uſed by the dyers to give a yellow colour; and for this reaſon called, in Latin, *luteola*, of *luteus*, yellow. For the characters, ſee RESEDA.

When the plants are pulled, they may be ſet up in ſmall handfuls to dry in the field, and when dry enough, tied up in bundles and houſed dry; care being taken to houſe them looſely, that the air may paſs between them to prevent their fermenting. That which is left for ſeeds ſhould be pulled as ſoon as the ſeeds are ripe, and ſet up to dry, and then beat out for uſe; for if the plants are left too long, the ſeeds will ſcatter. Mortimer and Miller.

Weld is much cultivated in Kent, for the uſe of the London dyers.

Mr. Hellot obſerves, in his Art de Teindre, that for dyeing with weld, the beſt proportions of alum and tartar for the preparatory liquor are four parts of alum, and one of tartar, to ſixteen of the wool; the quantity of the tartar being determined by the greater or leſs brightneſs of colour propoſed; and that the wool, thus prepared, is to be boiled again with three or four parts of weld to one of wool, but often much leſs: that for light ſhades, it is cuſtomary to diminiſh the alum, and omit the tartar; and that, in this caſe, cafe, the colour is more flowly imbibed, and proves lefs durable.

With a view to economy, the weaker fhades of colour are dyed in the fame bath, after the ftronger are finifhed. A golden yellow, more or lefs orange, is given by a weak madder bath, after the welding.

Silk is dyed of a golden-yellow, generally with weld alone, according to the following procefs: the ftuff is firft boiled in foap-water, alumed and wafhed, then paffed twice through a weld bath, in which, the fecond time, fome alkali is diffolved, which gives a rich golden hue to the natural yellow of the weld. The colour is further deepened by a little annotto. The folutions of lime with weld give to filk a bright clear yellow. In order to dye cotton yellow, Berthollet directs firft to cleanfe it with wood afhes and water, to rinfe, alum, and dry without further rinfing, and then to pafs it through a yellow bath, in which the weld is fomewhat more than the weight of the cotton. When the colour has fufficiently taken, the cotton is thrown into a bath of fulphate of copper and water, and kept there for an hour; after which it is boiled with white foap-water, and, laftly, wafhed and dried. In order to obtain a deeper jonquil-yellow, the aluming is omitted, and, inftead of this operation, a little verdigrife is added to the weld bath, and the cotton finifhed with foda.

Weld is particularly preferred to all other fubftances in giving the lively green lemon-yellow. It is, however, expenfive; and it is alfo found to degrade and interfere with madder colours more than other yellows. We may here add, that the fine delicate yellow, obtained from weld, is much ufed by the London paper-ftainers, and fold in the form of hard lumps, confifting chiefly of chalk faturated with the colouring matter. Meffrs. Collard and Frafer have given the following improved procefs:—Diffufe any quantity of fine whiting in boiling water; add to it one ounce of alum for every pound of whiting, which will occafion a brifk effervefcence, and ftir thefe materials well together till the gas is wholly difengaged. On the other hand, boil in a feparate veffel fome weld with water juft fufficient to cover it, for fifteen minutes, filter the yellow decoction, and then mix it with the whiting and alumine in fuch proportions, that the earths may appear to be faturated with the colouring matter. Then let the mixture remain a day at reft, and at the bottom will be the precipitated earth firmly united with the colour, and of a fine yellow tinge, which may be conveniently dried on chalk-ftones.

The weld yellow is a water colour, and is never mixed with oil.

Weld, in *Agriculture*, is a plant which is not unfrequently cultivated in the field by the farmer as a crop, for the purpofe of giving and affording a bright yellow and lemon colour to woollens, filks, cotton, and thread, as well as for its ufe in the manufacture of check and fuftian, and in fome other intentions. It is for the flower-ftems that it is principally grown, as being ufeful in the procefs of dyeing thefe feveral articles. It is often known by the names of *woold* and *dyer's weed.*

It may be noticed, that in the growth and culture of this plant, the foils moft fuitable are thofe of the fertile mellow kinds, whether of the loamy, fandy, or gravelly forts; but it may be grown with fuccefs on fuch as are of a poorer quality; but in the former, the plants will rife to a much greater height, and produce much larger leaves and ftems, than in the latter defcription of lands.

It has, however, been ftated, that the foil moft fuitable to it, in Effex, is the ftrong ftiff loam moderately moift, but not wet. A foil rather moift, but mellow, feems the moft fuitable and proper for it.

It is neceffary, in the preparation of the ground, that there fhould be a tolerable degree of finenefs produced in the mould of the foil, which may be effected by repeated ploughings given in the more early fpring months, and fuitable harrowings. The furface of the land in the feed furrow fhould be left as level as poffible, that the feed may be difperfed more evenly over it, and with greater regularity and exactnefs.

In this, as in many or indeed moft other cafes, the feed fhould be collected from the beft plants, and thofe which have remained upon the ftems till rendered perfectly ripe; as fuch only vegetates perfectly, and the plants in fuch cafes fhould not be left ftand too long, as the feed is liable to fhed. It fhould be perfectly frefh when ufed, as old feed never comes up well, or in fo regular a manner.

In regard to the proportion of feed which is neceffary, it is commonly from about two quarts to a gallon the acre, according to circumftances, when fown alone: but when mixed with other crops, a little more may be required, which fhould be blended with a little fand, or fome other fuch material, at the time of fowing it on the land, as rendering it capable of being fown more evenly.

It may be obferved in refpect to the time of fowing, that this fort of crop may be put into the ground either in the fpring, as about the latter end of April or beginning of May; or in the latter end of fummer, as the beginning of Auguft; being moftly fown in conjunction with other crops in the firft period; but when fown alone at the latter feafon, the produce is in general the beft and moft full. Some of the writers in the Effex Report on Agriculture fpeak of the culture of this fort of crop as fimply that of tranfplanting from the feed-beds about Midfummer. The feed, in thefe cafes, is fown in the beds in the early fpring, for raifing the plants. In the county of Norfolk, it is faid, that they fow it in the month of April with barley, in the proportion of from a quarter to half a peck to the acre, in the manner of clover, and frequently with clover at the fame time, to be mown or fed in the following year, after the weld is pulled.

