Ptolemy gives, at the end of his book, a table of shadows under different parallels; it is there shewn that the height of the gnomon being 60 parts, the length of the shadow at Marseilles was $20\frac{1}{2}$. This determination is attributed to Pytheas. These ancient observations agree very nearly in giving the obliquity of the ecliptic $23^{\circ} 51'$, 200 years before our era. If this obliquity be compared with that which is actually observed, $23^{\circ} 28'$, a diminution of $69''$ every century is discovered.

Riccioli endeavours to prove that the obliquity of the ecliptic was then only $23\frac{1}{2}''$; but he could not possess proofs sufficiently demonstrative to contradict four ancient observations, which could be easily made at least within an error of $10'$.

It is true, that consulting Pappus of Alexandria, who lived 200 years after Ptolemy, the obliquity of the ecliptic is found nearly the same as it is at present; but it is by admitting the interpretation of Comarradinus, which Vindelinius thought should not be relied on. Besides, Pappus was not so correct an observer as Eratosthenes, Hipparchus, and Ptolemy, and his object was not to give an astronomical determination of the obliquity of the ecliptic.

From the year 106 before our era, the Chinese astronomers give as a known principle, the obliquity of the ecliptic 24 Chinese degrees, which is $23^{\circ} 39' 18''$; this quantity is less than that of the Greeks; but it proves, nevertheless, a diminution in the obliquity of the ecliptic, which even agrees with many modern observations, and gives a diminution of $35''$ every century.

Albatengius, who lived about the year 880, says that he observed the zenith distance of the sun on the meridian, at Aracté, to be $59^{\circ} 36'$ in winter, and that the least was $12^{\circ} 26'$, from which he concludes the obliquity of the ecliptic $23^{\circ} 35'$. This observation was made with a very long and accurate staff: $40''$ must be added to it for the effect of refraction, minus the parallax, and we shall get $23^{\circ} 35\frac{1}{2}'$ for the obliquity of the ecliptic about the year 900; we should infer from this a diminution of $50''$ every century. This observation differs but little from that of Almamoun; the diminution which it gives is a medium between those which are deduced from more ancient observations. Edward Bernard has produced many other observations from the Arabians on the obliquity of the ecliptic, in the Philosophical Transactions of 1684. They may be found likewise in a long

memoir given by M. De la Lande on this subject, in the *Mem. de l'Academie*, 1780.

By the observations of Co-cheou-King it is found to be $23^{\circ} 32' 12''$, for 1278.

By those of Waltherus, made at Nuremberg, La Caille finds it $23^{\circ} 29' 47''$ for 1490. (*Mem. Ac.* 1757.) There results from hence a diminution of $34''$ in a century.

According to Tycho Brahe, the obliquity of the ecliptic, in 1587, was $23^{\circ} 31' 30''$; but calculating all his observations more correctly, it is found to be $23^{\circ} 29' 30''$, which gives the diminution $44''$.

The observations of Hevelius give for 1660, $23^{\circ} 29' 0''$, a diminution of $46''$ in a century. P. Ximenes, by means of the gnomon at Florence, constructed about 1480, found $34''$. (*Mém.* 1780.) The younger Cassini, by the observations of Richer, made at Cayenne in 1672, found the obliquity $23^{\circ} 28' 54''$; and by those made by his father, made with the gnomon, at St. Petri, $23^{\circ} 29' 0''$. This is what he employs himself in his tables. The observations of Richer have been discussed by M. Le Monnier. (*Mem. Ac.* 1769 and 1774.) They seem to give a diminution of $33''$ in a century.

Famstedt also, in 1689 and 1690, found by repeated observations, the obliquity of the ecliptic $23^{\circ} 28' 56''$; $8''$ must be taken from it, and we shall obtain the mean obliquity for 1690, $23^{\circ} 28' 48''$, a quantity greater by $3''$ than that given by all modern observations, and which gives the diminution $47''$. He examined the observations of Waltherus, Tycho Riccioli, Hevelius, Mouton, Richer, De la Hire, and Margraf, and he always found the same result from those nearest to each other as well as from those most distant; but the system which Famstedt had embraced, made him, perhaps, give the preference to those observations which were favourable to it.

Bianchini, in 1703, found the obliquity of the ecliptic $23^{\circ} 28' 35''$. Horrebow, by the observations of Reaumur, made in 1709, finds $23^{\circ} 28' 47''$.

The younger Cassini, by observations made in the last century, at the observatory of Paris, finds the diminution $63\frac{1}{2}''$. (*Mem. l'Acad.* 1773. *Connoiss. des Temp.* 1781.) M. Méchain, by a great number of comparisons, found it $39''$ in 1780. M. De La Lande considers that $33''$ reconciles the greatest number of observations. *Mem. l'Acad.* 1780.

Dr. Maskelyne, by the observation of many solstices, with excellent instruments, from 1765 to 1772, found the mean obliquity for the 11 of January 1769, to be $23^{\circ} 27' 55''$ (*Phil. Trans.* 1787.) If this be compared with that found by Bradley for 1750, $23^{\circ} 28' 19''$, a diminution of $55''$ or $54''$ in a century is found. M. Hornsby finds $58''$ since 1774. The observations of Almamoun, Albatengius, Co-cheou King, and Hevelius, give $50''$. The theory likewise gives $50''$, when the mass of Venus is taken according to M. De la Lande.

The new solar tables published by the Board of Longitude, at Paris, suppose the obliquity $23^{\circ} 27' 57''$ for the year 1800. According to Piazzi it is $23^{\circ} 27' 56\frac{1}{2}''$; and Dr. Maskelyne found $23^{\circ} 27' 56\frac{1}{2}''$, by observations of the three solstices of 1800, 1802, and 1803. Mr. Pond, by some observations made with an astronomical circle, by Troughton, at Westbury, found the obliquity, in 1800, to be $23^{\circ} 27' 56\frac{1}{2}''$.

Delambre's observations were made with the repeating circle of Borda, for twelve different solstices, and from his determination the French tables were constructed.

It is, then, proved by observations made on the obliquity of the ecliptic at every period, as well as by the quality of

ECLIPTIC.

stars mentioned by Ptolemy, that the ecliptic approaches the equator, as may be seen by the following table, in which the observations of astronomers of all ages have been collected together.

Author's Names.	Years before Christ.	Obliquity
Pytheas	324	23° 49' 23"

It remains now to give a physical explanation of this phenomenon, agreeable to the principles of attraction.

Euler was the first person who demonstrated that the at-

traction of the planets upon the earth ought to produce this effect. *Inegalites de Saturn.* Memoires de Berlin, 1754. Pieces de Prix, vol. vii.

M. De la Lande has given the demonstrations and calculations at full length in the Mem. de l'Acad. 1758, 1761, and 1780. M. De la Grange has given others in the Mem. de l'Acad. 1774.

Whenever two planets move round the same centre in the same direction, but in different planes, each of these planets makes the node of the other retrograde upon its orbit. Let us see what ought to take place upon the earth in consequence of this derangement, and let us take, for example, the attraction of Venus on the earth. Let EDQ (*Plate XII. Astronomy, fig. 101.*) be the equator, EGN the ecliptic, NVQ the orbit of Venus, so that the earth advances from E to N along the ecliptic, and Venus from Q to N in its orbit. The attraction of Venus on the globe of the earth causes the point N to retrograde to V, that is to say, that the node of the ecliptic on the orbit of Venus advances in a contrary direction to the motion of the earth.

The ecliptic will then change its situation, and will pass from N to DV, without the inclination being affected, that is to say, so that the angle V may be still equal to the angle N, but that the retrogradation of the node of the ecliptic upon the orbit of Venus may be equal to the quantity NV in a year. Now the equator EQ does not change its situation by the influence of which we are speaking, because the rotation of the earth is independent of its annual motion, and that the attraction of the planets is not sensible on the axis of our spheroid. Thus the ecliptic EN, instead of cutting the equator at the point E will, the succeeding year, bisect it in D. The equinoctial point E will advance the quantity ED along the equator, or the quantity EC along the ecliptic. And this alteration in the situation of the ecliptic will, in time, change the longitudes and latitudes of all the fixed stars, and the inclinations of the planetary orbits to the ecliptic.

In a triangle ENQ, in which the angles Q and N are constant, and in which the side NQ varies; for example, 2".39, as that seems indicated by the observed diminution in the obliquity of the ecliptic of half a second a-year; the change ED, which will result to the other side EQ, is equal $\frac{2'' \sin N, \cos EN}{\sin E}$. If a perpendicular DG be let fall on the ecliptic EGN, the small quantity EG will be equal ED, *cof. E*, therefore multiplying the preceding value of ED by *cof. E*, we shall get 2'' *fin. N, cof. EN, cotang. E*, for the quantity EG, by which the equinoctial point has moved along the ecliptic by the action of Venus. As to the change which the arc of the ecliptic DV undergoes at its other extremity V, it is useless to pay attention to it; it only affects the longitude of the node V of Venus on the ecliptic, but does not change the longitudes of the other stars which are reckoned from the equinoctial point E or D. These longitudes are only changed because the equinox and the star do not vary their position equally, with respect to this node, reckoning along the ecliptic; besides the quantity required is much smaller than the total change of position of the ecliptic.

The same result may be found by considering the poles of the three circles, the circumferences of which have been investigated. Let E be the pole of the ecliptic (*fig. 102.*); P the pole of the equator, or of the earth; V the pole of the orbit of Venus. The motion of the ecliptic on the orbit of Venus produces a motion of the pole of the ecliptic round the pole of the orbit of Venus, and it is the same thing to say, that

that ecliptic has a retrograde motion of 5" on the orbit of Venus, or that the pole of the ecliptic retrogrades round the pole of the orbit a quantity EM, the value of which is 5" of the circumference of the small circle E M N, the radius of which is the distance between the poles of the ecliptic and of the orbit of Venus.

In the spherical triangle PVE, the two sides PV and VE are constant, while the remainder varies by the motion of the pole E, in the circumference EMN, from hence it follows that the variation of the angle P, or the

$$\text{small angle EPM, is} = \frac{MX}{\text{fin. } \rho E} = \frac{EM \text{ fin. } XEM}{\text{fin. } PE} = \frac{2'' \text{ fin. } EV, \text{ fin. } XEM}{\text{fin. } PE} = \frac{2'' \text{ fin. } EV, \text{ cof. } PEV}{\text{fin. } PE}, \text{ but in}$$

the triangle PBE the variation of P is to that of E as radius is to the cosine of PE. Therefore the variation of the angle PEB, which is the same as that of the angle PEV, is = 5" fin. EV, cof. PEV, cotang. PE, which is the same as the preceding formula; for EV is equal to the inclination of the orbit of Venus; PE is equal to the obliquity of the ecliptic, and the angle PEV is equal to the longitude of the node of Venus, because it is the angle formed at the pole of the ecliptic E, by the colure of the solstices EP, which is 90° distant from the equinoxes, and the circle EV, which passes through the poles of the orbit of Venus, and which is 70° from its node. This change of the angle PEB is the quantity by which the colure of the solstices EP changes its place in taking the new situation MP, and consequently the change of the colure of the equinoxes, which is always at right angles with that of the solstices: it is therefore the quantity by which the equinoctial point departs from the line EMB, which is supposed to be fixed during the time which the pole takes to traverse the small space EM. This equinoctial point being always at the extremity of an arc of 90°, or of a circle of latitude perpendicular to EP, and the position of which changes as well as the position of the colure EP, all the celestial longitudes which are reckoned from the equinoctial colure, will change by this quantity, which will be, consequently, a part of the precession of the equinoxes.

In the triangle PEV the variation of the side PE is equal to 2" fin. EV, fin. PEV; this is the quantity by which the obliquity of the ecliptic varies every year by the action of Venus.

Substituting for VE its value 3° 23' 35", and for the angle E 74° 26', the longitude of the node of Venus in 1750, and multiplying by 100, we shall find 30".88 for the quantity by which the obliquity diminishes in a century from the action of Venus alone.

Making the same substitution in the other formula, which expresses the change in the angle E, we shall get 2' fin. 3° cof. 74°, cot. 23½° = 0".0887 for the quantity which the angle E (fig. 102.) or the point D (fig. 101.) varies every year, by the action of Venus, that is to say, that the precession of the equinoxes diminishes 8".87 every century by the action of Venus.

The quantity by which the longitudes and latitudes of the fixed stars vary from this alteration in the position of the ecliptic, may be calculated in the same manner. It may be demonstrated, that if the pole of the equator revolves round the pole of the ecliptic, the inequality of the positions of the stars along the ecliptic is equal to L fin. 23°, fin. RA, tang. declin. in which expression L represents the precession in longitude, that is to say, that in general the inequality of the positions reckoned upon the revolving circle is

equal to the motion of the revolving pole, multiplied by the sine of the distance of the two poles, by the sine of the distance of the star from the node of the two circles, measured along the revolving circle, and by the tangent of the distance of the revolving circle. If we apply this theorem to the motion of the pole of the ecliptic round the pole of Venus, we shall get for the change of longitude, which results to a fixed star every year, 5" multiplied by the sine of the inclination of Venus, by the sine of the distance of the star from the node of Venus, measured along the ecliptic, and by the tangent of the latitude of the star.

The change in the declination of the fixed stars is equal L fin. 23°, cof. RA. Hence it appears, that where the pole of the equator revolves round the pole of the ecliptic, the change in the distance of a star from the equator, or from the revolving pole, is equal to the motion of this pole, multiplied by the sine of the distance of the two poles, and by the co-sine of the distance of the star from the intersection of the two circles measured along the revolving circle. This expression, applied to the present case, shews, that if the pole of the ecliptic turns round the pole of the orbit of Venus, the change in the distance of a star from the ecliptic, or its latitude, is equal to the motion of the ecliptic, multiplied by the sine of the inclination of the orbit of Venus, and by the co-sine of the distance of a star from the node of Venus, measured along the ecliptic.

Let us call D the distance of a star from the ascending node of a planet, or the longitude of a star minus that of the planet's ascending node, I the inclination of the planet's orbit, L the latitude of the star, M the motion of the pole of the ecliptic round the pole of the planet, or the change NV (fig. 100.) of the planet's node along its orbit; we shall get M fin. I, fin. D, tang. L, for the change of the star in longitude, and M fin. I, cof. D, for the change in latitude.

The formula for the motion of the nodes (see NODES,) being applied to each planet, gives the actual motion of the node of the ecliptic on the orbit of each planet: this is the value of M in the preceding expressions.

The quantity D, or the distance of a star from the node of it, is variable, on account of the motion of the nodes of each planet, and that of the stars in longitude, but from the slowness of these motions, and the smallness of the quantities that are to be determined, the distance D may be considered as invariable for one century.

To obtain D, the place of the node of each planet for 1750 must be taken, and it must be taken from the longitude of the star; the inclination must be taken equal to I, the value of M is given by the motion of the node of the ecliptic on each orbit; thus, knowing the latitude of the star, we have all the data required for finding the value of these two formulas.

For example, we find 6".983 for the action of Jupiter for one year. This is the value of M; its inclination is 1° 18' 50" = I; then M fin. I = 0".1601; its node is at 3° 7' 56" of longitude; therefore the change of latitude M, fin. I, cof. D = 0".16 cof. (longit. - 98°.)

This expression may be put in a more commodious form, by considering that the co-sine of the difference of the two arcs is equal to the product of the co-sines, added to that of the sines; now the co-sine of 98°, is equal to that of 82° taken negatively; we shall therefore get 0".16 cof. (longit. - 98°) = - 0".16, cof. 82°, cof. long. + 0".16, fin. 82°, fin. long. = 0".1586, fin. long. - 0".0211, cof. longit.

Employing the motions of the nodes, and the inclinations of each of the other planets in the same manner to obtain the value of this formula M, fin. I, cof. D, and multiplying

the annual motion by 100, we get the secular motion of the northern stars, in latitude, from the action of each planet, such as they have been given by M. de la Lande, in the Mem. de l'Acad. for 1758. 1761, 1780, according to different suppositions for the mass of each planet. The following numbers are those which he has given, and are the same as those of M. de la Grange (Mem. de Berlin, 1782), with the exception of Venus, the mass of which M. de la Lande has diminished about one quarter, in order to find the secular diminution in the obliquity of the ecliptic 50'' in round numbers.

Saturn	1'' 39 fin long.	- 0'' 53 cof. long. of the star.
Jupiter	15.86	- 2.11
Mars	1.03	+ 0.95
Venus	30.83	+ 8.87
Mercury	0.84	+ 0.55

Total + 50'' 00 fin. long. + 8'' 03 cof. long.

The signs change for the stars which have southern latitudes. The change of signs must also be observed.

This expression is the same as 50'' 64 fin. (longit. + 9° 7') because $\frac{8'' 03}{50'' 00} = \text{tang. } 9^\circ 7' 26''$; for, if we call this quantity of 9°, y, and the co-efficient required, x, we shall get for 0° of longitude 8'' 0 = x sin. y, and for 90° 50'' = x cof. y; therefore, $x = \frac{8''}{\sin. y} = \frac{50''}{\text{cof. } y}$; therefore, $\frac{\sin. y}{\text{cof. } y} = \frac{8''}{50''} = \text{tang. } 9^\circ 7' 26''$, and $x = \frac{50'' 0}{\text{cof. } 9^\circ 7'} = 50'' 64$.

Example — Sirius had 3° 10' 38'' longitude in 1750; multiplying the 50'' of this formula by the sine of 79° 22', we shall get 49''.1; and multiplying 8'' 03 by the cosine of 79° 22', taken negatively, we find 1'' 5; the difference is 47''.6. This is the secular diminution of the latitude of Sirius in this century.

It would be necessary to know these quantities for more distant centuries; for example, instead of 3° 8', which is the place of Jupiter's node, its longitude 2° 20'' must be substituted for the year 50. If the motion of the node of Venus, 14° 38', be equally taken into consideration; and the change of latitude in the first century of our era will be found 46'' 66 fin. long. + 20'' 41 cof. long. This quantity is different from that which has been found for this century; and it is by taking a medium, that the secular change of the fixed stars in latitude may be found, from the age of Ptolemy to the present time. Besides, this change in the first century depends on the motion of the nodes of each planet, which is yet but imperfectly known; therefore, this effect cannot be determined with precision.

The same numbers will serve to find the change in the longitude of the fixed stars, M fin. I, sin. D, tang. L; because it is sufficient to change the words into *sine* and *co-sine of longitudes*, and to multiply the whole by the tangent of the latitude of the star. The value for the first century of our era, and for that in which we are, is as follows: The signs are for northern stars, and the sign minus indicates a diminution of longitude, (- 46'' 7 cof. long. + 20'' 4 fin. long.) tang. latit. year 50; (- 50'' 0 cof. long. + 8'' 03 fin. long.) tang. latit. year 1750. These expressions are equivalent to - 50'' 93 cof. (long. + 23° 37' 3'') tang. latit. year 50; A - 50'' 64 cof. (long. + 9° 7') tang. lat. year 1750. The change in the sign of the tangent of this latitude should be attended to when the star is south.

The change of the signs of the cosines and sines should also be observed. Thus, for Sirius, the longitude of which is 3° 10' 38', and the latitude 39° 33' fourth, we shall get - 50'' cof. long. = + 0'' 42; because the cosine of 3° 10' changes its sign, and + 8'' 03 sine long. = + 7'' 9, the sum is + 17'' 1, which, multiplied by the tangent of 39° 33', which is negative, gives - 14''.1 This is what must be taken from the precession 1° 23' 43'' to obtain the mean motion of Sirius 1° 23' 31''. The real precession is here taken, and not the mean, because the equinox and the star, each having their proper motion, both must be taken into consideration; thus, its longitude diminishes by 14'' in this century, from the attraction of the planets on the earth, independent of the general cause of the precession, and of the particular derangement of this star.

The motion in longitude and the motion in latitude, determined by the preceding formulæ, nearly agree with observation, as may be seen, by comparing the positions which are in the ancient catalogue of Ptolemy, with those which are observed at present. We see, for example, that the first star in Auriga, which, in Ptolemy's catalogue, has 30° latitude, is 30° 49' in Flamsteed's catalogue; on the contrary, the fourteenth star of Gemini, which is fourth of the ecliptic, has 1° 30' latitude in Ptolemy's catalogue, and only 0° 56' in Flamsteed's. It is the same with the latitude of almost all the stars. The differences of longitude appear equally changed, in a manner perfectly consonant to this theory. Between the twenty-seventh star of the Great Bear, and the tenth of the Dragon, of which the latitude is 81° 45', we find a difference of longitude less by 1° 21' than it is in Ptolemy's catalogue; because, one of the stars has augmented in longitude, while the other has diminished.

These differences can only be perceptible in stars that have considerable latitude; it is nothing for those situated in the ecliptic.

In the general formula for the precession of the equinoxes, (see PRECESSION,) there is one part, L cof. 23 3/4, common to every star; in this case, it would be equal to M cof. E V; this part indicates only that the line EV is more advanced than MV, by the quantity M cof. EV; this is the motion of the node of the planet, or of the pole E, referred to the ecliptic.

If an arc of a circle E M B C be drawn perpendicular to E V, and coinciding with the small arc E M, this will be the circle of latitude which passes through the node of the orbit of Venus. The change in longitude of a star S, found by the preceding formulæ, is the difference between the angle S E P, and the angle S M P; part of this difference arises from the variation of the angle E, in the triangle S C E, in which the side S C and the angle C are constant; this variation is equal E M sine E, cotang. E S. But, besides this change of the star S, relatively to the circle E M C, there is that of P E, or of the colure of the solstices, which passes from the situation P E into that of P M; the angle P E B changing itself into the angle P M B, is the variation of the angle E, in the spherical triangle P B E, in which P B, and the angle B are constant. Thus, this quantity is E M, fin. P E B cotang. E P; it is common to all the stars, and is a part of the precession.

The change of the obliquity of the ecliptic, and that of the angle P E B, which is the change of longitude common to all the points of the heavens, may be found in the same manner as we should find the variation in longitude of a star at P; that is to say, that in the preceding formulæ we may consider the pole of the equator as a star, of which the longitude

is 90° , and its latitude $66^\circ 32'$, and we may find, by the same formulae, how much it changes, relatively to the movable pole of the ecliptic, whether in longitude or latitude. We shall get $50''$ for the variation of the ecliptic in this century, and $46''.7$ for the first century.

The change of the pole in longitude is found by the same method to be $8''.03 \text{ tang. } 66^\circ = 18''$. This is the diminution of the precession of the equinoxes, which the action of the planets produces in this century by displacing the ecliptic, or the orbit of the earth. This would be $26''.1$ according to M. De la Grange. This difference arises from his making a different supposition relative to the mass of Venus.

M. De la Place has given more general and rigorous formulae for these calculations. (Mem. de l'Acad. 1788.) The following gives the variation of the ecliptic for any number of years n , beginning from 1700; $932''.56 \text{ cof. } 17''.7686 n - 3140''.34 \text{ fin. } 32''.8412 n$, supposing the change to be $50''$ in this century. The second term changes its sign for the years anterior to 1700: thus for the year 300 before our era, $17''.7686$, multiplied by 2000, give $9^\circ 5' 17''.2$, the cosine of which multiplied by $932''.56$ gives $918''.75$; the second term is $+ 933''.19$; the term $932''.56$ must be taken from the sum, which takes place when $n = 0$, or in 1700; there remains $969''.38$, which must be taken from the mean obliquity of the ecliptic in 1700, $23^\circ 18' 43''$; and we get $23^\circ 44' 52''$, which differs but little from that employed by M. De la Lande in the solar tables. This formula gives $46''.26$ secular for the variation, 2000 years ago; it is $46''.0$ according to the tables of M. De la Lande.

In the table which we have annexed the secular variation of the obliquity of the ecliptic is assumed $52''.1$ for the present century, and $48''.5$ for a period 2000 years back.

The obliquity of the ecliptic is likewise subject to a periodic change from the effect of nutation. (See NUTATION.) This inclination increases to $9''$ when the node is in Aries; the pole is then in A ($\sqrt{2}$, 103.); the distance of the poles E A becomes greater by $9''$ than when the node is in Capricorn or Cancer, and is greater by $18''$ than when the node is in Libra, and the pole in C. The obliquity of the ecliptic, in 1774, was $23^\circ 27' 57''$; in 1784, $23^\circ 28' 10''$; not only it has not diminished $5''$, as it ought to have done, but it has augmented $13''$, which gives $18''$ more for the effect of nutation alone, which is equal to A C.

When the pole of the earth is in O, the obliquity of the ecliptic is EO or EH, and the nutation is equal to PH; the arc AO, or the angle APO is equal to the longitude of the node, and PH is the cosine of it; now PH is equal $9''$ sine OD, or $9'' \text{ cof. } AO$; therefore the nutation $\text{PH} = + 9'' \text{ cof. of the node, or } 9''$ multiplied by the cosine of the longitude of the moon's node.

This is the change which Dr. Bradley remarked in the variation in declination which the stars situated near the solstitial colure had experienced during 19 years.

This nutation ought to be subtracted from the mean or uniform obliquity, while the moon's node is between three and nine signs: it is additive in the first and fourth quarter of the moon's longitude.

It is now several years since many astronomers who have been in the habit of constantly observing the sun at the summer and winter solstices for the purpose of ascertaining the obliquity of the ecliptic have noticed, that they obtained a different result from their winter and summer observations. The first astronomer who noticed this circumstance was Dr. Slop, who superintended the grand duke's observatory at Pisa. The instrument he used was a six feet mural quadrant constructed by Sison; as his determination

was founded on a comparison with stars that passed on the same parallax, this discordance could not be attributed to any error in the divisions of the instruments. The most plausible supposition was, that it arose from some temporary expansion which periodically affected the instrument in similar situations of the sun. This occurrence took place for many years: the difference observed varied from $6''$ to $12''$. About the year 1790 the above astronomer received a letter from Oriani, and the astronomers at Milan, who had begun to observe the solstices with a superb mural quadrant of eight feet radius, made by Ramsden, in which they remarked, that to their great surprize they found a discordance they could not explain in the determination of the obliquity of the ecliptic, as deduced from the summer and winter solstices. Neither of the above astronomers made these circumstances known to the public at that time, conceiving they arose from some accidental derangement of their instruments, which time would explain. They were communicated in conversation to the person who has favoured us with this account when in Italy.

It was at this period that Piazzi began to observe at Palermo with the great astronomical circle made by Ramsden. The same perplexing occurrence happened to him, though he was quite ignorant of the same thing having occurred to the astronomers above-mentioned. Finally, the French astronomers in using the repeating circle of Borda, which gave the altitude of the sun with greater accuracy than any instrument before invented, met with the same embarrassment before the observations of Piazzi were published. Mr. Pond, who observed several solstices at Westbury with a very capital circular instrument made by Troughton, found likewise the same discordance, and the difference was very nearly the same as the mean of that found by the French and Italian astronomers; the obliquity appearing about $10''$ greater in summer than winter. It may appear surprising that no notice has been taken of this in the Greenwich observations; it can only be accounted for by supposing that some deviation in the quadrant, has caused one error to counterbalance another. In the Philos. Transactions for 1806, Mr. Pond has given an investigation of the state of this instrument, which has been since confirmed by a mechanical examination by Mr. Troughton, by which it appears that the weight of that sine instrument has, in the course of time, caused it to defect from its original form, and to give a constant error, which increases as the observed objects approach the horizon. (See Dr. Maskelyne's Obs. for 1807, where a table of corrections is given.)

The cause of this want of coincidence in the summer and winter observations is by no means easy to be explained; it has been proposed as a prize by some foreign academies, but no satisfactory explanation has yet been given. The French astronomers, to reconcile their observations, alter both their latitude a small quantity, and likewise the mean refraction as established by Dr. Bradley, but M. Piazzi objects to this, and very properly observes, that his table of refraction was founded on his own observations made with the same instrument. Besides, this suits all latitudes, and it seems probable, that this discordance would be found general, as by the above account it seems to have happened to all those astronomers who had instruments sufficiently accurate to detect it. It has been suggested by M. Piazzi that it may be connected with some peculiar modification of the refractions of the sun's rays which may differ from those of the stars. Not being able to offer any satisfactory conjecture on the subject, we can only present the above statement of this curious fact to our astronomical readers.

TABLE of the Obliquity of the Ecliptic for forty Centuries, with its Secular Variation.

		Mean Obliquity.	Secular Var.	
A. C.	900	23° 50' 26".2		
	800	23 49 39.6	46".9	
	700	23 48 52.7	47.2	
	600	23 48 5.5	47.5	
	500	23 47 18.0	47.9	
	400	23 46 30.1	48.2	
	300	23 45 41.9	48.5	
	200	23 44 53.4	48.9	
	100	23 44 4.5	49.1	
	0	23 43 15.4	49.3	
	A. D.	100	23 42 26.1	49.7
		200	23 41 36.4	49.9
		300	23 40 46.5	50.1
		400	23 39 56.4	50.3
		500	23 39 6.1	50.5
	600	23 38 15.6	50.8	
	700	23 37 24.8	51.0	
	800	23 36 33.8	51.1	
	900	23 35 42.7	51.3	
	1000	23 34 51.4	51.4	
		1100	23 34 0.0	51.5
		1200	23 33 8.5	51.7
		1300	23 32 16.8	51.8
		1400	23 31 25.0	51.9
		1500	23 30 33.1	52.0
		1600	23 29 41.1	52.0
		1700	23 28 49.1	52.1
		1800	23 27 57.0	52.1
		1900	23 27 5.0	52.1
		2000	23 26 12.8	52.2
	2100	23 25 20.6	52.3	
	2200	23 24 28.3	52.2	
	2300	23 23 36.1	52.2	
	2400	23 22 43.9	52.2	
	2500	23 21 51.7	52.2	
	2600	23 20 59.5	52.1	
	2700	23 20 7.4	52.1	
	2800	23 19 15.3	52.1	
	2900	23 18 23.3	52.0	
	3000	23 17 31.3	52.0	

ECLIPTIC. Poles of the. See POLE.

ECLIPTIC Reduction to the. See REDUCTION.

ECLIPTIC, in Geography. &c. is a great circle of the globe cutting the equator under an angle of 23° 28'. See GLOBE.

The terrestrial ecliptic, therefore, is in the plane of the celestial ecliptic; like which it has its equinoctial and solstitial points, and is bounded by tropics.

ELOGARI, among the Ancients, were persons who selected the best pieces of the books they read, which, for that reason, were called *eclogues*, or select pieces. See ELOGUE.

ELOGUE, *Εκλογη*, in Poetry, a kind of pastoral composition, wherein shepherds are introduced conversing together. The eclogue is properly an image of the pastoral life.

The beauty of the eclogue, M. Fontenelle observes, is not attached to what is rural, but rather to what is calm and easy in the rural life.

Yet there are eclogues in Theocritus of a lofty character; and Virgil has some in the sublime style: the eclogue, therefore, occasionally raises its voice. Yet M. Fontenelle esteems it a fault in some modern poets, to have put matters of high concern in their eclogues, and to have made their shepherds sing the praises of kings and heroes. The sentiments in eclogues, the same author observes, should be finer and more delicate than those of real shepherds; only their form should be as simple and rural as can be. But this simplicity excludes none besides glaring and excessive ornaments.

Since the establishment of the academy or assembly of Arcadians at Rome, about the year 1690, the taste for eclogues has been greatly improved among the Italians. Those gentlemen, who are the flower of the wits of Italy, take the name of the shepherds of Arcadia, and will not allow their assembly to be treated as an academy. They have each of them a poetical name, which is always that of some shepherd; and apply themselves particularly to eclogues, as pieces most proper to their profession. See ACADEMY.

The word eclogue is formed from the Greek *εκλογη*, choice. So that, according to the etymology of the word, eclogue should be no more than a select or choice piece; but custom has determined it to a farther signification, viz. a little elegant composition in a simple natural style and manner. Idyllion and eclogue, in their primary intention, are the same thing: thus the Idyllia, *Ειδυλλια*, of Theocritus, are pieces written perfectly in the same vein with the Eclogues of Virgil.

But custom has made a difference between them, and appropriated the name of eclogue to pieces wherein shepherds are introduced speaking; idyllion, to those written like the eclogue, in a simple natural style, but without any shepherds in them. Some imagine the name eclogue to have been originally attributed to such poems as were written in imitation of others; such as the Eclogues of Virgil, which are only imitations of Theocritus.

Others are of opinion, the word was first formed from *αις*, *αιγοις*, goats, and *λογος*, discourse, *g. d.* a conversation or discourse of goats, or goatherds. But Rhenus, in his notes on Virgil, thinks they would then have made it *Αιγολογια*, *agology*, rather than eclogue; or, at least, the word would have been written in Greek with *αις*, and in Latin by *es*, not *e*.

Barthius advances another opinion, viz. that the name eclogue was given to all poetical compositions that were of a moderate length, though too short to give them the name of books; and that hence it is that Statius, in the epistle at the head of the third book of his *Sylvæ*, and in the preface of his fourth book, calls his poems eclogues, though he had not called them so in the title.

Anonius, in the preface to his *Cupid crucified*, calls also his idylls eclogues. Cruquius also, in his comment on Horace, declares that he had seen very ancient manuscripts, wherein the satires of the poet are called eclogues; in which he is seconded by our learned countryman, Mr. Baxter. See PASTORAL POETRY.

ELOGUE is also applied to certain compositions in prose. Thus we read of the eclogues of Diodorus, of Polybius, of Ctesias,

Ctesias, Theophrastus, Strabo, &c. In which sense the word only signifies *extract* or *collection*.

ECLÔPES, in *Botany*, Gærtner, t. 169. See REL-HANIA.

ECLUSE, L', in *Geography*. See SLUIS.

ECLUSE, *Fort de P*, or *Fort de la Cluse*, a small town of France, in the department of the Ain; 12 miles W. of Geneva, on the river Rhône, or rather, near the place where the Rhône, losing itself among rocks, disappears, as it were, under ground, and re-appears at no great distance.

ECLYSE, in the Greek *Musick*, was lowering the mode, or an alteration of the enharmonic genus, when a string was accidentally lowered three dièses below its usual standard.

ECLYSIS, from *εκλυσις*, I faint, a word used by the ancient Physicians, for a general faintness and feebleness of all parts of the body. Hippocrates uses it for a loss of voice, with a general decay of strength, and in some other places, for a great weakening of the body, by violent discharges of stool.

ECMARTYRIA, *Εκμαρτυρια*, in *Antiquity*, a kind of second-hand evidence, admitted in the Athenian courts. It was not founded on the knowledge of the witness himself, but on that of another person, who had been an eye-witness of the fact in question, but was at this time either dead, or in a foreign country, or detained by sickness; for, except in such cases, the allegations of absent persons were never taken for lawful evidence. Pott. Archæol. Græc. lib. i. cap. 21. tom. i. p. 117.

ECMELES, founds in the Greek *Musick*, which, like those of speech, were inappreciable, and in tune with no fixed tones of the musical scale; consequently, they could furnish no melody. This term was opposed to *enmeles*, or musical sounds.

ECNEPHIAS, from *εκ νεφθς*, a cloud, a word used by Galen, to express a peculiar sort of fever, which, he says, was at once hot and humid, and which he therefore resembles, by the name, to the sun breaking out from a watery cloud.

ECOBROGIS, in *Ancient Geography*, a town of Asia, in Galatia. Anton. Itin.

ECCOMMOY, in *Geography*, a small town of France, in the department of the Sarthe, chief place of a canton in the district of Le Mans, with a population of 2662 individuals. The canton contains 11 communes and 12,998 inhabitants, on a territorial extent of 220 kilometres.

ECCORCHEUR de MADAGASCAR, in *Ornithology*, the name given by Buffon to the *Lanius Curvirostris*, which see.

ECOS, in *Geography*, a small town of France, in the department of the Eure, chief place of a canton in the district of Les Andelys; nine miles S. of Gisors, with only 360 inhabitants. But the canton has a population of 9748 individuals, dispersed in 33 communes, on a territorial extent of 245 kilometres.