It is moftly fown broad-caft, whether grown in mixture with other plants or alone; and as the feeds are of a very fmall fize, it requires an expert feedfman to perform the bufinefs with regularity and exactnefs, which is a matter of much importance to the fuccefs of the crop, as, where the plants ftand too clofely together, much unneceffary trouble and expence muft be incurred in the thinning them out by the hoe afterwards; and where they ftand too thinly upon the ground, there muft be a great lofs from the deficiency of plants. That the fowing may be executed with more regularity, it is the cuftom with fome to blend other fubftances, fuch as the above, with the feed that has nearly the fame weight, as by this means they fuppofe it may be effected with greater exactnefs, facility, and readinefs.

It is ftated that weld, when grown with other forts of crops, fuch as barley, buck-wheat, beans, peas, clover, or grafs-feeds, is ufually put in after them; in fome cafes immediately, but in others not till fome time has elapfed. With the firft and fecond forts, when fown fo late as the beginning of May, it is moftly the practice to fow it directly afterwards, giving the land a flight harrowing with a very light clofe-tined harrow to cover it in. The barley being fown under furrow, the weld-feed with fome is immediately fown over the furface, and lightly harrowed in, and then rolled. Where the barley feeding is performed fo early as March,

March, or the beginning of April, the fowing of the weld-feed is beft deferred till May, when it may be difperfed over the land, and left in that manner to be wafhed in by the rains. With bean and pea crops, it is often fown before the laft breaking or hoeing of the crops in the latter end of June, or beginning of July. In cultivating it with clover and grafs-feeds, it is often fown at the fame time with them; but a better practice is, perhaps, to delay it till fome time afterwards, as both thefe crops require to be fown at too early a period for this plant to rife fafely. But in cafes where no other fort of crop is grown with weld, which is probably the beft method, it is ufually fown evenly over the furface of the land, and covered in by harrowing with a light bufh harrow, having afterwards recourfe to the roller in light forts of land.

Though it is common in cultivating crops of this fort, not to pay any attention to them after being fown; yet as the plants are of flow growth, and liable to be greatly injured in their progrefs by the rifing of weeds, it muft be of much benefit not only to keep them perfectly clean, but alfo to have the mould ftirred about their roots. In about a month from the time of fowing, the plants are moftly in a ftate to be eafily diftinguifhed; a hoeing fhould be then given when the weather is dry, which may be performed in the fame manner as for turnips only, ufing fomewhat fmaller hoes for the purpofe. Some direct that the plants in this operation fhould be fet out to the diftance of three or four inches; but it is better to let them have more room, as fix, feven, or eight inches; which not only leffens the expence of the bufinefs, but contributes to the advantage of the crop. In the fpring, a fecond flight hoeing may be practifed about March, in a dry time; and if any weeds rife afterwards, a third may be given in May. Where the land has been well prepared, one hoeing in autumn and another in the fpring may be fully fufficient. Hand-weeding, though practifed by fome, is in general too expenfive in thefe cafes.

It may be obferved, that the proper period for pulling this fort of crop is when the bloom has been produced the whole length of the ftems, and the plants are juft beginning to turn of a light or yellowifh colour, as in the beginning or middle of July in the fecond year. The plants are ufually from one to two feet and a half in height. It is thought by fome advantageous to pull it rather early, without waiting for the ripening of the feeds, as by this means there will not only be the greateft proportion of dye, but the land will be left at liberty for the reception of a crop of wheat or turnips; but in this cafe, a fmall part muft be left folely for the purpofe of providing feed. In the execution of the work, the plants are drawn up by the roots in fmall handfuls, and fet up to dry, after each handful has been tied up by one of the ftalks, in the number of four together in a fort of erect pofition againft each other, as is done in fome other kinds of crops.

It is remarked, that fometimes they, however, become fufficiently dry by turning, without being fet up. After they have remained till fully dry, which is moftly effected in the courfe of a week or two, they are bound up into larger bundles, that contain each fixty handfuls, and which are of the weight of fifty-fix pounds each; fixty of thefe bundles conftituting a load. Thefe laft are tied up by a ftring made for the purpofe, and fold under the title of woold cord, in many places where this kind of crop is much grown and provided for the dyer and calico-printer.

On account of the weld plant being extremely uncertain in its growth, and the whole crop feldom becoming in a ftate to be pulled at the fame time, it is proper to have an experienced labourer to direct the bufinefs of pulling, in order that the pullers may not proceed at random, but take the different parts as the plants become ready, or in danger from the blight. In which laft cafe, the greateft poffible difpatch fhould be made, as the lofs of weight in the produce will daily increafe, and the grower be of courfe greatly injured in the quantity of it.

After the weld is become fufficiently dried, which is known by the crifpnefs of the leaves, and the ftems turning of a light colour, and when the plants are ripe, the feeds fhelling out; according to fome, it fhould be ftacked up lightly in the barn, in order to prevent its taking on too much heat; while others advife, that it fhould be ftacked up clofely in the manner of wheat, being left to fweat in the fame way as hay, as the more this takes place, the better; the quality of the weld being thereby increafed, if there be no mouldinefs. When the crop has ftood till fully ripened, the feed may be taken before it is put into the barn, which may be eafily procured by rubbing, or flightly beating each of the little handfuls againft each other over a cloth, tub, or any other convenient receptacle, as, by threfhing, the quantity of the weld would be much reduced in weight. The price of this fort of feed is moftly about ten or twelve fhillings the bufhel, which may be fold to the feedfmen in a ready manner.

It may be obferved, that in crops of this kind the produce is in fome degree uncertain, depending much upon the nature of the feafon; but from half a load to a load and a half is the quantity moft commonly afforded, which is ufually fold to the dyers at from five or fix to ten or twelve pounds the load, and fometimes confiderably more.

This is a fort of crop which is moftly difpofed of to the dyers and calico-printers, as well as other manufacturers. The demand for it, however, is fometimes very little; while at other times it is fo great, as to raife the price to a very high degree.

Weld is a crop which is particularly liable to be injured by the blight, which probably has induced the growers of it to raife it with thofe of other kinds, efpecially of the grafs fort; becaufe, where the weld crop does not fucceed, a portion of fheep feed may be afforded by the others, for winter and fpring ufe. It is noticed, that the blight frequently comes on fo fuddenly, that crops which appeared healthy, and in a vigorous ftate of growth, during the whole of the winter and fpring, promifing a large produce, are about the month of May attacked by this vegetable difeafe, fo as to be nearly deftroyed. It is known to be prefent by the plants, efpecially about the lower parts of the ftems of them, turning of a yellowifh or pale reddifh colour, while the upper parts remain green, and feem healthy. When it appears early in the month of May, there is always danger of the crop being deftroyed; but when it comes on at a later period, or where the plants from other caufes, as the drynefs of the feafon, begin to change colour in the fhanks, the only chance is that of having them pulled as expeditioufly as the bufinefs can be performed, and in the readieft manner poffible.