ECOUCHE', a small town of France, on the river Orne, in the department of the Orne, chief place of a canton in the district of Argentan, and six miles W. of that place. It contains 1492 inhabitants. The canton has an extent of 190 kilometres, with 24 communes, and a population of 11,765 individuals.

ECOUEN, a small town of France, in the department of Seine and Oise, chief place of a canton in the district of Pontoise, with a population of 992 individuals. The canton comprises 22 communes, with 10,508 inhabitants, on a territorial extent of 110 kilometres.

ECOUIS, a small town of France, in the department of the Eure; six miles N. of Les Andelys, in a country which, till the revolution of 1789, was called La Vexin Normand.

ECOUTE', in the *Manege*, is used for a pace, or motion of a horse, when he rides well upon the hand and the heels, is compactly put upon his haunches, and hears, or listens, to the heels or spurs; and continues duly balanced between the heels, without throwing to either side. This happens when a horse has a fine fence of the aids of the hand and heel.

ECPHONESIS, *Εκφωνησις*, in *Rhetoric*, the same with *Exclamation*: which see.

ECPHORA, from *εκ, out*, and *φειρα*, I bear, *projeçture*, in *Architecture*, usually denotes the line, or distance, between the extremity of a member, or moulding, and the naked of the column, or other part its projects from.

Some authors, however, account the ecphora, or *projeçture*, from the axis of the column; and define it to be the right line intercepted between the axis and the outermost surface of a member or moulding. See *PROJECTURE*.

ECPHRACTICS, *Εκφρακτικα*, in *Medicine*, such remedies as have a faculty of opening and unstoping the vessels through which the humours are pass; or which incise and attenuate tough viscid humours, and thereby promote their discharge. They are the same with aperients and debilitants.

The word is formed from the Greek *εκφρασις*, to free from obstructions; of *εκ* and *φρασις*, *obstruo*, *sepio*.

The chief simple ecpfractics, are the little centaury, wormwood, agrimony, hyssop, chamædrys, bark of tamarisk, roots of aspers, scolopendrium, &c.

ECPHRAXIS, is taking away obstructions in any part. B'ancard.

ECPHYSESIS, from *εκ and φυσω*, I breathe, is a diffease in which the patient breathes thick.

ECPHYSIS, of *εκ and φω*, I produce, in *Anatomy*, is any process that coheres with, or adheres to a bone.

ECPIESMA, *Εκπιεσμα*, from *εκ and πιεζω*, I press, in *Surgery*, a kind of a fracture of the skull, &c. wherein there are several splinters, that press and disorder the inner membranes. See *FRACTURE*.

ECPIESMUS, *Εκπιεσμος*, in the ancient writers of *Medicine*, a word used to express a distemperature of the eye, which consists in a very great prominence of the entire globe of the eye, which is, as it were, thrust out of its socket, or orbit, by a great flux of humours, or an inflammation.

ECPLEROMA, of *εκ and πλερω*, I fill, in the writings of the Ancient Physicians, the name given to a kind of cushion of leather, stuffed with some firm substance, and fitted to the cavities of the arm-pits, used in reducing luxations of the humerus.

ECPLEXIS, from *εκπλεσσω*, I am disturbed, a word used to express a transport of mind, proceeding from some sudden perturbation. Hippocrates and Galen use the word to signify a stupor, or stupefaction, in which the patient lies without motion, without speaking, or stirring, and with his eyes open.

ECPNEUMATOSIS, in *Medicine*, the same with *expiracion*.

ECPNOE, from *εκ and πνεω*, I breathe, a word used, by medical writers, to express that part of respiration, in which the breath is expelled out of the lungs.

ECPATOMA, from *εκπτεω*, I fall out, a word used by the ancient physicians in three or four different senses. It is sometimes made to express a luxation or dislocation of a bone. Sometimes it is used for the falling off of any corrupted part, sometimes for the exclusion of the secundines after child-birth, and sometimes for a falling down of the womb, or a descent of the omentum or the intestine into the ferotum.

ECPOTOSIS, in *Surgery*, the same with luxation.

ECPUCTICA,

ECTUCTICA, from *εκτινω*, *I expurate*, in the *Materia Medica*, are condensing Medicines.

ECOPYEMA, in *Surgery*. This word is derived from *εκ* and *πυος*, pus, *suppuration*, an abscess.

ECREGMA, from *εκρηγνυμι*, *I break off*, in *Medicine*, properly the name of a part, piece, or segment of any thing; but Hippocrates has, in some places, used it as the name of an eruption.

ECRITHMUS, from *εκ* without and *ριθμος*, number, an irregular pulse, which observes no method, nor number, incident to any age. Blandeur.

ECSCAROMA, in *Surgery*, a fleshy excrescence. The term is divided from *εκ* and *σκαρξ*, *scab*.

ECSTASIS, in *Medicine*, is understood in a different sense by different medical writers. Sauvages considers it as distinct from catalepsy, inasmuch as the limbs are rigid, and retain the position in which they happen to be at the instant of the seizure; whereas, in the catalepsy they are flexible, and retain any position, into which they are moved by external force. In this acceptation, however, the ecstasis must be considered merely as an imperfect or spurious CATALEPSY and *r* which head we have already mentioned it. (See Sauvages Notul. Method. class. vi. genus 25.) Vogel, Binswanger, and others, view it in this light, and give the appellation of ecstasis to that variety of catalepsy, during the paroxysm of which the patient avers that he witnessed extraordinary visions, and is said to speak in unknown languages, and even to prophesy future events. "Quidam cataleptici," says Vogel, "sunt ecstasici sunt durante paroxysmo, atque mira phantasmata, visiones diuinas, confortium angelorum eucurrant; linguas, quas non didicerunt, loquuntur, si fabula vera; quin et futura pronunciantur." (De cognosc. et curand. præcip. corp. humani affect. § 509.) In this sense the word ecstasis seems to be synonymous with **TRANCE**, which see.

ECSTATICI, those who labour under the affection termed **ECSTASIS**.

ECSTATICI, *Εκστατικοί*, from *εκστημι*, *I am entranced*, in *Antiquity*, a kind of diviners, who were cast into trances or ecstasies, in which they lay like dead men, or asleep, deprived of all sense and motion; but after some time, returning to themselves, gave strange relations of what they had seen and heard. Pott. Archæol. Græc. lib. ii. cap. 12. tom. 1. p. 302.

ECSTROPHIUS, from *εκστροφη*, *I turn out*, a name given by the ancient writers in *Medicine*, to any thing that threw out the internal tumours of the piles, so that external remedies might be applied to them.

ECTENÆ, in *Ancient Geography*, a people who, according to Pausanias, first inhabited the territory of Thebes in *Æthiopia*. Ogygus is said to have been their first king, whence Thebes obtained the appellation of Ogygus. These people, being exterminated by a plague, were succeeded by the *Hyantes*.

ECTHESIS, in *Church History*, a name which the emperor Heraclius gave to a confession of faith published by him in 639.

The word is Greek, *εκθεσις*, and signifies *exposition*.

The ecclias favoured the error of the Monothelites, and established only one will and one operation in Jesus Christ. Heresy published it at the instigation of Athanasius, chief of the Jacobites, Cyrus, patriarch of Alexandria, and Sergius, patriarch of Constantinople, by whom it was composed; but the Roman church deemed it heretical, and rejected it in a council held at Rome, A. D. 639, under the pontiff John VIII. though Heraclius, in spite of his infidelity, had approved it; and another edict was issued, sup-

pressing the ecclias, called the *Type*, which soon after shared the same fate.

ECTHLEIA, from *εκθλιω*, *I press out*, an ulceration arising from a violent compression in the surface of the skin.

ECTHILIPSIS, in the *Latin Prosody*, a figure whereby an *m* is retrenched, or cut off entirely at the end of a word, when the following word begins with a vowel, or an *h*.

The word is Greek, *εκθλιψις*, which signifies *elision*.

Thus, in *multum ille, & terris gaudet & alto*. Virg.

In scanning the verse, we drop the *m* at the end of *multum*, and only make three syllables in the two first words, *mult-til-le*.

Some account the ecclipsis a poetical licence in the Latin verification; but, in reality, the elision of an *m* final, when the following word in the same verse begins with a vowel, is a matter of necessity, not licence.

Anciently the *s* was likewise retrenched before a consonant; as *facundia fugue*, for *facundus*, &c. In reality, the *m* and *s* were peculiarly rough and harsh in the Latin pronunciation; as appears from Quintilian; and it was this that led the poets to retrench them at the ends of their words, as the like cause induced the French to drop their *e* feminine before a word beginning with a vowel, to avoid the hiatus, or a recurrence of vowels.

ECTHYMA, from *εκθημι*, *I break out*, in *Medicine*, a name given by Hippocrates to any pustule, or cutaneous eruption.

ECTHYMOSIS, of *εκ*, *ect*, and *θυμος*, *animus*, *mind*, a vehement agitation and dilatation of the blood and spirits; such as happens in extraordinary emotions of joy.

ECTODURUM, in *Ancient Geography*, a town of *Rhæzia*, in *Lydia*, *Ptolemy*.

ECTOMIAS, from *εκτινω*, *I cut off*; a name used, by the ancient physicians, to express a calvated animal.

ECTOPIÆ, in the nosology of Sauvages and Cullen, is the appellation of an order of diseases, which are characterized by tumours, occasioned by the removal of some part of the body from its proper situation. This order includes the varieties of *hernia*, or rupture, of *prolapsus*, and of luxation, all of which are described at length by Sauvages. Class 1. ord. 6.

ECTRIMMA, from *εκτριβω*, *I rub off*, excoriation or palling. Hippocrates has used the word particularly to express excoriation in the skin about the os sacrum, contracted by lying long in one posture, in cases of fractures of the thigh, or in lingering illnesses, in which the patient is confined to his bed for a long time.

ECTROPIUM, (*εκτροπιον*, from *εκτροπω*, *to divert*) a turning out of the eye-lid. The lower one is the most subject to this disease, the upper one being very seldom affected. The displaced eye lid hangs down over the cheek, and does not apply itself properly to the eye-ball; consequently, the inner surface of the eye-lid becomes turned out, while the lower portion of the globe of the eye remains uncovered. This part of the eye, and the sensible lining of the eye-lid itself, in consequence of suffering incessant irritation from exposure to the air, and the stimulus of the extraneous particles always suspended in the atmosphere, very soon become affected with chronic inflammation, which is not only attended with pain, a continual discharge of tears, &c. but also with a preternatural redness and swelling of the membranous lining of the displaced eye-lid. At length, the inner surface of the latter part, in general, loses all its natural appearance, becomes thick, callous, dry, and insensible, and looks like an excrescence at the lower part of the eye.

The turning out of the eye-lid also obstructs the passage of the tears to the inner canthus, and hinders them from entering

entering the *puncta lachrymalia*. Hence, besides the above complaints, and the very considerable deformity which an ectropium occasions, the patient has the additional annoyance of an incessant flux of tears from his eye.

The most frequent cause of the disease is, either too great a relaxation and swelling of the lining of the eye-lids, or else too great a contraction and shortening of the skin of these parts, or of that on the adjoining part of the face.

Hence, in respect to causes, there are two kinds of ectropium; one depending upon a swelling of the lining of the eye-lid, which swelling occasions a separation of the edge of the palpebra from the globe of the eye, and, at last, turns the inside of the eye-lid completely out; the other arising from a contraction of the skin of the eye-lid, or adjacent parts, in consequence of which shortening of the integuments, the margin of the eye-lid first becomes drawn further from the eye, and, subsequently, inclined quite outward.

Scarpa remarks, that the morbid swelling of the lining of the eye-lids, which causes the first species of ectropium, (putting out of present consideration a similar affection incidental to old age,) arises mostly from a congenital laxity of this membrane, afterwards increased by obstinate chronic ophthalmias, particularly those of a serolulous nature, in relaxed unhealthy subjects. Sometimes the disease is the consequence of the small-pox, which has severely affected the eyes.

While the disease is confined to the lower eye-lid, as it most commonly is, the lining of this part may be observed rising in the form of a semi-lunar fold, of a pale red colour, like the fungous granulations of wounds, and intervening between the eye and eye lid, which latter it in some measure turns outward. When the swelling is afterwards occasioned by the lining of both the eye-lids, the disease assumes an annular shape, in the centre of which the eye-ball seems sunk, while the circumference of the ring presses and turns outward the edges of the two eye-lids, so as to cause both great uneasiness and deformity. In each of the above cases, on pressing the skin of the eye-lids with the point of the finger, it becomes manifest that they are very capable of being elongated, and would readily yield so as entirely to cover the eye-ball, were they not prevented by the intervening swelling of their membranous lining.

Besides the very considerable deformity which the disease produces, it occasions a continual discharge of tears over the cheek, and what is worse, a dryness of the eye-ball, frequent exasperated attacks of chronic ophthalmia, incapacity to bear the light, and lastly, opacity and ulceration of the cornea.

The second species of ectropium, or that arising from a contraction of the integuments of the eye-lids, or neighbouring parts, is not unfrequently a consequence of puckered scars, produced by the confluent small-pox; deep burns; or the excision of cancerous or encysted tumours, without a sufficient quantity of skin having been saved; or, lastly, the disorder is the effect of malignant carbuncles, or any kind of wound attended with much loss of substance. Each of these causes is quite sufficient to bring on such a contraction of the skin of the eye-lids, as to draw these parts towards the arches of the orbit, so to remove them from the eye-ball and turn their edges outward. No sooner has this circumstance happened, than it is often followed by another equally unpleasant, namely, a swelling of the internal membrane of the affected eye-lids, which afterwards has a great share in completing the ectropium. The lining of the eye-lids, though trivially turned out, being continually exposed to the air, and irritation of extraneous substances, soon swells and rises up, like a fungus. One side of this fungus-like tumour covers a part of the eye-ball; the other pushes

the eye-lid so considerably outward, that its edge is not unfrequently in contact with the margin of the orbit. The complaints, induced by this second species of ectropium, are the same as those brought on by the first; it being noticed, however, that in both cases, whenever the disease is very inveterate, the fungous swelling of the inside of the eye-lids becomes hard, coriaceous, and, as it were, callous.

Although, in both species of ectropium, the lining of the eye-lids seems equally swollen, yet the surgeon can easily distinguish to which of the two species the disease belongs. For, in the first, the skin of the eye-lids, and adjoining parts, is not deformed with scars, and by pressing the eye-lid, which is turned out, with the point of the finger, the part would with ease completely cover the eye, were it not for the intervening fungous swelling. But, in the second species of ectropium, besides the obvious cicatrix and contraction of the skin of the eye-lids, or adjacent parts, when an effort is made to cover the eye with the affected eye-lid, by pressing upon the latter part with the point of the finger, it does not give way, so as completely to cover the globe, or only yields, as it ought to do, for a certain extent; or else it does not move in the least from its unnatural position, by reason of the integuments of the eye-lids having been so extensively destroyed, that their margin has become adherent to the arch of the orbit.

From a comparison of the two species of ectropium, it clearly appears, that the cure of this disease cannot be accomplished with equal perfection in both its forms, and that the second species is even, in some cases, absolutely incurable. For, as in the first species of ectropium, the disease only depends upon a morbid intumescence of the internal membrane of the eye-lids, and the treatment merely consists in removing the redundant part; art possesses many efficacious means of accomplishing what is desired. But in the second species of ectropium, the chief cause of which arises from the loss of a portion of the skin of the eye-lids, or adjacent parts, which loss no known artifice can restore; surgery is not capable of effecting a perfect cure of the malady. The treatment is confined to remedying, as much as possible, such complaints as result from this kind of ectropium, and this can be done in a more or less satisfactory manner, according as the loss of skin on the eye-lid is little or great. Cases, in which so much skin is deficient that the edge of the eye-lid is adherent to the margin of the orbit, are to be abandoned as incurable. "*Si nimium palpebræ deest (says Celsus) nulla id restituere curatio potest.*" (lib. 7. cap. 7). Hence, in treating the second species of ectropium, the degree of success attending the cure may always be estimated by remarking to what point the eye-lid admits of being replaced, on being gently pushed with the end of the finger towards the globe of the eye, both before and after the employment of such means as are calculated to effect an elongation of the skin of the eye-lid; for it is to this point, and no further, that art can reduce the part that is turned out, and permanently keep it so replaced. With respect to the treatment of the first species of ectropium, when the disease is recent, the fungous swelling of the lining of the eye-lid is not considerable, and, consequently, the edge of the eye-lid not much turned out, and, in young subjects, (for in old ones the eye-lids are so flaccid, that the disease is irremediable,) it may be cured by destroying the fungous surface of the internal membrane of the eye-lid, with the *argentum nitratum*, which is to be done as follows. The surgeon must evert the whole of the affected eye-lid with his left hand, and with his right wipe it dry with a piece of rag; then he is to rub the caustic forcibly over the whole surface of the fungous swelling, so as to form an eschar. And, that the patient may

suffer as little as possible, an assistant is instantly to apply a little oil to the burnt part, immediately when the caustic is removed, by which means the argentum nitratum will be kept from dissolving in the tears, and spreading over the eye. Should, however, any part of the caustic be dissolved, and give the patient pain, the surgeon or attendants must immediately wash the irritating substance away, by repeatedly bathing the eye with new milk. The cauterization is to be repeated for several days in succession, until the argentum nitratum has produced a sufficient destruction of the internal membrane of the eye-lid, and of its fungous surface, particularly near the tarsus. Afterwards bathing the eye with plain water, or barley-water and mel. rosæ. will prove sufficient for healing the sore on the inside of the eye-lid. The result of such treatment will be, that in proportion as the wound within the eye-lid heals, the gaping of the eye-lid will gradually diminish, and its edge at last return into its natural position. Scarpa informs us, that this plan of cure can only be successfully put in practice in cases in which the ectropium is slight and recent. To remedy the considerable and inveterate form of the first species of the disease, in an expeditious and effectual way, the quickest and safest plan is, to cut away the whole of the fungous swelling closely to the muscular substance on the inside of the eye-lid. The patient being therefore seated, with his head a little inclined backward, the surgeon with the index and middle finger of his left hand is to keep the eye-lid steadily turned out, and, holding a small pair of curved scissors with convex edges in his right, he is completely to cut off the whole fungosity of the internal membrane of the eye-lid, as near as possible to its base. The same operation is then to be repeated on the other eye-lid, should that be affected with the same disorder. If the excrescence should be of such a shape that it cannot be exactly included between the edges of the scissors, it must be raised as much as possible with forceps, or a double pointed hook, and dissected off at its base, by means of a small bistoury with a convex edge. The bleeding, which occurs at the beginning of the operation, as if it would be copious, stops of itself, or as soon as the eye is bathed with cold water. The surgeon is then to apply the dressings, which are to consist of two small compresses, one put on the upper, the other on the lower arch of the orbit, and over these the uniting bandage, in the form of the monoculus, or so applied as to compress and replace the edges of the affected eye-lids, in order to make them cover the eye. On the first removal of the dressings, which should take place about twenty-four or thirty hours after the operation, the surgeon will find the whole, or almost the whole of the eyelid in its natural position. The treatment should afterwards consist in washing the ulcer on the inside of the eye-lid with simple water twice a day, or else with barley-water and mel. rosæ, until it is completely well. If towards the end of the cure the wound should assume a fungous appearance, or the edge of the eye-lid seem to be too distant from the eye ball, the wound on the inside of the eye-lid must be robbed several times with the argentum nitratum, for the purpose of destroying a little more of the membranous lining, so that when the cicatrization follows, a greater contraction of it may draw the edge of the eye-lid nearer the eye. In the mean time proper steps should be taken with a view of removing the causes by which the ectropium was originally induced. Chronic ophthalmia, and a weak and varicose state of the vessels of the conjunctiva, are frequently concerned.