It may be remarked, that it would feem better and more convenient to cultivate this crop alone, or without any mixture of other plants; as, in the former way, it muft be much injured and confined in its growth, on account of the clofenefs and fhade produced by the plants of the other crops that furround it. It is the cuftom, too, when grown with other crops, efpecially thofe of the grafs kinds, to very commonly feed them down in the winter and fpring feafons with

with ſheep, or ſome other light ſort of live-ſtock, under the notion that they will not touch the weld plants; but this is by no means the caſe, as they are found to feed upon them without any nicety, and muſt, of courſe, do very great injury to their growth and flowering. In caſes where weld is ſown among clover, as is not unfrequently the caſe, the beſt method is probably to pull it out when it has got to maturity, before the clover is cut. Where ſown on ſummer fallowed land with rape and graſs-ſeeds, towards the latter end of that ſeaſon, in which caſe it often does extremely well, the crops are moſtly fed by lambs in the courſe of a month or ſix weeks after the ſowing, when little or no injury can be ſuſtained by the cropping of the weld plants.

Weld, on account of the great conſumption of vegetable food which it cauſes, without contributing any thing to the amelioration of the land, can only be introduced with propriety, probably, in ſituations where manure or ſubſtances of that kind can be eaſily obtained. However, in caſes where the crops of this kind are cultivated with ſufficient tillage, care, and attention, they may be a good preparation for wheat or turnips, in ſome inſtances.

It may ſometimes, too, be grown with advantage in the neighbourhoods of large dyeing, printing, and other ſuch manufactories, where the conſumption, and conſequently the demand for it, are very great. If this ſort of produce cannot be diſpoſed of ſoon after it is pulled and tied up, it may be preſerved perfectly ſound for ſeveral years, by being ſtacked either in the barn or on ſtands in the open air, taking care to prevent the attacks and ravages of rats, or other vermin.

Weld, or *Weald*, in a *Chorographical Senſe*. See Weald.

WELDEREN, or Marienburg, in *Geography*, a town of Germany, in the biſhopric of Munſter; 3 miles N.E. of Dulman.

WELDING, in the *Manufactures*, denotes the forging of iron, when intenſely heated; or, more generally, the intimate union which ſubſiſts between the two ſurfaces of two pieces of malleable metal, when heated almoſt to fuſion, and hammered. This union is ſo ſtrong, that when two bars of metal are properly welded, the place of junction is as ſtrong relatively to its thickneſs as any other part of the bar. Welding heat is the heat neceſſary for producing this effect. Bar-iron cannot be welded to another piece of iron, unleſs both be heated to nearly 60° of Wedgwood's pyrometer, which is equal to 8.877 of Fahrenheit's ſcale, and is called the welding heat; but if caſt-ſteel be heated to this point, it would be fuſed, and run from under the hammer; and, therefore, it was for a long time thought to be impoſſible to uſe it in conjunction with iron, in the ſame manner as the other kinds of ſteel are employed. But ſir Thomas Frankland at length diſcovered, that if the caſt-ſteel be made only of a white heat, and the iron of a welding heat, the ſteel will then be ſoft enough to unite with the iron, and yet the former will not become fluid by the operation. It will, however, be proper to give the neceſſary temperatures to the two metals ſeparately, and then to unite them at one ſingle heat. (Phil. Tranſ. for 1795, p. 296.) Mr. Parkes obſerves, that ſome nicety is required in the proceſs of welding iron, ſo that the outſide of the weld does not oxidize too much and fly off in ſcales, before the inſide is brought up to a welding heat. When, therefore, a ſkilful workman is about to weld two pieces of iron, he carefully obſerves the progreſs of the heat; and if one becomes too hot, he rolls it in ſand to preſerve it from the action of the atmoſphere; and when one piece acquires the neceſſary temperature before the other, he covers that with ſand, whilſt he is bringing the correſponding piece up to a ſufficient heat for its uniting properly with the former. Silex, when mixed with the oxyd of iron, forms a very fuſible compound, which covers the work under operation, and prevents a further oxidation of the metal. Iron and platina are capable of a firm union by welding. See ſir John Hall's Experiments, in vol. vi. of Edinb. Phil. Tranſ. p. 71. Parkes's Eſſays, vol. iv.

Welding, the proper heat ſmiths give their iron in the forge, in order to double up the ſame, when wanted to weld a work in the doublings, ſo as to be in one piece thick enough for the purpoſe it is wanted for.

Welding-*Heat* is the ſtrong heat, when the iron is propereſt to bind.

WELDON, Great, in *Geography*, a ſmall market-town in the hundred of Corby, and county of Northampton, England, is ſituated in Rockingham foreſt, 4 miles E.S.E. from the town of Rockingham, and 84 miles N.N.W. from London. A weekly market is held on Wedneſdays, but on a ſmall ſcale; and here are four annual fairs. The market-houſe, over which are the ſeſſions-chambers, ſupported by columns, was built by lord viſcount Hatton. The pariſh is famous for its quarries of rag-ſtone, which takes a high poliſh, and is in great eſteem for chimney-pieces, ſlabs, &c. In the vicinity of this place were diſcovered, in the year 1738, ſome fragments of Roman teſſelated pavements, one of which was ninety-ſix feet long, and ten broad. Connected with this were the floors of ſeven rooms; the centre one, being the largeſt, was terminated at one end with five ſides of an octangular projection. Among the ruins were found ſeveral Roman coins of the lower empire. A wall has been built round the Roman pavement, and a wooden roof placed over it. Near Great Weldon, and forming part of the pariſh, is Little Weldon, a village ſo called in reference to the town, though exceeding it in population. The whole pariſh, according to the return to parliament in the year 1811, contained 166 houſes, and 815 inhabitants.—Beauties of England and Wales, vol. xi. Northamptonſhire, by Rev. J. Evans, and J. Britton, F.S.A., 1810.

WELDS, a river of America, which runs into the Connecticut, in the ſtate of Vermont.

WELEDIA, a town of Egypt, on the left bank of the Nile; 5 miles N. of Siut.

WELFORD, a town of England, in Northamptonſhire, with 931 inhabitants, including 683 employed in manufactures; 15 miles N.W. of Northampton.

WELHARTITZ, a town of Bohemia, in the circle of Prachatitz; 8 miles N.W. of Schuttenhofen.

WELIN, a town of Bohemia, in the circle of Chrudim; 12 miles N.E. of Chrudim.