In the second species of ectropium, or that originating from a contraction of the skin of the eye-lids, or adjacent parts, Scarpa observes, that the indication is not different

from what it is in the case already described. In the same manner, as the shortening of the integuments has occasioned a turning out of the eye-lid, the destruction of a part of its internal membrane, and the consequent cicatrix, may replace the eye-lid in its natural position. However, as the part of the skin, which is lost, can never be regenerated, and, in whatever degree the eye-lid is shortened, so it must perpetually continue, even after the most successful operation; it follows, that the second species of ectropium can never be so completely cured, as the first. Although the eye-lid may be restored to its natural position, it will always remain shortened in a degree proportioned to the quantity of skin which is deficient. But, Scarpa very accurately explains, that, in a great number of cases the ectropium seems to be more considerable than might be expected, considering the little portion of the integuments which is wanting. The Italian professor refers this circumstance to the increase of the ectropium always happening, when once the affection has commenced, and caused by the swelling of the lining of the eye-lid. In this manner, the turning out of the part is rendered complete, even when the contraction of the skin would produce a very partial ectropium.

Scarpa assures us, that, in these cases, the operation proves successful in a degree, which inexperienced persons would never suppose. When the fungous thickened portion of the membranous lining of the diseased eye-lid has been cut away, and its edge brought near the eye-ball, the shortening of the eye-lid, which now continues, is so trivial, compared with the grievances and deformity which it occasioned while the part was turned out, that the ectropium may be regarded as being quite relieved. Hence, when the shortening of the integuments of the affected eye-lid is not so very great, as utterly to prevent it from being brought up again and partially covering the eye-ball, the surgeon ought always to have recourse to the operation which we have above described. The curved scissors, or the convex-edged bistoury, or both, may be used according to circumstances. When the disease has been of very long duration, and the lining of the eye-lid has become indurated and callous, the part affected with ectropium should be covered for a few days before the operation, with a soft bread and milk poultice, with a view of rendering it less rigid.

Scarpa lays it down as a positive and demonstrable truth, that dividing the scars in the skin, which have shortened, and turned the eye-lid out, never produces any permanent lengthening of the part, and, of course, no lasting benefit. This author accurately notices, that the same circumstance may be remarked, after large deep burns on the skin of the palm of the hand and fingers. In these cases, when the parts have healed, the fingers become immediately bent, notwithstanding the greatest pains may have been taken to keep them continually extended during the whole of the treatment. The same circumstance may also be frequently noticed after burns of the face and neck. Fabricius ab Aquapendente knew very well how useless it was to make a semilunar division of the integuments, with a view of rectifying their shortened state, and the turning out of the eye-lids. This writer recommends stretching these parts with pieces of adhesive plaster, applied on them and the eye-brow, and firmly tied together.

Whatever beneficial effects may be produced in this manner, Scarpa has learnt, from experience, that equal good arises from the employment of the bread and milk poultice for a few days; then using oily liniments, and, lastly, the uniting bandage, put on in such a way, as to stretch the contracted eye-lid, in a contrary direction to that in which the part is drawn by the cicatrix.

When the operation is to be performed, Scarpa directs that the patient, if an adult, is to sit down in a chair, and, if a child, it is to be laid on a table, with its head a little elevated, and well supported by the assistants. The operator is next to take a bistoury with a convex edge, and make an incision of proper depth, into the lining of the eye-lid, along the tarsus. He must use great caution to avoid wounding the puncta lachrymalia. The edge of the divided membrane is now to be raised with a pair of forceps, and detached, by means of the knife, from all the inner surface of the eye-lid, until the separation is made as far as the place where the membrane is about to leave the eye-lid, and cover the front of the eye-ball, under the name of the tunica conjunctiva. The surgeon is now to raise the detached part of the membrane still more, and then cut it away with the scissors, near the deepest part of the eye-lid.

A compress and the uniting bandage are to be afterwards applied, with a view of promoting the return of the eye-lid, affected with ectropium, towards the eye-ball. When the dressings are changed, a day or two after the operation, the eye-lid will be found to have resumed, in a great degree, its natural position, and the deformity to be materially diminished.

The operation is seldom followed by any disagreeable symptoms, such as vomiting, pain, violent inflammation, &c. Should vomiting happen, however, Scarpa states, that it may be relieved by an opiate clyster. Inflammatory symptoms are to be lessened by applying soft emollient poultices to the part, and employing antiphlogistic means in general, until suppuration has begun on the inside of the eye-lid. The part is then to be washed, twice a day, with barley water, containing a little of the mel. roseæ. The wound may also be now and then touched with the argentum nitratum, so as to keep the granulations from becoming too high. Saggio di Osservazioni e d'esperienze sulle Principali Malattie degli Occhi. Venezia, 1802. Richter's Anfangsgr. der Wunderzn. B. and Q.

ECTROTICA, from *εκτροπικη*, I cause to miscarry, a name given, by the ancient physicians, to such medicines as have a power to occasion abortion.

ECTYLOTICS, *Εκτυλωτικα*, from *εκ* and *τυλος*, *callus*, remedies proper to consume and eat off caluses, warts, and other excrescences, formed on the flesh.

ECTYPE, *Εκτυπος*, amongst *Medallists*, an embossed figure, or impression of a seal, ring, or medal; or a figured copy of an inscription, or other ancient monument.

The word is Greek, *αρχτυπος*, denotes the *original*, or *model*; *εκτυπος*, the *copy*, or *image*, moulded, or struck in brass; and *ακτυπος*, *εθυρον*, the image in relief, or embossed.

ECTYPE *Craticular*. See ANAMORPHOSIS.

ECU, or ESCU, the French crown. See CROWN, ESCU, and COIN.

Ecu *Arms*, in *Heraldry*, a term signifying the ancient shield. By this they mean the antique triangular-shaped shield, on which the arms of the noble families of France have been painted. This shield is to be seen on old gems, and some ruins; but the modern shield, which is square, and rounded and pointed at the bottom, has banished the use of this.

ECUEILLE, in *Geography*, a small town of France, in the department of the Indre, chief place of a canton, in the district of Chateauroux, with a population of 1200 individuals. The canton has a territorial extent of 245 kilometres, on which there are 13 communes, and 5695 inhabitants.

ECUR, or ICUR, in *Ancient Geography*, a town of India, on this side of the Ganges, placed by Ptolemy in N. lat. 16° 40'.

ECURIE, in the *Manege*, the covert place for the lodging, or housing of horses. The word is French. We use stable in common discourse.

ECURY. See EQUERY.

ECURY *sur Coole*, in *Geography*, a small town of France, in the department of the Marne, chief place of a canton, in the district of Châlons-sur-Marne. It has only 355 inhabitants, but the canton contains 50 communes, and a population of 7242 individuals, on a territorial extent of 440 kilometres.

ECUSSON, in *Heraldry*, an insectcheon, or little escutcheon. See ESCUTCHEON.

ECUYER, in the French *Manege*, is used for the riding-master. Sometimes it denotes certain officers formerly in the king of France's household, who helped the king in mounting his horse and alighting, and followed him on horse back, and carried his sword. These are called *ecuyers de quartier*.

Gentlemen ushers to the queen of France, and the masters of the horse to princes, and persons of quality, are also called *ecuyers*. Besides these, there are others, called *ecuyers cavalcadours*. See CAVALCADOUR.

ECZEMA, (from *εκζωω*, to boil out,) a hot painful eruption, or pustule. Mr. Pea son implies, by mercutial eczema, a particular kind of eruption, occasioned by the employment of mercury. See ERYTHEMA.

ED, in *Geography*, a town of Sweden, in the province of West Gothland; 33 miles N. of Uddevalla.—Also, a town of Sweden, in the province of Smaland; 80 miles N. of Calmar.

EDA, in *Ancient Geography*, a river of the Peloponnesus, in Messenia. Suidas.

EDA, in *Geography*, a town of Sweden, in the province of Warmeland; 40 miles N. of Carlstadt.—Also, one of the Orkney islands, about 7 miles long, and half a mile to two miles broad; situated about 8 miles N. N. E. from Pomona. N. lat. 59° 2'. Long. 0° 33' E. of Edinburgh.

EDAM, or EYDAM, a small but populous town of the kingdom of Holland, in the department of the Amstel, situated about 9 miles N. of Amsterdam, and 6 S. of Hoorn, not far from the Zuyder Zee, with which it communicates by means of a canal. E. long. 5°. N. lat. 52° 53'. There are a great many ships built at Edam; it has a good timber trade; but it is chiefly noted for its cheese trade, being the chief mart for all the cheese made in North Holland, and remarkable for its red erast.

EDBO, a town of Sweden, in the province of Upland; 30 miles E. N. E. of Upsal.

EDDA, in *Antiquities*, is a system of the ancient Icelandic, or Runic mythology, containing many curious particulars of the theology, philosophy, and manners of the northern nations of Europe; or of the Scandinavians, who had migrated from Asia, and from whom our Saxon ancestors were descended. Mr. Mallet apprehends that it was originally compiled, soon after the Pagan religion was abolished, as a course of poetical lectures, for the use of such young Icelanders as devoted themselves to the profession of a seald, or poet. It consists of two principal parts; the first containing a brief system of mythology, properly called the Edda; and the second being a kind of art of poetry, and called *Scalda*, or Poetics. The most ancient Edda was compiled by Soemund Sigfusson, surnamed the Learned, who was born in Iceland about the year 1057. This was abridged, and rendered more easy and intelligible about an hundred and twenty years afterwards, by Snorro Sturleson, who was

supreme judge of Iceland in the years 1215 and 1222; and it was published in the form of a dialogue. He added also the second part in the form of a dialogue, being a detail of different events transacted among the divinities. The only three pieces that are known to remain of the more ancient Edda of Sæmund, are the Voluspá, the Havamaal, and the Runic chapter. The Voluspá, or prophecy of Vola, or Fola, appears to be the text, on which the Edda is the comment. It contains, in two or three hundred lines, the whole system of mythology, disclosed in the Edda, and may be compared to the Sbylline verses, on account of its laconic yet bold style, and imagery and obscurity. It is professedly a revelation of the decrees of the Father of nature, and the actions and operations of the gods. It describes the chaos, the formation of the world, with its various inhabitants, the functions of the gods, their most signal adventures, their quarrels with Loke, their great adversary, and the vengeance that ensued; and concludes with a long description of the final state of the universe, its dissolution and conflagration, the battle of the inferior deities, and the evil beings, the renovation of the world, the happy lot of the good, and the punishment of the wicked. The Havamaal, or "Sublime Discourse," is attributed to the god Odin, who is supposed to have given these precepts of wisdom to mankind; it is comprised in about a hundred and twenty stanzas, and resembles the book of Proverbs. Mr. Mallet has given several extracts of this treatise on the Scandinavian ethics. The Runic chapter contains a short system of ancient magic, and especially of the enchantments wrought by the operation of Runic characters, of which Mr. Mallet has also given a specimen. A manuscript copy of the Edda of Snorro is preserved in the library of the university of Upsal; the first part of which hath been published, with a Swedish and Latin version, by Mr. Goranson. The Latin version is printed as a supplement to Mr. Mallet's Northern Antiquities. The first edition of the Edda was published by Resenius, professor at Copenhagen, in a large quarto volume, in the year 1665; containing the text of the Edda, a Latin translation by an Icelandic priest, a Danish version, and various readings from different MSS. Mr. Mallet has also given an English translation of the first part, accompanied with remarks; from which we learn, that the Edda teaches the doctrine of the Supreme, called the Universal Father, and Odin, who lives for ever, governs all his kingdom, and directs the great things as well as the small; who formed the heaven, earth, and air; made man, and gave him a spirit, or soul, which shall live, after the body shall have moulder'd away; and then all the just shall dwell with him in the place called Gimle, or Vingolf, the palace of friendship; but wicked men shall go to Hel, or death, and from thence to Nifheim, or the abode of the wicked, which is below in the ninth world. It inculcates also the belief of several inferior gods and goddesses, the chief of whom is Frigga, or Frea, *i. e. lady*, meaning hereby the earth, who was the spouse of Odin, or the Supreme God; whence we may infer, that, according to the opinion of these ancient philosphers, this Odin was the active principle, or soul of the world, which, uniting itself with matter, had thereby put it into a condition to produce the intelligences, or inferior gods, and men, and all other creatures. The Edda likewise teaches the existence of an evil being, called Loke, the calumniator of the gods, the artificer of fraud, who surpasses all other beings in cunning and perfidy. It teaches the creation of all things out of an abyss, or chaos; the final destruction of the world by fire; the absorption of the inferior divinities, both good and bad, into the bosom of the grand divinity, from whom all things proceeded, as emanations of his essence, and who will survice all

things; and the renovation of the earth in an improved state; Tables 1, 2, 10, 16, 33. For a further account of the Edda, see Mallet's Northern Antiquities, vol. ii. 1770, passim.

EDDANA, in *Ancient Geography*, a town of Asia, situated on the Euphrates; built by the Phœnicians, who established in it a colony. It is said to have derived its name from Eddanos, the chief of the colony.

EDDARA, a town of Arabia Deserta. Ptolemy.

EDDISH, or EADISH, the latter pasture, or graze, which comes after mowing or reaping; otherwise called *ear-grass*, *earf*, and *etb*.

EDDISTO, in *Geography*, a river of America, in South Carolina, which runs into the sea by two streams, called N. and S. Eddilo; the former 16 and the latter 25 miles S.W. of Charlestown.

EDDRED-SI, a small island in the Red sea, two leagues from the coast of Arabia. N. lat. 17° 10'. E. long. 41° 33'.

EDDY, or (as it is more commonly used in the plural) *Eddies* (from the Saxon *ed*, backward, again, and *ea*, water), in *Hydrodynamics*, denotes the irregular movements of water, or of wind, *viz.* those deviations from the principal direction of the whole stream, which are occasioned by obstacles of any kind. And when these irregular motions become rotatory or circular about a certain centre, then they are more particularly called *vortex-pools*.

Eddies in navigation, in hydrodynamics, or in hydraulics, are highly deserving the attention of the seaman and of the engineer, on account of their being often productive of very serious consequences. The principal causes upon which they depend are the momentum of a fluid in motion, and all sorts of impediments to the direction of the fluid. This will be easily understood by attending to the annexed figure, which represents a river, or stream of water, flowing towards W. (*Plate III. Hydraulics, fig. 3*) From A as far as B the channel is regular, and the water runs uniformly through it. Near B, a part of the stream, meeting with the obstacle C, is forced to alter its course in the direction *a b*, whence, acquiring a momentum in that direction, it proceeds a certain way towards *c*; but the other part of the stream A B, which has not met with any solid obstruction, crosses in great measure the direction *a b c*, which produces an eddy, and the two parts of the stream obstruct each other. From the ruffling of the surface of the water, or from the motion of light bodies floating upon the surface, this obstruction may be easily perceived. Farther on, the water passes from the narrow part O R into the broader channel P Q, and its momentum will enable it to move on in the straight direction *e d*; but, in consequence of the attraction between the particles of water, it will drag part of the water at *e*, towards *d*, which occasions a depression of the level of the water about *e*; hence the water runs from the adjacent parts *f, g*, to supply that defect, and thus a curvilinear, or whirling motion *d f g e*, is produced. The velocity of the water, then, is checked not only in consequence of its passing from a narrow into a larger channel, but likewise in consequence of the above-mentioned eddy; when these whirling eddies are pretty strong, both at sea and in large rivers, a depression is always observed about the centre thereof, which sometimes is very considerable, and becomes very dangerous to small vessels, for they are sometimes swallowed up by it. Mackenzie (in the Phil. Trans. for 1749) says, that eddies of this whirling kind, with a cavity of two or three feet, which sometimes swallow up small boats, may be broken and filled up by throwing in an ear. The cause of the hollow in the middle of these whirls, and of the absorption of boats, &c. will be pointed out in the sequel.

The inequalities of the bottom of a river are likewise productive of similar derangements in the motion of the water. Thus, for instance, when the motion of the stream is rapid, and the bottom, or bed, of it rises abruptly in some particular part, a sensible rising of the water may be perceived over it, and in many such cases, even sand or mud is forced up to the surface of the water at that particular place.

At sea, and especially amongst islands, or in channels, the eddies arising from tides, currents, winds, &c. are so very frequent, so uncertain, and so impetuous, particularly in stormy weather, as to render the navigation extremely dangerous. Several spots are peculiarly remarkable for such irregularities of motion, and they are, for that reason, well known to all experienced sailors. The Eddy-stone rocks, near Plymouth, well known for the light-house which is built upon one of them, are said to have obtained their name from the great and powerful eddies that do almost at all times take place among them. But eddies have also been observed in open seas far from any land, where they are produced by the opposition of the wind to a current, or to the tide, or to a swell occasioned by a previous wind. When a vessel is sailing, unless it proceeds with the stream, the eddies which are formed by it are very evident, and they may be perceived for a considerable way behind the vessel. The seamen call that eddy, which seems to throw the water on the rudder of a ship under sail, the *dead water*.

In pipes, conduits, or aqueducts, all sorts of bendings, internal contractions, elongations, enlargements, and projections, of the conducting pipe, diminish the quantity of discharge, more or less, according to the number and form of such irregularities; sharp angular bendings hindering the motion of the fluid, more than those of a regular curvature. The cause of this retardation is undoubtedly owing to the eddies, and to the crossing of the various parts, or (as they are otherwise called) *filaments* of the fluid, which, according to what has been said above, must necessarily take place at those irregularities: for all eddies and cross directions must unavoidably destroy part of the moving force. This production of eddies in the inside of pipes may be rendered sufficiently evident, if an irregular glass tube be applied to a pretty large vessel full of water, and if with the water there be mixed some particles of pounded amber, or other substance, whose specific gravity differs but little from that of water; as these particles will easily shew the irregularities of the motion of the water in its passage through the glass tube.

Whenever an irregularity of the shape of the aperture, or some particular conformation of the vessel; (or even an obstacle to the stream at some distance from the aperture,) compels the particles of the fluid to run obliquely towards an aperture, a circular motion is readily communicated to the fluid, and an hollow whirl, or eddy, is formed above the aperture. By this circular motion the particles of the fluid acquire a centrifugal force, in consequence of which they endeavour to recede from the centre, or from the axis of motion, where, of course, a hollow is formed, which is larger or smaller, according as the rotation of the fluid is more or less rapid. When the whirling motion is pretty considerable, if any light bodies float upon the fluid, they will be readily drawn towards the centre, and then downwards towards the aperture; for since the specific gravity of the fluid is greater than that of those bodies, the fluid will acquire a greater degree of centrifugal force, and will recede farther than those bodies from the axis of the whirl. This may be easily observed in a common funnel, when water or other fluid is running out of it.

It needs hardly be observed, that such eddies as occur in

water, must likewise take place in other fluids under similar circumstances; due allowance being made for their different specific gravities, tenacities, densities, elasticities, &c.

The eddies, and whirls, of air are so commonly met with in the streets of a town, especially when the wind is pretty brisk, and they are so often indicated by the smoke which issues out of chimneys, as to require no farther illustration in this article. Amongst seamen, the *eddy wind* is that wind which is returned, or beat back, from any sail.

EDDYSTONE, or EDDYSTONE-Rocks, in *Geography*, the name of a cluster of rocks situated in the English channel, at the distance of about 14 miles from Plymouth-sound, lying nearly in the direction of vessels coasting up and down the channel; they formerly proved very dangerous, and many vessels were cast away on them. To guard against these disasters, it was deemed necessary to erect a light-house here; but to effect this in a complete and permanent manner, so as to resist storms and afford light, was a task of extreme difficulty. The rocks are so peculiarly exposed to the swells of the ocean from the south and west, that the heavy seas break upon them with uncontrolled fury. Sometimes, after a storm, when the sea is apparently quite smooth, and its surface unruddled by the slightest breeze, the growing swell, or under current meeting the slope of the rocks, the sea beats tremendously upon them, and even rises above the light-house, overtopping it for the moment as with a canopy of frothy water. Notwithstanding this awful swell, Mr. Henry Winstanley undertook, in the year 1696, to build a light-house on the principal rock, for the rest are under water; and in 1700 he completed it. So confident was this ingenious mechanic of the stability of his edifice, that he declared his wish to be in it during the most tremendous storm that could arise. This wish he unfortunately obtained, for he perished in it during the dreadful storm which destroyed it Nov. 27, 1703. Another light-house, of a different construction, was erected of wood on this rock, by Mr. John Rudyard, in 1709: which being consumed by fire in 1755, a third, of stone, was begun by the justly celebrated Mr. John Smeaton, April 2, 1757, and finished Aug. 24, 1759, which has hitherto withstood the attacks of the most violent storms. The rock, which slopes towards the south-west, is cut into horizontal steps, into which Portland stone and granite are dove-tailed and strongly cemented: for Mr. Smeaton discovered that neither could be used exclusively, as the former would be subject to the depredations of a marine animal, and the working of the latter would have been too expensive. He therefore used the one for the internal part of the structure, and the other for the external. Upon the principle of a broad base and accumulation of matter, the whole, to the height of thirty-five feet from the foundation, is a solid mass of stones engrafted into each other, and united by every possible augmentation of strength. The light house consists of four rooms, one over another, with a gallery and lantern at the top. The stone floors, which are flat above, but concave below, are prevented from pressing against the sides of the building by a chain let into the walls. The edifice is eighty feet in height; and has now stood fifty years, during which time, though frequently assaulted by all the fury of the element, it has withstood the most violent attacks without sustaining the smallest injury: and, in all probability, as Mr. Smeaton said, nothing but an earthquake can destroy it. The wooden part was burnt in the year 1770, but renewed in 1774. Its situation is long. 4° 21' W. Lat. 50° 3. N. For an interesting, scientific account of this structure, and for much useful information concerning similar buildings, the reader is referred to Smeaton's "History, &c. of Eddy-stone Light-house."

house," with plates, 8vo. Many additional particulars respecting it are recorded in the "Beauties of England and Wales," vol. iv.

EDDYSTONE, a rock on the coast of Patagonia. S. lat. 48° 30'. W. long. 64° 56'.

EDDYVILLE, a post town of America, in the state of Kentucky, and county of Livingston; 82 1/2 miles W. by S. from Washington.

EDEBASSUS, in *Ancient Geography*, a town of Asia Minor, in Lycia. Steph. Byz.

EDELBACH, in *Geography*, a town of Germany, in the archduchy of Austria; 6 miles E.S.E. of Bavarian Waidhoven.

EDELINCK, GERARD, in *Biography*, was an engraver of considerable eminence, a member of the French royal academy of painting and sculpture, and one of the constellation of distinguished artists that shed lustre on the reign of Louis XIV. He was born at Antwerp, but resided at Paris after the year 1665, where he was honoured with the title of Chevalier, and had, by the king's appointment, an apartment in the Gobelins. He engraved both portraits and history with admirable skill. His portraits are chiefly those of artists and men of science; and some of his historical engravings are very large, particularly his "Crucifixion," and his "Tent of Darius," both after Le Brun, and an "allegorical" engraving in honour of the king. He died at Paris, at a very advanced age, in the year 1707. For some further particulars of this artist, see *FRENCH School of Engravers*.

EDELING. See EDHILING, and ATHELING.

EDELMANN, JOHN FRIED., born at Sualbourg, 1749, a harpsichord master, and composer for that instrument, long resident at Brussels. He had a lively finger and played his own pieces with great neatness and spirit. But his style of composition would now be called flimsy and rattling. It is a bad copy of Schobert's nervous symphonic strains. Emanuel Bach's refinements in melody, and science in harmony and modulation, had not reached Brussels, or, at least, touched the heart of Edelmann, when he composed any of his lessons which have come to our knowledge. We believe this musician, who had the character of an innocuous good natured man, much esteemed by his pupils, had removed to Paris previous to the revolution, in the horrors of which he was early involved, and suffered under the guillotine at Strasbourg; we never heard why, except that it was Roberfpierre's pleasure.

EDELSTEIN, in *Geography*, a town of Silesia, in the principality of Neisse; five miles S. of Ziegenhals.

EDEMA, in *Ancient Geography*, a town of Judea, in the tribe of Naphtali.

EDEN, *Land or Country of*, in *Scripture Geography*, a district or province of Asia, in which was "Paradise" or the "Garden of Eden." The word *Eden*, according to its primary meaning in the Hebrew language, denotes pleasure or delight; and hence it was used as an appellative for several places, whose situation was peculiarly pleasant and delightful. Such was the *Eden*, or Bith-Eden, mentioned by the prophet Amos (ch. i. v. 5) which, as Huet, bishop of Soissons, thinks, was a valley situated between the mountains of Libanus and Antilibanus, in that part of Syria, of which Damascus was the metropolis. Some have supposed that the paradise of our first parents was situated in this valley; and they have been induced to adopt this opinion by having discovered in its vicinity a town called "Paradisa," and mentioned both by Ptolemy and Ptolemy. There is also a village called *Eden*, near Tripoli in Syria, seated on mount Libanus, near which were the river Adonis and the cedars of Lebanon. Maundrell also mentions this village. In this

place some have sought the site of the terrestrial paradise. But in order more precisely to ascertain the situation of the "Garden of Eden," those who acquiesce in the literal description of it given by Moses, refer to his account of it, and investigate the country in which it was situated by the attendant circumstances, which he has recited. (See Gen. ii. 8—14.) From the scripture account it appears, that the Eden, in which was planted the garden of paradise, lay on a river or single channel, which out of Eden was parted into four heads or rivers, called Pison, Gihon, Hiddekel, and Perath or Euphrates. We are, therefore, to investigate some single channel or river, common to these four rivers; supposing that their course has not been materially altered in subsequent times, and particularly by the catastrophe of the deluge. *Pison*, the first of these rivers, *compasseth*, says the sacred historian, *the whole land of Havilah*, where *there is gold; and the gold of that land is good; there is bdellium and the onyx-stone*. In order to discover this land of Havilah, we find that it is mentioned in two other places of scripture, *viz.* Gen. xxv. 18. and 1 Sam. xv. 7. In both these places we may well suppose; that the expression "from Havilah unto Shur" denotes the whole extent of that part of Arabia, which lies between Egypt to the west, and a certain channel or river (which empties itself into the Persian gulf) to the east. Shur appears to have been the western extremity of this part of Arabia, (Exod. xv. 22.) which came up to the bottom of the Red sea or Arabian gulf, and so joined on to Egypt. Havilah, therefore, was the eastern extremity of this part of Arabia. Moreover, sacred and profane authors have highly commended the gold of Arabia. (See Ezek. xxvii. 22, 23. Diod. Sic. l. ii. and iii.) As for the *bedolach*, or *bdellium*, mentioned by the historian, writers have differed concerning the meaning of the term; some having supposed that it signified pearls, and others, that it was a peculiar kind of gum. Both these, it is said, are to be found in the land of Havilah. The sea about Baharen, an island in the Persian gulf, which sea lies next to the land of Havilah, has always abounded with pearls of the finest kind; as we learn from the testimonies of Nearchus, one of Alexander's captains, Idorus of Charax, Pliny, Arrian, Elian, Origen, Benjamin of Navarre, Teixeira, a Portuguese, and many other modern travellers. If by *bedolach* or *bdellium* we understand a gum, this is likewise found in the land of Havilah, as we learn from Dioscorides, Idorus, Galen, Pliny, Strabo, Arrian, &c. &c. Precious stones have been also found from time immemorial in the same country. (See Ezek. xxvii. 22, 23.) Nearchus, Strabo, Diodorus, and Pliny, testify to the same fact, and Pliny, in particular, says, on the authority of the ancients, that the *onyx-stone*, if we understand this to have been the "schoham" of the text, was no where else to be found but in the mountains of Arabia. It further appears, that a channel, or river, called by Moses Pison, bounds Havilah eastward, and discharges itself into the Persian gulf, and consequently answers to his description. Besides, as Moses is supposed to have written his history in Arabia Petraea, or some place nearly adjoining it, this river was the nearest to him of the four rivers which he names, and, therefore, it is natural to imagine, that it must be the first which he would mention. The etymology of Pison, derived from *push*, to be full or increase, or from *pushba*, to spread itself, corresponds to the situation of this river, for the tides in this part of the Persian gulf are so violent and so high, that no trenches furnish a sufficient defence against their intrusion into the neighbouring grounds, which are soft and low. No name could be more appropriate to that channel, which was apt so often to overflow, as that of Pison.

Of the second river Moses says; *the name of the second river is Gihon; the same is it that compasses the whole land of Cush.* As Pison was the first river with respect to the place where Moses was writing, it is natural to imagine, that Gihon, being the second, was the river next to it, and the most easterly channel of the two, into which the Euphrates, after its junction with the Tigris, is again divided. The name Cush did formerly belong to the country washed by this easterly river. By the Greeks and Latins it was called Sufiana, and it is now called Chuzestan or Chufistan, evidently indicating its original appellation Cush.

The third river is thus described; *and the name of the third river is Hiddekel, that is it which goes before Assyria.* Hiddekel, the Hebrew name, is rendered by the LXX interpreters Tigris; and that this was the Hiddekel of Moses has been argued from the etymology of the word Tigris. In the Levant they call it Diglath; and if we take away the aspiration from Hiddekel, we have the word Dekel, which the Syrians termed Diklat, called by Josephus and the Chaldee paraphrasts, and also by the Arabians and Persians Diglath, and by the modern orientals Degil and Degolah, by Pliny Diglito, and by the Greeks, instead of Digli, Tigris. Hence it is inferred, that the names Tigris and Diglito are one and the same, varied according to the diversity of dialects or languages. The method observed by Moses in reckoning up these four rivers is also alleged as a presumptive argument, that the Hiddekel is the Tigris. Having named the Pison and the Gihon, it was natural for him to return towards the place where he was writing, and to mention the first river he met with on his return, and this was the Tigris. Besides, the river Tigris actually runs along Assyria, the province or district surrounding Niniveh the capital, so considered with respect to the place where Moses was writing.

As to the fourth river, or the Euphrates, it would naturally be the last mentioned by Moses. This river and the Tigris join together into one channel, which is afterwards divided again into two channels, the westerly one of the two being the river Pison, and the easterly one the river Gihon. Now, the country of Eden was situated on the common channel of these four rivers; and the words of Moses obviously intimate, that the Garden of Eden, or the terrestrial paradise, lay on the single channel, which is common to all the four rivers, for *from thence*, that is, out of Eden, it was parted and became four heads. Some other circumstances have been adduced in order to ascertain the situation of Eden; The fertility of the soil has been alleged as affording a concurring argument in favour of the district to which it has been now referred. It has been further argued, that Moses, by saying the garden was planted *eastward* in Eden, designed to mark out to them, in what part or place of the land of Eden Paradise was situated. Since, then, Paradise lay in the easterly part of the land of Eden, and the river that watered it ran through that province before it entered into Paradise, it must follow, that Paradise was situated on one of the turnings of this river, that goes from west to east, and probably at the easterly end of the southerly branch of the lowest great turning, taken notice of by Ptolemy.

It has been imagined that the "Garden of Eden" was the original of those curious gardens, which the princes of the East caused to be made, and by which they would represent this delightful spot. Such was that golden garden valued at 500 talents, which Aristobolus, king of the Jews, presented unto Pompey; and which Pompey afterwards carried in triumph, and consecrated to Jupiter in the capitol. It has been also apprehended, that the conformity between the words "Garden of Eden" and "Garden of Adon" seems to shew,

that to the garden of Eden was owing the rise of those gardens consecrated to Adonis, which the Greeks, Egyptians, and Assyrians, planted in earthen vessels and silver baskets, for the purpose of adorning their houses, and which they carried about in their processions. Hence it has likewise been supposed, that the poets formed their "Fortunate islands," the "Elysian fields," the "Meadows of Pluto," and the gardens of the Hesperides, of Jupiter, and of Alcinoüs, as well as those of Adonis. Wells's Geography of the Old Testament, vol. i. Shuckford's Creation and Fall of Man.

EDEN, in Geography, a town of Germany, in the circle of Westphalia, and county of Rietberg; one mile E.S.E. of Rietberg.

EDEN, a river of England, which rises in Westmoreland, on the borders of Yorkshire, traverses the county of Cumberland, and discharges itself into an arm of the sea, called Solway Frith; about seven miles below Carlisle.

EDEN, a river of Scotland, which runs into the Tweed, not far from Coldstream.

EDEN, a poll town of America, in Hancock county, and state of Maine, incorporated in 1796, taken from the northerly part of mount Desert; 764 miles easterly from Washington.—Also, a township of Orleans county, in the state of Vermont, N.W. of Craftsbury, which adjoins to it.

EDENBURG, a town of Hungary, 29 miles S.W. of Presburg, and 36 S. of Vienna.

EDENBERRY, a town of Ireland, in King's county; 29 miles W. of Dublin.

EDENKOBEN, a small town of France, in the department of Mont Tonneur, chief place of a canton in the district of Spire, with a population of 3014 individuals. The canton has 26 communes, and 16,468 inhabitants.

EDENTON, a district of America, on the sea coast of N. Carolina, bounded N. by the state of Virginia, E. by the ocean, W. by Halifax district, and S. by Newbern. It is subdivided into nine counties, *viz.* Chowan, Pasquotank, Perquimans, Gates, Hertford, Bertie, and Tyrrel. It contains 56,986 inhabitants, of whom 21,632 are slaves. The lands in this district are level, rich, and well watered, and produce abundance of wood, chiefly pine, oak, cypress, and juniper.

EDENTON, the capital of the above district, is a poll town and port of entry, situated at the head of a bay on the N. side of Albemarle sound, and at the N.E. side of the opening of Chowan river. It contains more than 150 wooden buildings, and 1302 inhabitants, of whom 713 are slaves. Its public buildings are an ancient brick episcopal church, a court-house, and a gaol. The prosperity of this town, though its situation is favourable for trade, has been retarded by its insalubrity. It is 97 miles N. of Newbern and 440 S.S.W. of Philadelphia. N. lat. 36° 6'. W. long. 77° 11'.

EDER, a town of Africa, in Morocco, on the coast of the Atlantic; 10 miles N.E. of Cape Cantin.—Also, a river of Bohemia, which runs into the Elbe, at Leitmeritz.—Also, a river of Germany, which runs into the Felda; seven miles S. of Cassel.

EDERIC, a town of Asia, in the country of Tibet; 40 miles S.S.E. of Tofun-Hotun.

EDERITZ, a town of Germany, in the circle of Upper Saxony, and principality of Anhalt-Cothen; four miles S. of Cothen.

EDESHEIM, a town of Germany, in the circle of the Upper Rhine, and bishopric of Spire; 14 miles W. of Spire.