WELITZEN, a town of Pruſſia, in the province of Natangen; 5 miles S.S.E. of Marggrabown.

WELKI, a town of Bohemia, in the circle of Kaurzim; 7 miles N.E. of Prague.

WELL, a town of Hindooſtan, in Viſiapour; 12 miles E.S.E. of Raibaug.—Alſo, a town on the north coaſt of the iſland of Sumatra. N. lat. 4° 40′. E. long. 97° 20′.

WELL, a hole dug under ground, below the level or ſurface of the water collected in the ſtrata.

It is uſually of a cylindrical figure, and commonly walled with ſtone, and lined with mortar.

In ſinking wells, it is a conſideration of ſome importance, that they ſhould be lined with free-ſtone, and not, as is uſually the caſe, with bricks; becauſe moſt of the bricks which are made in this country, have the property of hardening the water; but the ſtone does not produce this effect.

M. Blondel informs the Royal Academy of Sciences of a device they ufe, in the Lower Auftria, which is encompaffed with the mountains of Stiria, to fill their wells with water; *viz.* that they dig in the earth, to the depth of twenty or twenty-five feet, till they come to a clammy earth, which they bore into, continuing the operation till the water breaks forcibly out; which water, in all probability, comes from the neighbouring mountains, in fubterraneous channels. Caffini obferves, that in many places of Modena and Bologna, they make themfelves wells by the fame artifice. Dr. Derham adds, that the like has been fometimes found in England, particularly in Effex.

In the Philofophica Tranfactions we are informed, by Mr. Norwood, that, in Bermudas, wells of frefh water are dug within twenty yards of the fea, and even lefs, which rife and fall with the tides, as the fea itfelf does. He adds, that, in digging wells in that ifland, they dig till they come almoft to a level with the furface of the fea; and then they certainly find either frefh water, or falt: if it prove frefh, yet, by digging two or three feet deeper, they always come at falt water. If it be fandy ground, they ufually find frefh water; but if hard lime-ftone rock, the water is commonly falt, or brackifh.

Lay-well, near Torbay, ebbs and flows very often every hour; though fomewhat oftener in winter than in fummer. Dr. Oliver obferves, its flux and reflux fometimes return every minute; though, at other times, not above twenty-fix or twenty-eight times in an hour. Philof. Tranf. No. 104.

In Scotland they have a well, which Sibbald has mentioned as foretelling ftorms. It is a deep and large well near Edinburgh, and from the noifes heard in it at certain times is called by the people the *routing well.* They go to this to liften after the prefages of weather, and it is faid that ftorms are particularly foretold by it; and that noifes are not only heard in it before ftorms happen, but that they are always heard determinately and diftinctly on that fide whence the ftorm will come.

In the Philofophical Tranfactions we have an account of a boiling-well, &c. See Spring.

Well, in *Rural Economy*, a deep circular opening, pit, or fort of fhaft, funk by digging down through the different ftrata or beds of earthy and other materials of the foil, fo as to form an excavation for the purpofe of containing the water of fome fpring or internal refervoir by which it may be fupplied, for domeftic or other ufes of different kinds.

It is ufual to have wells bricked round from the bottom to the top, and frequently to have pumps fixed in them. The width is moftly from three to four feet, which, where the fprings are ftrong, may afford and contain a fufficient quantity of water.

As wells are fupplied from fprings, and thefe are formed in the bowels of the earth, by water percolating through the upper ftrata, and defcending downwards until it meets with a ftratum of clay or other impervious material that intercepts it in its courfe, it may naturally be concluded, that an abundant fpring for this ufe need never be expected in any diftrict or place that is covered to a great depth with fand, without any ftratum of clay to force it upwards, as is the cafe in the fandy deferts of Arabia, and the immeafurable plains of Lybia. Neither are we to expect abundant fprings for wells in any foil that confifts of an uniform bed of clay from the furface to a great depth; for it muft always be in fome porous ftratum that the water flows in abundance, and it can be made to flow horizontally in that only, when it is fupported by a ftratum of clay, or other fubftance that is equally impermeable by water. By this means is explained the *rationale* of that rule fo univerfally eftablifhed in digging for wells, that if begun with fand, gravel, or other fuch matters, it need feldom be hoped to find water until clay is come to; and that if clay be begun with, none can be hoped for in abundance till fand, gravel, or porous rock is met with.

Hence, as the doctrine of wells is fo much and fo intimately connected with the nature of the ftrata and the fprings afforded by them, it may not be unneceffary to obferve, that in cafes where differently formed ftrata of fand, to a confiderable depth, reft upon beds of clay, and have a free iffue at the loweft ends of them, if wells were funk into the fand-beds higher up no water could be there permanently found until they penetrated quite through the ftrata of fand, and went to fome depth into the beds of clay that lie below them. In fuch cafes, the water could never rife in the wells much higher than a certain point; becaufe, whenever it rofe as high as the porous fand, it would flow along through it until it made its efcape below; and if the beds of clay fhould extend backwards under the ground a great way, and at a great depth below the furface, fo as to form an abundant and never-ceafing ftream under the beds of fand, it muft neceffarily follow, that the wells will continue conftantly at the fame height, exactly as in the cafe of a ftrong bafon at a fountain, into which a pipe of water conftantly flows, fo as to keep it running over.

If, however, the ftreams that run below the beds of fand be fmall, and the draught of water from the wells, at particular times, be uncommonly large, the furface of the water in the wells will of courfe be made to fink: they may be, indeed, quite drained of water at times, fo as to require to be left for a while till they fhall fill again. This may be occafionally a very ferious inconvenience, and ought to be guarded againft by enlarging the refervoir, which may be effected either by widening the diameter of the wells, or by finking them to a greater depth in the clay, or by both thefe means. Hence it appears, it is faid, that in cafes of this fort, very wide wells ought always to be made. Other cafes, however, will come to be noticed in the courfe of this article, in which the ftraiteft well that can be made, would fupply a quantity of water as abundant as thofe that are wider. In thefe cafes, pipes as above will be found very ufeful.

Nor would the phenomena here defcribed, it is faid, be in the leaft varied if the wells, inftead of being dug in the fand immediately below the vegetable mould, fhould be firft funk through a confiderable thicknefs of fome other ftrata. The depth of the well only would be greater, and all other circumftances the fame.