EDESSA, in *Ancient Geography*, a city of Asia, in Mesopotamia, and the capital of Mygdonia, which formed a part of Osroene; seated on the bank of a small river called Scirtus,

Scirtus, N.E. of Zeugma, and E.S.E. of Samofata. It was about 20 miles beyond the Euphrates, into which the Scirtus discharged itself. Edessa is said to have been one of those numerous cities, which were built by Seleucus Nicator about 300 years B. C. It was once a place of great celebrity, and famous for a temple of the Syrian goddess, which was one of the richest in the world; and hence it was denominated Hierapolis, or the holy city. During the intestine broils, which greatly weakened the kingdom of Syria, Abgarus, or Abgarus, seized on the city of Edessa, and its fruitful territory, which he erected into a new kingdom, styling himself king of Edessa, and transmitting the same title to his posterity. He left this small principality in a very flourishing condition, and was succeeded by his son Abgarus II.; the name of Abgarus being common to all the kings of Edessa. This prince made himself master of the province of Osrhoëne, and entering into an alliance with Pompey against Tigranes the Great, king of Armenia, supplied his army with provisions. In the Parthian war he pretended to take part with Crassus, but maintaining a private correspondence with the enemy, contributed to the great overthrow which the Romans sustained at Carrhæ. From him the royal authority descended to Abgarus III. a prince celebrated by ecclesiastical historians on account of the letters which are supposed to have passed between him and our Saviour. (See *ABGARUS*.) We learn from St. Austin, (apud Aug. Epist. 230.) that our Saviour promised Abgarus that the city should be impregnable; and Evagrius (Hist. Ecclæs. b. iv. c. 27.) observes, that although this circumstance was not mentioned in our Lord's letter, it was the common belief; which was much confirmed, when Cosroes, king of Persia, having set down before it, was obliged to raise the siege. The deliverance of the city is ascribed to the picture of Christ, which was the perfect impression of his face on linen, and which being exposed on the rampart, served as a palladium to the besieged. This image was revered as a pledge of the divine promise already mentioned, that Edessa should never be taken by a foreign enemy. After this important service, the image of Edessa was preserved with respect and gratitude. This fable, as Gibbon imagines, (Rom. Emp. vol. ix.) was invented between the years 521 and 524, most probably after the siege of Edessa in 540. Abgarus V. reigned in the time of the emperor Claudius, and joined C. Cassius, governor of Syria, who had been ordered by that emperor to place Meherdates on the throne of Parthia; but abandoning the Romans in the heat of an engagement, he occasioned the defeat of their army. Abgarus V. was contemporary with Trajan, and was declared by him friend and ally of the Roman people. But he afterwards destroyed and burnt the city of Edessa. Another prince of the same name reigned at Edessa in the time of the emperor Severus, and having assisted him in his wars in the East, attended him to Rome, where he was received and entertained with extraordinary pomp and splendour. But being afterwards suspected by Caracalla of holding a correspondence with the enemies of Rome, and being summoned to justify himself before the emperor, he was, by his order, confined, and his kingdom reduced to a Roman province. The emperor Julian took occasion, on account of the disorderly conduct of the Arians in this city, to confiscate the whole property of the church, and to distribute it among the soldiers. In the time of the crusades, towards the close of the 11th century, count Baldwin, being called to the assistance of a Greek or Armenian tyrant, who had been suffered under the Turkish yoke to reign over the Christians of Edessa, accepted the character of his son and champion; but no sooner was he introduced into the city, than he inflamed the

people to the massacre of his father, occupied the throne and treasure, extended his conquests over the south of Armenia and the plain of Mesopotamia, and founded the first principality of the Franks or Latins, which subsisted 54 years beyond the Euphrates. About the middle of the 12th century, Zenghi, son of Alcantar, a valiant Turk, having commenced his military career by the defeat of the Franks at Antioch, proceeded to the siege of Edessa, and after 25 days, he stormed the city, and recovered from the Franks their conquests beyond the Euphrates.

EDESSA, in *Geography*, a town of European Turkey, in the province of Macedonia, near the Vitricza, called by the Turks "Moglena"; 316 miles W. of Constantinople. N. lat. 40° 50'. E. long. 22° 3'.

EDESSENUM, the name of a famous collyrium, reckoned among the number of the monochemera, or such as cured certain disorders of the eyes in one day. It is supposed to have had its name edesseium from the city of Edessa, where it was first invented, and in great use. Its composition was this: take gum arabic, tragacanth, farcocolla, acacia, and starch, of each two drams; opium, four drams; ceruse, eight drams; cadmia, sixteen drams; these were all to be reduced to a fine powder, and afterwards mixed with a sufficient quantity of water, to be used to wash the eyes.

EDETA, *LIRIA*, in *Ancient Geography*, a very ancient town of Spain, situated towards the south, at some distance on the left of the river Turia, N.W. of Valencia. It has given name to the *Edetani*, whose territory extended from the Iberus to the river Xucar, and was bounded by Celtiberia on the well, and on the east by Iberia. This territory contained, besides Edeta, several other towns, as Salduba or Saragossa; Celsa below Salduba, and on the opposite side of the river; Belsa, Carthago Vetus, S. of Celsa; Turbula or Teriv. near Abarcaçin, where the Edetani were defeated by Quintus Minucius, A. U. C. 577; Segobriga or Segorbe, on the right bank of the Morvicdro; Saguntum or Morvicdro, destroyed by Hannibal and restored by the Romans, famous for its clay; and Valentia or Valencia.

EDFUERIM, in *Geography*, a town of Norway; 36 miles N. of Berga.

EDGAR, in *Biography*, one of the most distinguished of the Saxon kings of England, was son of Edmund. When he was but 13 years old, he was placed by the insurgents, who had rebelled against his brother Edwy, at their head, and upon the death of Edwy he succeeded peaceably to the throne, in 959. The monks and Dunstan had been the instruments of Edgar's elevation, and to them he gave great powers, allowing them the government of all monasteries instead of the secular canons, who were accused of a general dissoluteness of manners. This prince, however subservient to the monks in religious concerns, never gave the civil and military concerns of his kingdom out of his own hands. He maintained a large body of troops to repel the invasions of the Scots, and fitted out a navy, which he always kept under strict discipline, to prevent any attack of the Danes; hence he secured the submission of the little independent princes of Wales and Ireland. One of the most remarkable circumstances in the reign of Edgar, is the extirpation, or at least, the great diminution of wolves in the southern parts of the island. This he effected by commencing the punishment of certain crimes for a fine of wolves' tongues, and by exchanging a tribute in money from Wales for a payment of the heads of those animals. Edgar, in the monkish histories, is celebrated for his piety, but he was a man of very licentious morals. As his reputation allotted a great number of foreigners to his court, they imported all the vices of their respective countries, and contributed to encourage the king's licen-

licentiousness, and to corrupt the simple manners of his subjects. One of his amours has afforded an interesting subject for a tragedy. Elfrida, daughter of Olgar, earl of Devonshire, was highly celebrated for her beauty; the report reached the king, who sent his favourite, the earl of Athelwold, to discover if the praises bestowed upon her were such as her beauty claimed. The earl found it too great for him to withstand. He satisfied the king by a false report, that it had been greatly exaggerated, and then obtained leave to marry her as a very rich heiress. Edgar soon discovered the artifice, and desired to be introduced to his wife, who, perhaps, ambitious of being the wife of the king rather than of one of his subjects, displayed her person in the most striking manner. Edgar, transported with rage, drew Athelwold to a retired place in a wood under pretence of hunting, stabbed him with his own hand, and shortly after married the widow. King Edgar, says judge Blackstone (vol. iv.), who, besides his military merit, as founder of the English navy, was also a most excellent civil governor; observing the ill effects of three distinct bodies of laws, *viz.* the Dane-lage, West-Saxon-lage, and Mercian-lage (see *COMMON LAW*), prevailing at once in separate parts of his dominions, projected and begun what his grandson king Edward the Confessor afterwards completed, that is, one uniform digest or body of laws to be observed throughout the whole kingdom; this was probably no more than a revival of king Alfred's code, with some improvements suggested by necessity and experience; particularly the incorporation of some of the British, or rather Mercian customs, and also such of the Danish as were reasonable and approved, into the West-Saxon-lage, which was the ground-work of the whole.

EDGARTON, in *Geography*, a port of entry and post-town of Massachusetts, and chief town of Duke's county, situated E. of the island of Martha's Vineyard. The fertile island of Chabaquidick is within the jurisdiction of Edgerton, and has a small trade to the West-Indies. It is 100 miles S. S. E. of Boston, incorporated in 1671, and containing 1226 inhabitants.

EDGCOMB, formerly *Freetown*, a township of America, in Lincoln county and state of Maine, E. S. E. of Wiscasset, containing 989 inhabitants. It was incorporated in 1774, and is distant 180 miles N. by E. from Boston.—Also, a county of Halifax district in N. Carolina, bounded S. by Pitt county, S. W. by Wayne county, and Tar river, which affords a communication with several counties in the state, W. by Nash county, and E. by Martin and Halifax counties. It contains 9898 inhabitants, of whom 3580 are slaves.

EDGCUMB-BAY, a bay on the N. E. coast of New Holland. S. lat. 20°.

EDGCUMB-Island, one of the cluster called "Queen Charlotte's islands," in the South sea, so called by Capt. Carteret in 1767. It has a fine pleasant appearance, and lies in S. latitude 11° 10'. E. long. 165° 14'.

EDGE in *vish a ship*, in the *Sea Language*, is said of a chace, that is making up to it.

EDGE away, is to decline gradually from the shore, or from the line of the course which the ship formerly steered, when she fails nearer the direction of the wind, or larger before the wind.

EDGECOMBE, MOUNT, in *Geography*, a high round mountain, so called by Cook in 1769, situated upon the main land S. W. by S. of the island of Mowtohora, in the South Pacific ocean, and not far from the sea. It stands in the middle of a large plain, and on this account is the more conspicuous. S. lat. 37° 59'. E. long. 192° 7'.

EDGECUMBE, Cape, a cape on the west coast of North

America, in the north Pacific ocean. It is a point of land that shoots out from a round elevated mountain, called by Capt. Cook, in 1778, "Mount Edgcombe." N. lat. 57° 3'. E. long. 224° 7'.

EDGEFIELD, a district of South Carolina, in America, bounded N. by Saluda river, which separates it from Newbury district, S. W. by Savannah river, which divides it from the state of Georgia, and W. by Abbeville. This district is about 45 miles long and 24 broad. The post-office in this district, called "Edgefield court-house," is 20 miles from Abbeville court-house, 25 from Augusta, and 60 from Columbia.

EDGEMONT, a township of America, in Delaware county, Pennsylvania, containing 509 inhabitants.

EDGEWARE, a town of England, in the county of Middlesex, on the borders of Hertfordshire, with a weekly market on Thursday; 8 miles N. W. of London.

EDGHILL, the name of an elevated place in Warwickshire, situated about 14 miles from the town of Warwick, and near the village of Kington, or Kenton. It is memorable in the military annals of the kingdom for a battle fought here in the time of the civil wars between king Charles and the parliament: on which occasion nearly 1500 persons were killed in the field, among whom were several of the nobility. It occurred October 23, 1642, and the monarch's army proved victorious. They afterwards marched to Banbury, took possession of its castle, and then proceeded to Oxford. Mr. Jago, in a poem entitled "Edge-hill," has related many interesting events concerning this engagement, and has described the features of the country with much felicity and propriety.

Near this place is the noted vale of Redhorse, so called from a figure of a horse cut on the side of a hill. The figure is supposed, by Mr. Wise, who has written a dissertation on the subject, to have been cut in commemoration of the valorous feats performed by Guy, earl of Warwick, who possessed Fulbrook castle in the vicinity.

EDGINGS, in *Gardening*, rows of shrubs, herbs, or flowers, placed by way of borders around beds, compartments, &c. For the edgings of compartments, box seems the most proper. See *Box*.

EDHILING, **EDHILINGUS**, an ancient appellation of the nobility among the Anglo-Saxons.

The Saxon nations, says Nithard, Hist. lib. iv. is divided into three orders, or classes of people; the edhilingi, the frilingi, and the lazzi; which signify the nobility, the freemen, and the vassals or slaves.

Instead of edhiling, we sometimes meet with atheling, or atheling, which appellation was likewise given to the king's son, and the presumptive heir of the crown. See *ATHELING*.

EGHIR, in *Geography*, a town of Hindoostan, in the country of Golconda, 10 miles W. of Rachore, and 75 S. W. of Hydrabad.

EDICT, an instrument, signed and sealed by a prince, to serve as a law to his subjects.

Edicts have no room in England, where the enacting of laws is not lodged in the king, but in the parliament.

In the Roman law we find frequent mention of the edict of the prætor, *quod prætor edixit*, which was a phrase appropriated to the ordinances of the prætor; though it was sometimes also used on other occasions.

These occasional edicts of the prætors supplied the silence or ambiguity of the laws. This ancient prerogative of the Roman kings was transferred, in their respective offices, to the consuls and dictators, the censors and prætors; and a similar right was assumed by the tribunes of the people, the ædiles, and the pro-consuls. At Rome, and in the provinces, the duties of

the subject, and the intentions of the governor, were proclaimed, and the civil jurisprudence was reformed by the annual edicts of the supreme judge, the praetor of the city. As soon as he ascended his tribunal, he announced, by the voice of the crier, and afterwards inscribed on a white wall, the rules which he proposed to follow in the decision of doubtful cases, and the relief which his equity would afford from the precise rigour of ancient statutes. A principle of discretion, ever congenial to monarchy, was introduced into the republic: the art of respecting the name, and eluding the efficacy of the laws, [was improved by successive praetors; subtleties and fictions were devised to defeat the plainest meaning of the decemvirs, and where the end was salutary, the means were frequently absurd. A jurisdiction thus vague and arbitrary was exposed to the most dangerous abuse: the substance, and also the form of justice were often sacrificed to the prejudice of virtue, the bias of laudable affection, and the grosser seductions of interest or resentment. But the errors or vices of each praetor expired with his annual office; and the temptations of injustice were removed by the Cornelian law, which compelled the praetor of the year to adhere to the letter and spirit of his first proclamation. It was reserved for Adrian to accomplish the design, which had been conceived by Caesar; and the praetorship of Salvius Julian, an eminent lawyer, was immortalized by the composition of the "Perpetual Edict." Dion Cassius fixed the perpetual edict in the year of Rome 686. (tom. 1. l. 36.) This well digested code was ratified by the emperor and senate; the long divorce of law and equity was at length reconciled; and instead of the twelve tables, the perpetual edict was fixed as the invariable standard of civil jurisprudence. This perpetual edict was formed by a selection from all the ancient edicts of praetors, and Adrian ordained that this should be always considered as a law, from which no deviation should be allowed.

The celebrated "Edict of Milan" was announced by Constantine about five months after the conquest of Italy, A. D. 313, as a solemn and authentic declaration of his sentiments; and was the means of restoring peace to the Catholic church. In the personal interview of the two western princes, Constantine, by the ascendant of genius and power, obtained the ready concurrence of his colleague Licinius; the union of their names and authority disarmed the fury of Maximian; and after the death of the tyrant of the East, the edict of Milan was received as a general and fundamental law of the Roman world. (The Latin original of this edict is preserved by Cæcilius (De Mort. Persecut. c. 48.); and Eusebius (Ecc. Hist. l. x. c. 3.) has given a Greek translation of it, which refers to some provisional regulations. The wisdom of the emperors provided by this edict for the restitution of all the civil and religious rights of which the Christians had been so unjustly deprived. It was enacted, that the places of worship and public courts, which had been confiscated, should be immediately restored without any expence. The salutary regulations which guard the future tranquillity of the faithful are formed on the principles of enlarged and equal toleration: and the two emperors concurred in proclaiming to the world that they granted a free and absolute power to the Christians and to all others, of following the religion which each individual might prefer, as the best adapted to his life. They also exacted from the governors of the provinces a strict obedience to the true and simple meaning of an edict, which was designed to establish and secure, without any limitation, the claims of religious liberty, and they assign two weighty reasons, which induced them to allow this universal toleration: the humane intention of consulting the peace and happiness of their people,

and the pious hope, that by such a conduct, they shall appease and propitiate the Deity, whose seat is in heaven. Gibbon's Hist. Rom. Emp. vol. iii.

In the French law, edicts, *édits*, make a great figure; they are of various kinds; some importing a new law, or regulation, as the edict of duels, that of second marriages, &c. Others, the erection of new offices, establishment of duties, rents, &c. Sometimes articles of pacification, as the edict of Nantz, passed by Hen. IV. in 1598, and revoked by Louis XIV. in 1685, &c. Edicts are all sealed with green wax, to shew that they are perpetual and irrevocable.

Edicts with them were much the same as proclamations with us; but with this difference, that the former had the authority of a law in themselves, from the power which issued forth; whereas, the latter are only declarations of a law, to which they refer, and have no power in themselves.

EDICT, *chamber of the*. See CHAMBER.

EDIFICE, *Ædificium*, a building. See BUILDING.

The word is formed of the Latin *ædis* and *facio*, I make.

EDILE, or rather *Ædile*. See *Ædile*.

EDINBURGH, in Latin *Edenburgum*, or *Aneda*, in Geography, the capital of Scotland, is a large, populous, and ancient town situated in the northern part of the county of Mid Lothian, or Edinburghshire, about two miles south of the estuary of the river, or frith of Forth; 380 miles N.W. of London, and 225 N.E. of Dublin, in W. long. 3° 35' N. lat. 55° 56' 22".

The origin of Edinburgh is involved in much obscurity. That part of Scotland where it is situated formed, in the days of Agricola, the Roman province of Valentia. On the departure of the Romans from Great Britain, this province fell into the hands of the Saxon invaders, under their leaders Osta and Ebusa, in the year 452, and continued in their possession till the defeat of Egrid, king of Northumberland, by the Picts, in 685.

The earliest mention of Edinburgh has been detected by the industry of Mr. David Macpherson, in the "Annales Ultoniennes," a manuscript in the British Museum, where this passage occurs, under A. D. 657, "Bellum Gine Murefan et Obfessio Edm." In 950, Eden town is mentioned, in an old manuscript quoted by Camden, as being evacuated by the Saxons, and abandoned to Indulf, king of the Scots. In a charter of Alexander I., Edinburgh is called *Edensburgh*; in one of David I., *Edwynsbure*; in the Chronicle of Melrose, *Edenbure* and *Edinburh*; by Simon of Durham, *Edwinesburgh*; in the Chronicle of Lanercost, *Edwynesburgh*; by Hemingford, *Edenburgh*; in the Polychronicon of Hgden, *Edenburgh*; by Knighton, *Edynsberg* and *Edensburgh*; by the prior of Inchleven, *Eödynburc*, *Edynbrowch*, *Marydn-calle*, and the *Sorrowful Hill*; by the highlanders *Dun Edin*; and by the Welsh, *Myned Agned*. This last appellation of *Myned Agned*, or *Caer Agned*; in English, *Maiden-castle*; and, in Latin, *Castrum Puellarum*, might, in time, have been mistaken into *Aned*, and then inverted into *Edan*, a conjecture, which was first suggested by the Edinburgh reviewers, and which appears, in some degree, supported by the Latin *Aneda*.

Mr. J. Sibbald, in his "Chronicle of Scottish Poetry," thinks, that Snadoun East must have been Edinburgh, because Stirling was Snodon, or Snodie West; so that its name was first *Sæddinburgh*, then *Neddenburgh*, and, lastly, *Edinburgh*. Others derive its name from Edwin, a Saxon monarch. But the most probable etymology is from the Gaelic *Edin*, the steep face of a rock, a compound which occurs in *Edenbely*, *Edinmore*, and other local appellations. When the Saxons acquired possession of the for-

EDINBURGH.

tracs, Dun Edin, of course, became Edinburgh; the former name being still retained by the highlanders.

To David I. Edinburgh must have been indebted for the distinction of being a royal borough, as this king is supposed to have been the first who erected royal boroughs in Scotland, and in his charter of foundation of the abbey of Holyroodhouse, in the year 1128, the town is mentioned by the title of "Burgum meum de Edwinesburg."

In the year 1215, the first parliament was held at Edinburgh, in the reign of Alexander II., but it was only after the year 1456, when parliaments continued to be held regularly in this city, that it was looked upon as the capital of Scotland. Little is known of the history of Edinburgh before this period. The oldest charter in the archives of the town, is one granted by king Robert I., on the 28th of May, 1329, in which he bestows upon Edinburgh the town of Leith, with its harbour and mills, and his grandson John, earl of Carrick, who afterwards ascended the throne by the name of Robert III., conferred upon the burghesses the privilege of erecting houses in the caisle, on the sole condition of their being persons of good fame.

When James III. was at variance with his nobles, in 1482, the inhabitants of Edinburgh distinguished themselves in his behalf, and he granted them two charters, in which, among other privileges, the provost was made hereditary high sheriff within the city, an office which is still enjoyed by the chief magistrate; the town council invested with the power of making statutes for the government of the city; and the corporated trades were presented with a banner, known by the name of the "Blue Blanket," which still exists, and is always confided to the convener of the trades.

A considerable degree of alarm was excited at Edinburgh, in 1497, by the first appearance of the venereal disease, which, being considered as a species of plague, all persons affected with it were sent to Inchkeith, a small island in the middle of the frith of Forth.

In the year 1504, the tract of ground to the south of the city, called the Burrough Muir, or Porrough Moor, or Myre, being covered with wood, the town-council enacted, that whoever should purchase as much of the wood as was sufficient to make a new front to his house, might extend it seven feet farther into the street. Edinburgh, in a short time, was filled with houses of wood, instead of stone, and the principal street was reduced fourteen feet in breadth.

The loyalty which Edinburgh displayed to James IV. on his expedition into England, led to the establishment of the town-guard. A considerable number of the inhabitants, headed by the earl of Angus, their provost, joined the royal army, and shared in its defeat at Flodden, in 1513. This disaster obliged, at first, every fourth man to keep watch at night: but when the alarm had subsided, the militia, known by the name of the town-guard, was raised for the defence of the city. The plague raged with violence at Edinburgh during the general conflagration which succeeded that unfortunate expedition.

In 1542, Edinburgh was plundered and burnt by the English forces, under the earl of Hartford, and when it had recovered from this misfortune, it fell again into the hands of the same commander, after the defeat of the Scottish army at Pinkey: but though exposed to pillage, it escaped conflagration.

The progress of the reformation of religion, which, about that time, spread over the greatest part of Europe, occasioned several disturbances at Edinburgh, particularly in 1559, when the boisterous Knox was appointed a preacher in the city, and French troops, whom the queen regent had called to her assistance, seized Edinburgh. These troubles were allayed

by the powerful help of queen Elizabeth of England. A parliament was held, which sanctioned the confession of faith of the reformed church.

On the 1st of September, 1561, Mary, queen of Scots, made her public entry into Edinburgh, to take possession of the throne: but the different religion in which she had been educated soon created fresh disturbances in 1563, when the town council caused the picture of St. Giles to be cut out of the town's standard, and the thistle to be inserted in its place.

During the commotions which distracted Scotland after Mary's retreat into England, Edinburgh suffered much from the divided interests of the different factions, being sometimes in the possession of the one, and at other times under the power of the other, till, at length, the castle surrendered to the English, and James, having a short time after attained his majority, a parliament was convened at Edinburgh. On the 17th of October, 1579, James made his public entry.

The spirit of fanaticism which succeeded the reformation not having yet subsided, violent commotions continued to take place at Edinburgh. In the year 1588, when the kingdom was alarmed at the approach of the Spanish armada, the people entered into a bond, known by the name of the "Covenant," for the maintenance of the true religion, and the defence of the king's person, on which occasion the town-council raised three hundred men for the protection of the city.

In December, 1591, the inhabitants of Edinburgh defeated the earl of Bothwell's attempt to seize the king. In 1592, the Presbyterian church government was established in Scotland by law: but the mutual distrust of the monarch and the clergy occasioned a fresh commotion in 1596. James, with all his attendants, withdrew to Linlithgow. Parliament, and the courts of justice, were ordered to leave a city where it was no longer consistent either with their safety or dignity to remain. Deprived of its magistrates, deserted by its clergy, who fled to England, abandoned by the courts of justice, and proscribed by the king, the capital of the kingdom was left to desolation and despair, until Elizabeth of England interceded with the offended monarch in its behalf.

On the Sunday previous to the departure of James to take possession of the English throne, in 1603, he repaired to the church of St. Giles, at Edinburgh, to bid a formal farewell to his northern subjects. Six years after, the differences between the king and the inhabitants of Edinburgh appear to have been entirely buried in oblivion. The provost was allowed to have a sword of state carried before him, and the magistrates were permitted to wear gowns on public occasions. In 1618, when James paid his last visit to Edinburgh, he was received by the magistrates with uncommon magnificence.

A perfect harmony seems to have subsisted between the court and the city of Edinburgh in the beginning of the reign of Charles I.: but this good understanding was not of long duration. The establishment of episcopacy was a favourite object with Charles, and Presbyterianism was too deeply rooted in Scotland to yield to his attempts. The people renewed the covenant against popery. Some of the bishops were assaulted, and narrowly escaped with their lives. Yet, when Charles visited Edinburgh, in 1641, he was sumptuously entertained by the magistrates.

During the civil war, which ended in Cromwell's usurpation, Edinburgh was again desolated by the plague; and almost depopulated in 1645.

Upon the accession of king William to the British throne,

the populace plundered the abbey church of Holyrood-house, having first defeated a party of about one hundred men stationed in the abbey, who adhered to the interests of James.

The union of the two kingdoms of North and South Britain caused fresh disturbances at Edinburgh in 1707. Whilst the act was passing in the Scottish parliament, four regiments of foot were introduced, in addition to the regular guards, for the purpose of preserving the peace of the city. But, during the rebellion of 1715, Edinburgh remained faithful to the cause of the house of Brunswick. An attempt of the rebels upon the castle was rendered abortive. The loyalty of Edinburgh was still more conspicuous in 1725, when the Excise Bill excited disturbances in almost every part of Great Britain.

The year 1736 was disgraced by the execution of captain Porteus of the town guard by the populace. This unfortunate officer had been found guilty of having ordered the soldiers to fire upon a mob that had assailed the guards, when they escorted to the scaffold a criminal, who had become an object of general compassion, for having enabled his companion to escape, at the peril of his own life. The queen, in the absence of the king, had granted captain Porteus a reprieve, and it was the supposition that his life would ultimately be spared, which led to this atrocious insult on government.

In the month of September, 1745, Edinburgh was occupied by the army of prince Charles, the Pretender's eldest son. General Gueft, governor of the castle, on being apprised of the circumstance, discharged several guns, as a warning for the inhabitants not to approach the castle-hill. On the 25th of the same month, he fired upon the rebels stationed at the West-port, or West-gate. This occasioned the prince to order a guard to be placed at the Weigh-house, to prevent all intercourse between the city and the castle. On the 1st of October, several persons, who were carrying provisions to the castle, were fired at by the highlanders, who, in their turn, were fired upon from the castle. Many houses in the city were damaged, and some persons wounded. To cut off all communication between the castle and the town, the prince placed guards in St. Cuthbert's church and Livingstone's yards. On a sally from the castle, one of the guard-houses was set on fire, a few of the rebels were killed, and some taken prisoners. But as these unimportant skirmishes did not raise the blockade, a cannonading was commenced against the rebel's posts, on the 4th of October; in the following night, a party from the castle burnt some houses on the eastern side of Castle-hill, where the rebels used to shelter themselves. The Pretender's army raised the blockade on the 5th, and on the 31st the prince left Edinburgh, on his march to England. His defeat at Culloden put an end to the rebellion. The provost of Edinburgh was tried for not having defended the city; but acquitted.

Several tumults of inferior importance have agitated Edinburgh in the years 1756, 60, 63, 65, 78, 79, and 84, mostly on account of a temporary scarcity of provisions, and on the repeal of the penal laws against the Roman Catholics.

The French revolution of 1789 occasioned also some disturbances at Edinburgh, and caused the trial and condemnation of a few individuals. But in the war of 1793, and in that which commenced in 1803, and is still raging, (1809) the inhabitants of Edinburgh have evinced their attachment to the genuine principles of the British constitution, by the voluntary arming of all ranks. Every attempt to disturb the peace of the city on account of a temporary high price

of provisions, has latterly been checked in its origin by the spirited conduct of the magistrates.

Edinburgh is on an island surrounded by lofty hills, except northwards, where the ground gently declines to the frith of Forth. Arthur's seat, Salisbury Craigs, and Calton hill bound it on the east; the hills of Braid and the extensive ridge of the Pentland hills on the south; and the beautiful Corstorphine hill on the west. The principal part of the old town is built upon a hill of singular form, which, rising gradually from east to west, is terminated towards the west by a precipice three hundred feet in height. On the rock forming this extremity of the hill, stands the castle, and along the summit of the ridge is carried a street, which, under the several denominations of the Lawn-market, High-street, and Canon-gate, extends from the castle to the place where the rise of the hill commences, a distance of somewhat more than a mile. At its eastern extremity, it is terminated by the palace of Holyrood-house. On each side of the hill, which thus forms the central parts of the town, is another ridge of ground inferior, however, in elevation, and terminating much less abruptly. The southern hill is covered with what may be termed the new part of the old town, which, though it contains many good streets and buildings, is laid out with little attention to that regularity which distinguishes the new town. It is connected with the central ridge by a bridge of nineteen arches, only one of which is visible. This is named the South-bridge. The intervening valley is occupied by a long, narrow, and dirty street, called the Cow-gate, from which numerous streets and alleys run up the sides of the hill to High-street.

The new town is the peculiar pride of Edinburgh, and as far as regards regularity of design and beauty of situation, it may be considered as one of the most splendid assemblages of buildings in the kingdom. It stands on the ridge to the north of the old town, from which it is separated by a deep valley, formerly a morass, called the North Loch. The communication between the two towns is effected by the North-bridge, and by an earthen mound, thrown across the valley, a little further to the west. This mound was formed entirely from the soil and rubbish obtained in laying the foundations of the new town. The north bridge is remarkable for the lightness and elegance of its structure, and for the singularity of the views which it commands.

The plan of the new town is extremely simple. Three principal streets, extending nearly a mile in parallel lines from east to west, are intersected at right angles and at equal distances by six cross streets, about a quarter of a mile in length.

The improvements of Edinburgh began in the year 1753, by the erection of the Royal Exchange. At that time Edinburgh occupied the same space of ground which it had done for two centuries before; but since that period, it has been enlarged to more than twice its former size. The extent of Edinburgh, from east to west, is about two English miles, and from north to south nearly the same distance. The circumference of the whole is upwards of eight miles.

Edinburgh is governed by a town council of 33 members, twenty-five of whom constitute the ordinary council, the remaining eight are named extraordinary councillors. The chief magistrate, whose office is much the same with that of the lord mayor in London, is styled lord provost. He is high sheriff, coroner, and admiral within the city and liberties, and the town, harbour, and roadstead of Leith. Under him are four magistrates, called bailies, equivalent to the aldermen in London. There is also a dean of guild, who has the charge of the public buildings, and without whose warrant no house can be erected within the city. The revenue

venue of the town consists of an impost on wines, shore dues at Leith, duties on markets, &c. and is supposed to amount to 10,000*l.* sterling, annually. The hall, where the magistrates meet, is situated at the north-west entrance of the Parliament square, or Parliament close.

Of the principal public buildings the most ancient is the castle, situated on the western and rugged extremity of the central hill, on which the old town is built. It is separated from the buildings of the city by a space of about 350 feet in length and 300 in breadth. The area of the rock, on which it stands, measures about seven English acres. It is 294 feet above the level of the sea, and accessible only on the eastern side; all the other sides are nearly perpendicular. It is chiefly used as a station for soldiers. A long range of new barracks affords accommodation to about one thousand men, and the other buildings together may accommodate as many more. The governor is generally a Scottish nobleman. It has besides a deputy governor, who resides in the garrison, a fort-major, a store-keeper, a matter-gunner, and a chaplain.

Holyrood house, the royal palace of Edinburgh, stands at the eastern extremity of the city, at the bottom of Canon-gate. It is a beautiful building of a square form; the area in the centre measures 230 feet in circumference. The western front consists of two lofty double towers, joined by a gallery adorned with a ballustrade, in the middle of which is a portico decorated with four Doric columns, which support a cupola in the form of an imperial crown. Underneath the cupola is a clock, and over the gateway are the royal arms of Scotland. Round the area in the inside is a handsome arcade. The more ancient parts were built by James V. about the year 1528. It was destroyed by Cromwell's troops, and repaired and altered into its present form by Charles II. The duke of Hamilton is hereditary keeper of the palace. Some years ago, apartments were fitted up in Holyrood house for the residence of the count of Artois. Adjacent to the palace is the ruined abbey of Holyrood-house, founded by David I. in 1128, and destroyed by the English about the middle of the fifteenth century.

The buildings of the mint of Scotland, which were erected in 1574, but in which no money has been coined since the union, form a small square, which, as well as the abbey of Holyrood house, is an asylum for insolvent debtors.

The parliament house occupies the south and west angles of the square, to which it gives its name. It was begun in 1632 and completed in 1640. It forms no inconsiderable ornament to the city; but yields in point of grandeur to the register office, a building erected in 1774 for preserving the public records. This noble edifice stands at the east end of Prince's-street, and its front looks southward along the north bridge. In its centre is a large dome 50 feet in diameter, and 80 in height, lighted from the top by a window 15 feet in diameter.

On the north side of the High-street is the Royal Exchange, an elegant building in the form of a square, with a court in the centre. The bank of Scotland, at the head of the entrance to the earthen moand, is likewise one of the architectural ornaments of Edinburgh. Two other public buildings of lesser importance are the tollbooth and the weigh-house.

In the old town the houses are all remarkably high, some having not less than thirteen stories. Each story, or *flat*, as it is termed in Scotland, is inhabited by two families.

The population of Edinburgh, including the port of Leith, was in 1678 computed at 35,500 persons; in 1755 at 70,430; in 1775, according to Mr. Arnot, at 13,806 families, which he supposed to have given 82,836 individuals; in 1791, ac-

ording to Sinclair's statistical account, at 84,886 persons; and in 1802, Mr. Pinkerton supposed it to fall little short of 90,000. But in 1806, as there had been fifty new streets built since 1791, Mr. J. Stark was of opinion, that Edinburgh, with its suburbs and the seaport town of Leith, might fairly be supposed to contain considerably upwards of 100,000 inhabitants.

The religious establishments of the P. A. byt-rian church are upheld by twenty-four ministers. The number of parishes into which Edinburgh is divided, and of which they are the pastors, are fourteen, including the suburb of Canon-gate, St. Cuthbert's, and Leith. The number of churches is the same; but some of the buildings contain under their roof more than one place of worship. There are also three chapels belonging to the old episcopal church of Scotland, in which are retained all the ancient forms of this establishment. One of the bishops resides in the town. Besides these, there are three chapels of the English episcopal establishment, where the form of worship is similar in every respect to that observed in England. The places of worship belonging to the different dissenters from the established church, and other sectaries, are numerous. The Antiburghers have two; the Burghers three; the Relief three; the G. afflers, or Sandimanians, one; the Quakers one; the Bereans one; the Baptists one; the Methodists one; and the Roman Catholics two. There is likewise a chapel where the service is performed in the Gaelic or Erse language for the benefit of the highlanders. Tabernacles have been lately established on Mr. Whitefield's plan, under the auspices of Mr. Haldane. That in Leith walk is perhaps the largest place of worship in Scotland. The total number of churches and chapels is forty-four. Considered as architectural objects, the principal churches are St. Giles's church, a magnificent Gothic fabric, Tron church, St. Andrew's church in the new town, and St. George's chapel. Edinburgh has a society for propagating Christian knowledge, and a military society.