It may be here noticed, that quickfand, when it comes in the way of well-digging, affords impediments which can only be furmounted with great labour and difficulty. The beft and moft obvious remedy in fuch cafes when they occur, is probably to endeavour to find the means of opening an outlet by which the water may be fuffered to run off or difcharge itfelf. This, where the quickfand is fituated above the level of the fea, or fome adjoining plain, may in many cafes be effected at very little expence, if due attention be beftowed upon the pofition and natural dip of the ftrata, which may be difcovered by various means befides boring. But there are cafes, particularly where the quickfand is produced by a cavity like a bafon fcooped out of the entire bottom, fo as to contain water to a confiderable depth, which in fome particular fituations may be deemed incurable.

It deferves alfo to be remarked, as a circumftance neceffarily

ceffarily accompanying fprings of this kind, that the digging wells in a higher pofition, will not fenfibly diminifh the quantity of water that flows over the lower furface of the clay ; for, as the well, as foon as it is filled, muft overflow, that will not intercept one drop more water than what is drawn up out of it. Were it even poffible to pump the water from the well as faft as it falls into it, fo as never to allow one drop to run over, the cafe would not be much altered, becaufe no more water could be thus intercepted than that which would have flowed into the mouth of the well in its defcent ; fo that every drop that would pafs the mouth of the well, on either fide, would flow forward to the lower fituation, as if no well had ever been made. Hence we fee that fprings of this fort can never be intercepted by wells, or fenfibly affected by other wells placed either higher or lower than them. Wherever this caufe exifts, water will be found nearly in equal abundance, whatever the relative fituation of the well may be in refpect to others : nothing but an uninterrupted trench, of a fize fufficient to intercept all the water as it flowed, and to carry it off, could dry up the fprings or wells below it.

It may alfo be obferved, that if the bed of fand be of great extent, if it be at laft fupported by a bed of clay or other impervious matter, water will undoubtedly be there found, whatever may be the depth of the bed of fand above it, if a well be dug through it ; for, as the water that falls in fhowers upon the earth's furface neceffarily finks through that pervious ftratum, it is foon beyond the reach of the fun, fo as not to be evaporated, and muft fink downwards till it meets with an impervious ftratum, fo that there can be no doubt but that under the immeafurable deferts of Lybia, there muft be water in abundance to fupply any number of perfons, were wells there funk to the requifite depth ; nor is that depth, perhaps, in many cafes, nearly fo great as has been in general apprehended.

There are many other cafes of ftrata and fprings, as concerned in the opening and forming of wells, that conftitute different claffes of fprings for this ufe, as thofe where the water is confined and pent up in retentive beds, fo as to be capable of fupplying wells by fimply boring down into them, or making flight openings in other ways, by which the water may flow up. Some inftances of thefe and other forts will be noticed and confidered below.

In the execution of the work of digging wells, there is no great difficulty, the perfon employed in the bufinefs chiefly working down by means of a fmall fhort-handled fpade and a fmall implement of the pick-axe kind ; the earthy materials being drawn up in buckets by the hand or a windlafs fixed over the opening for the purpofe. Where perfons converfant with this fort of bufinefs are employed, they ufually manage the whole of the work, bricking round the fides with great facility and readinefs ; but in other cafes, it will be neceffary to have a bricklayer to execute this part of the bufinefs. As the expence and trouble of digging and getting up the materials in thefe cafes are confiderable, other means have been had recourfe to, in order to leffen or prevent them. The moft ingenious of thefe is that propofed by a French philofopher, who has advifed that the ground fhould be perforated to a fufficient depth by means of an auger, or borer : a cylindrical wooden pipe being then placed in the hole and driven downward with a mallet, and the boring continued, that the pipe may be forced down to a greater depth, fo as to reach the water or fpring. In proportion as the borer becomes filled with earth, it fhould be drawn up and cleared, when by adding frefh portions of pipe, the boring may be carried to much extent under ground, fo that water may in moft cafes be thus reached and obtained. It is ftated that wells made in this manner are fuperior to thofe conftructed in the common method, not only in point of cheapnefs, but alfo by affording a more certain and abundant fupply of water, while no accident can poffibly happen to the workmen employed. In cafe the water near the furface fhould not be of a good quality, the perforation may be continued to a ftill greater depth, till a purer fluid can be procured ; and where wells have become injured or tainted from any circumftance or accident, when previoufly emptied, and the bottom perforated in a fimilar manner, fo as to reach the lower fheet of water, it will rife in the cylindrical tube in a pure ftate into the body of the pump fixed for the purpofe of bringing it up.

This is certainly an ingenious, ready, and fafe method of forming wells ; but it requires a large expenfive boring auger, and which, if carried to any great depth, would ftand in need of an apparatus for being wrought by means of horfe-power. Befides, other parts would be neceffary, fuch as punches, chifels, and other fuch mouth-pieces, for being fixed on occafionally, in order to work through hard ftrata of many different kinds ; and, in fome inftances, it would be liable to be wholly impeded by the nature of the fubftances through which it had to get in its paffage to the water or fpring. In fome cafes, it may, however, anfwer in a ready and perfect manner, and be of great ufe and convenience. There would be much difficulty, too, in driving down the wooden pipes in many cafes, efpecially if to any confiderable depth, and great nicety be required in making them fo as pretty exactly to fit the aperture formed by the boring auger. And, befides, from their fmallnefs, except they were made from caft-iron, or fome other proper metal, they would not by any means be durable, but fpeedily become leaky and out of order. The beft mode would therefore probably be that of having metallic-pipes caft for the purpofe, and fo formed as to fit exactly upon each other, to any depth that might be neceffary in finking wells.

In fome cafes and kinds of ftrata, wells formed in this manner could not, however, anfwer perfectly, as they require much width or fpace at the bottom parts, and fometimes to be dug confiderably into the impervious bed or matter, as feen above.

It may be neceffary and ufeful to fhew the nature of the different beds or layers of materials which are dug or funk through in forming the openings for wells in different cafes, as well as the manner and heights to which the water or fprings rife in them under various circumftances. Some cafes of wells are ftated in the Corrected Report on Agriculture, for the diftrict about the metropolis, that explain thefe points in a pretty clear manner.

It is noted, that in the year 1791, the prefent vicar of Northall, then Mr. archdeacon Eaton, agreed with Mr. White, of Putney, to fink a well in the court adjoining to the vicarage. The workmen firft dug through a bed of folid blue clay 60 feet in depth, under which was a ftratum of rough porous ftone about a foot thick. To this fucceeded a fecond ftratum of clay, differing a little from the former in colour, 29 feet in depth ; then a ftratum of fine grey fand, intermixed with extraneous foffils, as oyfter-fhells, bivalves, &c. This ftratum continued for twenty-three feet, and was fucceeded by another of clay, of a red or ferruginous colour, lefs firm in its confiftence than that which occurred before, and intermixed now and then with gravel and ftones of a confiderable fize. After digging through this ftratum for fifty-one feet, at the depth of one hundred and fixty-four feet from the furface, water was found, which, on the removal of the ftone which lay imme-

 diately

diately over, the ſpring burſt up with ſuch force, and in ſuch abundance, that the workmen immediately made the ſignal to be drawn up. Within the firſt four hours after its diſcovery, the water roſe to the height of eighty feet, in the next twenty-four hours about forty feet more; after which it continued to riſe gradually for the next fortnight, till it reached its preſent level, which is only four feet from the ſurface of the earth, the depth of the water being now only one hundred and ſixty feet.

Depths of ſtrata paſſed through:

		Feet.
1	Clay	60
2	Stone	1
3	Clay	29
4	Sand	23
5	Clay	51
		164

At Mr. Munday's brewery at Chelſea, a well was dug about the year 1793, to the depth of three hundred and ninety-four feet, within twenty or thirty feet of the edge of the river, moſtly through a blue clay or marl. At the depth of near fifty feet, a quantity of looſe coal, twelve inches in thickneſs, was diſcovered; and a little ſand and gravel were found about the ſame depth. The well-digger uſually bored about ten, fifteen, or twenty feet at a time lower than his work, as he went on; and on the laſt boring, when the rod was about fifteen feet below the bottom of the well, the man felt, as the firſt ſignal of water, a rolling motion, ſomething like the gentle motion of a coach paſſing over pavement. Upon his continuing to bore, the water preſently puſhed its way by the ſide of the auger with great force, ſcarcely allowing him time to withdraw the borer, put that and his other tools into the bucket, and be drawn up to the top of the well. The water ſoon roſe to the height of two hundred feet.

In 1794, a well was ſunk at Norland-houſe, for Mr. Vuliamy, a little on the road towards the town of Uxbridge, to the depth of two hundred and thirty-ſix feet, and then a hole of five inches and a quarter was bored down, and a copper pipe of the ſame diameter as the borer, was driven down to the additional depth of twenty-four feet into a ſtratum of ſand filled with water; when a mixture of ſand and water inſtantly ruſhed upwards through the aperture of the pipe in ſuch abundance, as to riſe one hundred and twenty-four feet, that is, one hundred feet in the well part, and twenty-four in the pipe, in the courſe of eleven minutes, and one hundred and nineteen feet more in one hour and nine minutes; or on the whole it roſe two hundred and forty-three feet in one hour and twenty minutes. A ſound line was then let down, which diſcovered that ſand had roſe in ſuch quantity as to fill the well to the height of ninety-ſix feet. This was under the neceſſity of being repeatedly dug out, by which the ſand was ultimately reduced ſo conſiderably as to permit the water to riſe through it more and more freely, until it flowed over the top of the well at the rate of forty-ſix gallons in the minute. There is ſtill, however, a great body of ſand in the well, through which the water filters by aſcent, which is excellently calculated for freeing it from every ſort of impurity. If a greater ſupply of water at this well were neceſſary for the valuable purpoſe of turning machinery of any ſort, or for any other ſuch uſe, it might certainly, it is ſaid, be obtained after the rate of ſeveral hundred gallons in the minute, by continuing to clear out the ſand until the obſtruction it affords ſhould become of little conſequence; but, in this caſe, the quality of its water is of more importance than the quantity. The water, in this inſtance, is now had in a very high ſtate of purity, as the originally excellent water, rendered ſo by flowing in a ſtratum or body of clear ſand, is further purified and improved by filtrating by aſcent through many ſeet in thickneſs of the ſame material.

Other circumſtances have occurred in digging and forming wells in different ſituations. It is ſtated in the Rural Eſſays, that in ſinking a well at Sheerneſs, near the mouth of the river Thames, ſometime ſince, ſome extraordinary phenomena or appearances occurred, many of which were deemed, by different perſons, rather of a wonderful kind. They were theſe: that ſort is placed upon a neck of land, very little elevated above the ſurface of the ſea. In digging the well, they paſſed firſt through a bed that conſiſted wholly of ſand to the depth of thirty feet, the whole of the water found in which was of a ſalt taſte, when at that depth they diſcovered a ſpring of *ſalt*-water, which, not being irreſiſtibly abundant, they found themſelves enabled to wall out; which being accompliſhed, they then ſunk further, through a bed of clay for ſome fathoms more. They here found another ſpring of ſalt-water, as before; which having walled out in a ſimilar manner, they continued to dig through the ſame bed of clay, for three hundred feet more; at the bottom of which they found a bed of gravel, from which iſſued a copious ſtream of freſh water, which ſoon filled the well within five feet of the top; at which height nearly it has ever ſince remained.

Extraordinary as theſe circumſtances may appear, they are perfectly explicable on the principles and appearances which take place in boring and tapping ſprings. The freſh water, in this caſe, being confined and pent up at a very great depth in the earth, by impervious beds of materials, when the gravel or porous ſtratum that contained the water was ſunk down into it, was forced up and roſe, of courſe, to the height of the internal ſource or reſervoir from which the water originally came in the diſtant high ground. If the ſpring in this inſtance ſhould afford more water than is taken from the well, it will continue always about the above height; ſo that the water can only ſink in the top of the well, when more is drawn from it than the ſpring can ſupply in a given time. See TAPPING *Springs*.

The ſprings of ſalt-water in this caſe are capable of being explained on the ſuppoſition of fiſſures or openings having been formed by the working of ſome ſort of animal, or other unknown cauſe, ſo as to have penetrated the bed of clay, from the edge next the ſea to ſome diſtance, as far inward, at leaſt, as the opening of the well; through which, of neceſſity, ſalt-water would flow into the well as ſoon as it was opened. See Philoſophical Tranſactions, vol. 74.

Another inſtance of a ſomewhat ſimilar kind, though leſs complicated, as being diveſted of the circumſtance of the ſalt-water, is mentioned to have taken place at Derby, under the direction of a late eminent phyſician and philoſopher. A well was ſunk in that place, which lies in a bottom, ſurrounded by many different hills; in which, after digging through a bed of clay for ſome conſiderable depth, an abundant ſpring of freſh water was found, which, as in moſt caſes of this nature, ruſhed up with great impetuoſity, and ſoon filled the well to the top, where it flowed over in a pretty full ſtream. This was inſtantly ſeen, and conceiving that it probably deſcended through ſome narrow ſubterraneous paſſage, from a height greater than that of the houſes of the town, readily imagined that if the ſides of the well could be raiſed to a ſufficient height, making them at the

the ſame time ſtrong enough to bear the preſſure of the water within, it might be conveyed by this means to the higheſt floors of the houſes; which was actually effected to the great convenience and advantage of the family.

The ſame circumſtances might be taken advantage of in many other ſituations and caſes, with equal benefit and convenience in this way, and ſtill more in many others, eſpecially in the turning of machinery.

Even the ſituation of the metropolis itſelf is ſaid to afford a ſtrong example in elucidation of the ſame general principle. It is well known that this is every where built upon a ſolid bed of clay, that extends to a great depth, and which lies above a large baſon of water there confined and pent in, that can in no way be let off or diſcharged; in conſequence of which, it is with certainty known, that water may be found by ſinking a well in any place; and that the well-diggers are become ſo expert, that they can with little difficulty tell, until within a few feet of the depth to which the well muſt be ſunk before water be found. They know, too, that when the water is found, it always riſes in the well until it reaches a certain height, where it remains ſtationary ever after, never riſing or falling ſcarcely more than an inch from its level under any diverſity of ſeaſon: and if the workmen be permitted to take their levels from a known point, they can tell, before they begin to dig, the preciſe length of pump that will be required to raiſe the water to the ſurface.

Thus, if a well be ſunk in one of the loweſt ſituations in the city, as about Fleet-market, and it ſhould be found that it there requires to be dug forty feet before water is met with, and that the well makes a ſort of drawing or tapping, the water will riſe in the well to the height of a certain level, where it will, of neceſſity, become ſtationary, which is at the height of about ten feet from the ſurface of the ground. If in St. Paul's church-yard, which by a careful level has been found to riſe fifty feet above the former ſituation; the well in this place will require to be ſunk about ninety feet before it reaches the water, and that the water will riſe to the certain level, and no higher; ſo that there the water will require to be lifted fifty feet to reach the ſurface of the ground. If in a lower part of the town, as about Aldgate and Fenchurch-ſtreet, the water there is found at ſixty feet, and will riſe to within thirty feet of the top. If about Thames-ſtreet, and its continuations near the river, the depths to which the wells muſt be dug, and the diſtance from the ſurface of the ground to the water will be rather various: in ſome caſes, the water would riſe within three or four feet of the ſurface, and in low places, run over the top. The depth of digging will be moſtly much leſs than in the laſt caſe before the water is reached.

A caſe, which is ſtrikingly illuſtrative of wells where they flow over the tops, is recorded by the above writer, as having alſo lately occurred in the vicinity of the metropolis. A gentleman bought a houſe and farm a little beyond Kenſington gravel-pits, on the right-hand ſide of the road, nearly oppoſite to Holland-houſe. The premiſes were entirely deſtitute of water, which appeared to the occupier to be ſo great an inconvenience, that he determined to try if he could find any there by ſinking a well, and reſolved, rather than not ſucceed, to go to a very great depth. He began digging, and went down very far without diſcovering any ſymptoms of water; but not diſcouraged by this circumſtance, he ſtill proceeded. At length, when he had gone very deep, he found water, and was infinitely more fortunate than he expected; for he feared that after he had found water, it would be neceſſary to raiſe it by artificial means from ſo great a depth, as muſt greatly enhance the price of it. The water, however, roſe in the well very quickly till it reached the top, and there it ran over in a very copious ſtream, overflowing the field around it, till it found out a level for itſelf, forming a living rill, that continues to flow at all times of the year. The owner of the ground, after having made of it a fine piece of water for his pleaſure, and ſupplied all his building with it abundantly, made that part of it iſſue through a pipe into a ſtone baſon by the road ſide, for the accommodation of paſſengers of every ſort; where it ſtill continues to flow, running from thence along the ditch to the bottom of the eminence on which it ſtands; the ſurplus water from the pond being conveyed off by another channel.

Theſe caſes of wells are ſtill further illuſtrated and explained by the nature of what happens in ſinking deep pits and ſhafts in many places for different purpoſes, and from the large burſts of internal waters which take place in many inſtances and ſituations. See Quarries, &c. *Draining of*, and Spring-*Draining*.

On the whole, the facts and ſtatements which have been given above, may ſufficiently explain and elucidate the manner in which water is ſupplied and obtained in the digging and forming of wells, as well as the nature and diſtribution of the ſtrata by which it is conducted, contained, and forced up into them. However, in moſt caſes, before the ſinking of wells is undertaken or begun upon, the nature of the different circumſtances of the particular caſes ſhould be well and fully inquired into and conſidered, and the probability of ſucceſs coolly and maturely weighed from a nice examination of the different ſprings and wells in the immediate neighbourhood; as where this is not the caſe, much labour, trouble, and money, may often be expended to little or no purpoſe, and great diſappointment be ſuſtained.

Well-*Digging*, the art of ſinking wells, and lining them with ſtone or brick, that they may preſerve their figure; as this operation is neceſſary for wells in all ſoils except rock. There are two methods of building the ſtone or brick within the well, which is called the ſteining. In one of theſe a circular ring is formed, of the ſame diameter as the intended well; and the timber of which it is compoſed is of the ſize of the brick-courſes, with which the well is to be lined. The lower edge of this circle is made ſharp, and ſhod with iron, ſo that it has a tendency to cut into the ground; this circular kirb is placed flat upon the ground, and the bricks are built upon it to a conſiderable height, like a circular wall. The well-digger gets within this circle, and digs away the earth at the bottom; the weight of the wall then forces the kirb, and the brick-work with which it is loaded, to deſcend in the earth, and as faſt as the earth is removed it ſinks deeper, and the circular brick-wall is increaſed or raiſed at top as faſt as it ſinks down; but when it gets very deep, it will ſink no longer, particularly if it paſſes through ſoft ſtrata: in this caſe, a ſecond kirb of a ſmaller ſize is ſometimes began within the firſt.

When a kirb would not ſink from the ſoftneſs of the ſtrata, or when it is required to ſtop out water, the bricks or ſtones muſt be laid one by one at the bottom of the work, taking care that the work is not left unſupported in ſuch a manner as to let the bricks fall as they are laid: this is called under-pruning.

Well-diggers experience ſometimes great difficulty from a noxious air which fills the well, and ſuffocates them if they breathe it.

The uſual mode of clearing wells of noxious air, is by means of a large pair of bellows and a long leathern pipe, which is hung down into the well to the bottom, and freſh air is forced down to the bottom by working the bellows.

This

This is intended to difplace the damp air or gas, but is not very efficacious, becaufe the damp air is of a greater fpecific gravity than pure air; fo that ten gallons of frefh air is perhaps blown into the well, before two gallons of noxious air is difplaced: and this probably happens becaufe the atmofpheric air is fpecifically lighter than the noxious air, and afcends through the latter to the top of the well, difplacing but a fmall quantity of it. Such bellows, &c. are feldom to be procured on the fpot when wanted, and are too weighty and cumberfome to carry about. If water is thrown down in a fhower, it will fometimes clear the air; but this is laborious, in a deep well, to draw it up again.

The following apparatus may be ufed with great fuccefs in fuch cafes; and as with fifty feet of pipe its weight amounts only to thirty pounds, it may eafily be carried to any diftance. Tubes of every kind being perpendicularly fituated, and having their internal air rarefied, caufe a current or ftream of air to afcend through them. Suppofe fix lengths of metal pipe, each eight feet long, and two inches diameter, all made of tin plate, except the upper one, which is of copper, the better to bear the heat; let a cylindrical veffel be alfo made of copper, holding about two gallons, fixed faft to the upper pipe, and having through the fides of it a number of holes to admit air for the fupport of the fire, which is kindled within it. The veffel muft be fo fixed as to have at leaft five feet of pipe above its top.

The method of placing it in the well is, firft, to lower down the bottom length, into the upper end of which, the lower end of the fecond length is joined, paffing a wire through both to prevent their drawing apart again in holes made for that purpofe; then fill the joint round with oil-putty, fo as to render it air-tight. The upper end of each length of tube is wired, to prevent bending; which wiring alfo forms a receptacle for the putty. Then proceed in the fame manner, with the remainder of the pipes, until the bottom one nearly reaches the furface of the water, but not quite. The fire-pan is to be fupported on two timbers, placed for that purpofe acrofs the top of the wall, and a conical cover may be fitted over it to prevent the heat from paffing away too rapidly, and to confine it to the fides of the pipe. The apparatus being thus fixed, it foon becomes filled with air of the fame quality as that in the well; and as their power of gravity is the fame, both the external and internal air become ftationary, from which there can be no good effect. To put the experiment into execution, fill the fire-pan with lighted charcoal or wood, &c. the copper-pipe which is furrounded by the fire, being by this means heated, a rarefaction of the internal air takes place, which air by this means is lightened, and the external denfe air, continuing to prefs with the fame weight as firft into the bottom of the tube, the equilibrium is deftroyed, and a fucceffion of noxious air paffes up through the pipe, as through the funnel of a chimney, till the whole quantity is carried off; after which the pure air, which has in the meantime introduced itfelf into the well, begins to pafs off by the fame paffage fo long as the fire is continued, though the ftream of air paffing out of the top of the vertical-pipe feems fmall, yet the effect is great, becaufe that ftream confifts entirely of noxious air that is required to be removed. The effect will be greater when the fire-pan is placed lower on the pipe, as by that means more external air becomes rarefied; but if the fire-pan is placed too low down in the well, the charcoal fire produces carbonic acid gas in great quantities, and renders the air in the well unfit for refpiration.

WELL, in *Agriculture*, a term fometimes applied to a fort of pipe-chimney or vent-hole left in a ftack, rick, or mow of hay, or other fimilar materials, in order to prevent its being overheated. Such vent-holes fhould be avoided as much as poffible in all cafes, as injuring and deftroying much hay about them, and being hurtful in other ways. See STACKING *Hay*.

WELLS, *Ebbing* and *Flowing*, in *Rural Economy*, fuch as have their waters rifing and falling in an almoft momentary alternate manner. See SPRING, and WELL.

WELLS, *Farm* or *Field*, in *Agriculture*, fuch as are dug in thefe fituations for the ufe of live-ftock.

Wells of this fort are of much ufe and convenience, as they prevent the trouble and difadvantage of driving cattle to diftances for the purpofe of getting water. See POND.

WELL, in the *Military Art*, denotes a depth which the miner finks into the ground, from which he runs out branches or galleries, either to prepare a mine, or find out, and difappoint, the enemy's mine.

WELL, in a *Ship*, an apartment formed in the middle of a fhip's hold to inclofe the pumps, from the bottom to the lower deck. It is ufed as a barrier to preferve thofe machines from being damaged by the friction or compreffion of the materials contained in the hold, and particularly to prevent the entrance of ballaft, &c. by which the tubes would prefently be choaked, and the pumps rendered incapable of fervice. By means of this enclofure, the artificers may likewife more readily defcend into the hold, in order to examine the ftate of the pumps, and repair them as occafion requires. Falconer.

WELL *of a Fifhing Veffel*, an apartment in the middle of the hold, which is entirely detached from the reft, being lined with lead on every fide, and having its bottom pierced with a fufficient number of fmall holes, paffing alfo through the fhip's floor, fo that the falt-water running into the well is always kept as frefh as that in the fea, and yet prevented from communicating itfelf to the other parts of the hold. Falconer.

WELL alfo implies in the fame range, or even with a furface.

WELL-*Drain*, in *Agriculture*, that fort of vent or difcharge for the wetnefs of land, which is conftructed in fomewhat the well or pit manner. See WELL-*Draining*, and SPRING-*Draining*.

WELL-*Draining*, that means of clearing lands from wetnefs which, in certain flat fituations, is accomplifhed by making large deep pits or wells, and the conftant or occafional ufe of fuitable machinery. In the execution of the bufinefs of forming a draining well in loofe ground, a ftrong wooden frame is neceffary to be funk, as the work of digging the well or pit proceeds; the fides of which being made, fo as in the end to be fufficiently open or permeable, to admit the water to enter freely within it, and clofe enough to prevent groffer matters from interrupting the machinery; efpecially when of the mill kind. The fize of the frame for this purpofe muft, confequently, be adapted and fuited to the nature of the engine which is employed. The laves of a mill, it has been obferved, would require a length of frame, which muft neceffarily be proportionally ftrong; but, that for a pump, a frame of inconfiderable expence would be fufficient; whether of wood or uncemented brick-work.

In this fort of draining, which is applicable in many cafes of cold wet flat lands lying in the valley-tracts in moft parts of the country, the wetnefs is drawn off by thefe forts of powerful machinery, working in the fpring time, after wet feafons, or at other periods when neceffary or wanted. See SPRING-*Draining*.

WELL-*Grown*, in *Ship-Building*, implies, that the grain of the wood follows the fhape required, as in knee-timbers, &c.

WELL-

WELL-*Hole*, in *Building*, is the hole left in a floor, for the ftairs to come up through. See STAIRS.