Among the charitable institutions of Edinburgh, the Royal Infirmary, founded in 1736, claims the first rank. The male and female patients are kept entirely distinct. Two hundred and twenty-eight sick individuals can be accommodated in separate beds. It has a well lighted theatre, where upwards of 200 students may attend, when chirurgical operations are performed. The Public Dispensary is an useful supplement to the Royal Infirmary. The principal hospitals are Heriot's, Wattson's, Gilkies's, Merchant maiden, Trades maiden, Trinity, orphan, and Lying-in-Hospital. Edinburgh has also a society for the relief of ministers' widows, and for the sons of the clergy, a madalen, and an asylum for the blind. A new house of industry was opened in January 1801, for the reception of poor and destitute women, who are willing to work but unable to procure employment, and for poor female children who are taught lace working. The whole of their earnings is regularly paid to them; they have a warm comfortable room to work in, their dinners gratis, and such of the women as have young children fix pence weekly in addition; they come in the morning and go home at night.

The celebrity which Edinburgh has derived from the splendid talents of Hume, Blair, Home, Robertson, Black, and others, is still kept up by a numerous body of literary and scientific men, whose valuable productions are daily issuing from the Edinburgh presses. In the year 1763, Edinburgh had only six printing offices; in 1790 their number had increased to twenty-one; in 1800 to thirty; and in 1805 to forty. They employ upwards of 120 printing presses.

The university of Edinburgh was established in the year

1782, by king James VI. and from that period to the present has been progressively advancing in its reputation as a school of literature and science. The buildings connected with this institution are situated in the old town on the most southerly of the three ridges. They were originally constructed on so small a scale, that a new building was commenced in 1789, the greatest part of which, however, is still in an unfinished state. It is called the college; the university business is conducted in what remains of the old building, and in that part of the new structure which is completed. The plan of education pursued in the college of Edinburgh is the same with that of the Protestant German universities, and differs materially from that adopted in the English universities. The students are dispersed in lodgings in different parts of the town, and no direct obligation is imposed upon them to attend to the daily business of the college. They are taught through the medium of lectures, delivered by the several professors of the different departments of science and literature. The number of professors is about thirty, of whom eleven are connected with the several branches of medical study, three with the study of divinity, and three with that of the law. The remainder are occupied with the classes of general literature, mathematics, and philosophy. Their emoluments depend almost entirely on the fees which they receive from the students. As a school of medicine, the university of Edinburgh ranks higher than any other in Europe. The anatomical theatre, situated in the new part of the college buildings, is remarkable for its spaciousness and elegance. There are no academical honours conferred except in the medical line, and the number of graduates frequently exceeds forty in a year; foreigners generally compose the fifth part of this number. An idea may be formed of the progress of the school of medicine at Edinburgh, from its commencement in 1720, till the year 1800, from the following statement.

From 1720 to 1790, consequently during 70 years, the number of students in medicine amounted to	12,800
And from 1790 to 1800, during ten years only, do	3,130
Total	15,930

Upon an average of five years the total number of students is supposed to be 1400 annually. Mr. Thomas Forsyth, in his "Beauties of Scotland," states the university to be attended by from 1200 to 1400 students.

Connected with the university are the observatory and the botanic garden. The latter contains about five English acres of ground; its collection of plants is very large. The observatory is situated on the top of Calton hill. It was completed in 1792, but in a style far inferior to what its utility deserved. Astronomy has made very little progress at Edinburgh. The library of the university is valuable and extensive.

The grammar school of Edinburgh, called the High school, was established in the year 1578; the number of scholars, by whom it is annually attended, is upwards of 600.

But it is not only its scholastic institutions that Edinburgh owes its literary celebrity. Several courses of lectures are delivered during both the winter and summer sessions, by individuals who have no immediate connection with the university. There are also several learned societies, among which the Royal Society assumes the first place. It was founded in 1783, and published the first volume of its Transactions in 1788. The Society of Antiquaries was likewise

established in 1713, and published its first and only volume in 1792.

Societies established for the verbal discussion of questions of literature and science are numerous at Edinburgh. They are attended not merely by the students, but by many respectable and well informed inhabitants of the place. The principal are the Medical Society, remarkable for a large and valuable medical library, and the Speculative Society, where the subjects discussed are of a more general nature.

The advocate's library, which is by far the most considerable in Scotland, is chiefly supported by the money paid by advocates on their admission into the faculty. It has valuable collections of manuscripts, prints, coins, and medals. Of printed books there are upwards of 60,000 volumes.

Theatrical entertainments, music, and dancing, constitute the principal public amusements at Edinburgh. The theatre stands at the north end of the North bridge, in the middle of a small square, called Shakespeare-square. Contrasted with the other public edifices it has but a mean appearance. Subscription concerts are performed in the assembly rooms and at Carr's, formerly the royal circus. The equestrian company, which annually resorts to Edinburgh, performs in a temporary wooden building erected on the north side of the college.

The police of Edinburgh is well conducted. A new court of police was opened on the 13th of July, 1805. It is under the superintendance of a judge of police and a clerk. There are six inspectors for the different wards, into which the city is divided. All offenders under the police act are prosecuted by the inspectors. The old prison, in the building called the Tolbooth, is, however, deficient in those accommodations which the benevolent Howard has so humanely recommended. The new Bridewell, or house of correction, finished in 1796, is on a larger and more liberal scale, and particularly well situated, being on a high hill on the east of the suburb, named the Calton.

Edinburgh is supplied with excellent spring water, which is conveyed in pipes. The markets afford all the necessaries, and many of the luxuries of life, in considerably variety. The fruit, greens, veal, poultry, butcher, and fish markets, on the north side of the High-street, occupy part of the declivity of the hill on which the old division of the city is built. They are disposed in terraces, which communicate with one another by flights of stairs; and being all in one place, they are very convenient for the inhabitants. There are, besides, butcher's shambles and shops in different parts of the city and suburbs.

The want of a proper regard to cleanliness in the inhabitants of Edinburgh, and the abominable practice of discharging filth from the windows into the streets, have been severely and frequently noticed. The New Town, however, is not liable to these animadversions, and by the strict attention of the police, the nuisance is in a great measure removed in the Old Town. Edinburgh is lighted in winter by crystal lamps, but their number is far from being sufficient for the convenience of the inhabitants.

Manufactures of different kinds are carried on at Edinburgh and in its neighbourhood. The manufacture of shawls and kerseymeres, and that of printed cottons and linens, are very extensive. For the latter Edinburgh is reported to be indebted to thirteen French protestant families from Picardy. In the environs are many large paper mills, manufactures of glass, and several cast-iron founderies. The distillation of malt spirits occupies large capitals, and candles and soap are manufactured on an extensive scale.

Edinburgh is surrounded with many fine walks, the principal of which are, the Castle-hill, the King's park, the meadows

dows and the Calton-hill, on the western side of which is a burying ground, in which are deposited the remains of the celebrated David Hume. A large rotund monument, with a simple inscription, marks the spot. This hill is also remarkable for a naval monument in honour of the hero of Trafalgar. J Stark's Picture of Edinburgh, 1806. Aikin's *Athenæum*, vol. ii. 1807.

EDINBURGHSIRE. See **MID LOTHIAN.**

EDINGTON, or **EDDINTON**, anciently *Æthendune*, a parish in the hundred of Whorlton, and county of Wilts, England, contains 170 houses and 334 inhabitants. This place is noted in the annals of English history, for a conquest, which king Alfred obtained over the Danes here. On the summit of a hill near Edington is a large encampment, called Bratton cattle, where it is stated that Alfred besieged his enemies for fourteen days, when they capitulated. The calcination covers an area of about 24 acres; is nearly of an oval form, and has very deep ditches. On the south-west face of the same hill is a monument of antiquity, said to have been cut, or formed by the Saxons, in commemoration of the event already noticed. It is a representation of a large white horse, which is formed by cutting off the surface of the ground, and laying bare the substratum of chalk.

The church at Edington was built by bishop de Edington, who was a native of this place, and who also founded here a college for secular canons. This prelate was treasurer and chancellor to king Edward III. For further particulars relating to Edington and the bishop, see *Beauties of Wiltshire*, vol. ii. 8vo.

EDISTO, or **POMPON**, a navigable river of America, in S. Carolina, which rises in two branches from a remarkable ridge in the interior part of the state. These branches, meeting below Orangeburgh, form Edisto river, which is navigable for 100 miles.—Also, a post town of Orange county, in S. Carolina; 577 miles from Washington.

EDITOR, of *eds*, I publish, in the commonwealth of learning, a person who takes care of publishing the work of another author, frequently an ancient author.

Erasmus was a great editor of ancient writings; the Louvain doctors, Scaliger, Petavius, Fa. Sirmond, bishop Walton, Mr. Hearn, &c. are learned editors; the Benedictines, of the fathers; the Dauphins, of the classics; Hardouin, of the councils. &c.

EDMER, in *Biography*, a learned English Benedictine monk, who flourished about the end of the eleventh century. He belonged to the order at Canterbury; was abbot of the monastery of St. Alban's, and afterwards raised to the see of St. Andrew's, in Scotland. He was a voluminous writer, chiefly in biography; and from his pen we have the lives of St. Anselm, archbishop of Canterbury; of St. Oswald, archbishop of York; of St. Dunstan, archbishop of Canterbury, with a letter to the monks of Glastonbury; of the blessed Bregwin, archbishop of Canterbury; and of Odo, archbishop of Canterbury. He wrote likewise "A Treatise on the Liberty of the Church," in vindication of Anselm, in his contests with king William Rufus; and the history of his own times from 1066 to 1122, which was published by the learned Selden, with notes, in folio, 1623. Moreri has mentioned the titles of his other works, which, however, being of less repute, need not be noticed here.

EDMONDES, *Sir Thomas*, was born at Plymouth, in Devonshire, where his father was chief officer of the customs. He was introduced to court by his namesake, Sir Thomas Edmondes, comptroller of the queen's household, and being initiated into public business by Sir Francis Wallingham, secretary of state, he was, through his means, employed by the illustrious queen Elizabeth in several embassies.

In 1592 he was appointed her resident or agent at the court of France, with a salary of twenty shillings a day; and on the 17th of May, 1596, she made him a grant of the office of secretary to her majesty for the French tongue. Between this and the spring of 1603, he was employed in divers foreign embassies. At this period he received the honour of knighthood from king James I. and, upon the conclusion of the peace with Spain, was appointed ambassador to the archduke at Brussels. He was about the same time chosen one of the representatives for the borough of Wilton, in the parliament which was to have met at Westminster Nov. 5, 1605, but was prevented by the discovery of the gunpowder-plot. He was, in 1608, sent ambassador into France, where he continued, with some intervals of absence, till the year 1617, when he returned, and was appointed successively to the offices of comptroller of the king's household, privy councillor, and treasurer of the household. In 1625 he was elected one of the burgesses for the city of Oxford, but on the meeting of parliament his election was declared void, and he was chosen for another place. In June 1629 he went out again ambassador to the French court, and with this concluded all his foreign employments. The remaining ten years of his life he spent in privacy. He died Sept. 20, 1639. Sir Thomas was a man of sound understanding, uncommon sagacity, and indefatigable industry; he was firm and unshaken in the discharge of his duty, beyond the influence of terror, flattery, or corruption. Some of his parliamentary speeches have been printed. His letters and papers, in 12 vols. folio, were once in the possession of secretary Thuloe, and afterwards of lord chancellor Somers. The style of them is clear, strong, and masculine; free from the pedantry and purities which infected some of the best writers of that age. *Biog. Brit.*

EDMUND I. king of England, was son of Edward the elder, and succeeded his brother Athelstan. This was in the year 941, but the Northumbrians, ever restless and seeking for opportunities of rebelling, threatened the peace of Edmund's reign. The king marched suddenly against them, and reduced their leaders to the most abject submission. As a surety for future good behaviour, they offered to embrace Christianity, "a religion," says Hume, "which the English Danes had frequently professed, when reduced to difficulties, but which, for that very reason, they regarded as a badge of servitude, and shook off as soon as a favourable opportunity offered." Edmund, however, was a man of spirit and penetration; he put it out of the power of the Northumbrians to become his enemies, and conquered Cumberland, conferring its government on Malcolm king of Scotland, on condition that he should do him homage, and protect the north from all future incursions of the Danes. This prince was young and full of spirit, but his reign was short, and his death violent. At a festival in Gloucestershire he saw Leolf, a notorious robber, who had been condemned to banishment to expiate his crimes. Enraged at his insolence in joining the royal party, he bid him depart, and not complying with the order, Edmund seized him with his own hand, when the villain, taking advantage of the struggle, stabbed the monarch to the heart. This event happened in the year 946, before he had completed the sixth year of his reign. Hume, *Hist.* vol. i.

EDMUND II. surnamed Ironside, king of England, was eldest son of Ethelred II. He obtained the name of Ironside from the hardy valour which he displayed in the contests maintained between his father and the Danish kings, Sweyn and Canute. Edmund had no sooner succeeded to the crown, than he found himself obliged to contend for it in the field. In a battle with Canute, which he meant to

be decisive, he was defeated, in consequence of the defection of Ederic, duke of Mercia. Edmund was not destitute of resources, but assembling a new army at Gloucester, he felt himself capable of disputing the field, when the Danish and English nobility, equally harassed with these convulsions, obliged their kings to come to a compromise, and to divide the kingdom between them by treaty. To Canute were ceded the northern and midland parts of the kingdom, while the southern provinces were left to Edmund. This prince survived the treaty only a short month, being murdered at Oxford by two of his chamberlains, who were instigated to the bloody deed by Ederic. Canute now became sole master of the kingdom, but the line of Edmund was again introduced by the marriage of his great grand-daughter Matilda to Henry I. Hume, vol. i.

EDOIA, in *Ancient Geography*, a town of Arabia Felix, placed by Diodorus Siculus in the isle of Panchaea.

EDOLO, in *Geography*, a town of Italy, in the Bressan; 15 miles N.N.W. of Breno.

EDOM, in *Scripture History and Geography*, a name given to Esau, the eldest son of Isaac, and signifying *red*. (See Gen. xxv. 24—34.) He was the progenitor of the Edomites, afterwards called Idumæans. The place of their first habitation was mount Seir (Gen. xxxv. 6—9.) which had been originally occupied by a people called Horites, and the mountain itself was denominated Hor. (See Numb. xx. 22—28. Deut. ii. 12.) Some time before Esau's settlement in this place, this region had taken the name of Seir, probably from that of a considerable person among the Horites, and retained it afterwards to the exclusion of Hor, which was restricted to a part of this mountainous district. (Numb. xx.) This country was situated on the south of the Salt, or Dead sea, extending from this sea to the Red sea, or Arabian gulf. (1 Kings, ix. 26.) From this circumstance we deduce the origin of the appellation of Red sea, which was given to the Arabian gulf, as it denoted the same with the sea of Edom, or Idumæan sea. Some of the Greeks, in allusion to the signification of the Hebrew word Edom, called it the Erythrean sea, from the term which denoted red in their language. This country, when first inhabited by the Horites, was probably governed by patriarchs, or heads of families, which was the most ancient form of government, afterwards by kings, elected into their office, and, in process of time, by governors, styled dukes, and succeeding one another by primogeniture. The Edomites, who occupied the country after the Horites, were first governed, like them, by dukes, and afterwards by kings; which change, in the form of their government, seems to have taken place, with a view to their greater security against the hostile attacks of invaders, during the emigration of the Israelites in the wilderness. The king of the Edomites refused to grant these emigrants from Egypt, towards Canaan, a free passage through their country, though they requested it in a very respectful manner; and first threatened to oppose them with the whole force of his kingdom, if they made an attempt for this purpose, and afterwards, upon their renewed solicitations, actually took the field, and marched to oppose them. At length, however, he furnished them, for money, with such supplies as his country afforded. (Numb. xx. 14. 21. Deut. ii. 28, 29.) After this transaction, we find no account of the Edomites, till the reign of king David. In the mean time, however, they appear to have extended their dominion, to have applied themselves to trade and navigation, and to have seized on the empire of the sea, at least in the Arabian gulf. They trafficked in very rich commodities, such as pure gold, gold of Ophir, the topaz of Ethiopia, coral, and pearls, (Job, xxviii. 15—20.) and established a very considerable

kingdom. But, in the height of their prosperity, their country was invaded by the victorious arms of Israel, about the year 1040 B. C., and Edom began to feel the effects of Isaac's prophecy, that "the elder should serve the younger." For David, after having gained several victories over the Syrians, Moabites, and Ammonites, finished his conquests with Idumæa. Hadad, their king, being a minor, and the party that accompanied him, sought the protection of Pharaoh, and the young prince was kindly received by him, and supported with the dignity becoming his royal rank; and the queen's sister was given to him in marriage. (1 Kings, xi. 15—20.) Whilft Hadad made his way into Egypt, others of the Edomites took different routes; some fled to the Philistines and the sea-ports, and fortified Azoth, or Azotus. Accordingly, they contributed to improve the inhabitants of those parts in the arts of navigation and commerce, and laid the foundation of the future celebrity of the Phœnicians, who are known to have migrated from the Red sea, about the time when David conquered and dispersed the Edomites. Hence it was, that the Philistines called many places Erythra, in memory of their being Erythreans, or Edomites, and of their coming from the Erythrean sea. Edom, Erythra, and Phœnicia, it is said, are names of the same signification, the words denoting a "red colour;" and hence, it is probable, that the Erythreans, who fled from David, settled in great numbers in Phœnicia, that is, in all the sea-coasts of Syria, from Egypt to Zidon; and by calling themselves Phœnicians, in the language of Syria, instead of Erythreans, gave the name of Phœnicia to that whole sea-coast, and to that only. Other Edomites, who dealt in shipping, escaped the rage of the conqueror, by taking a longer route, and went towards the Persian gulf. In a word, the Edomites dispersed into all parts, when they found that they could have no security in their native country. Hadad, after remaining for a considerable time in the court of Pharaoh, obtained a dismissal, and, returning to Idumæa, made several unsuccessful attempts to regain his dominions. In the mean time, the kingdom of Edom remained under the house of David till the days of Jehoshaphat, being governed by deputies, or viceroys, appointed by the kings of Judah. At length, about the year 889 B. C. the Edomites, anxious to recover their ancient liberty, embraced an opportunity which offered itself for this purpose, and succeeded. For, in the days of Jehoram, the son of Jehoshaphat, the whole nation arose, and, assassinating, or expelling their viceroy, appointed for themselves a king; and, having gained a considerable advantage over Jehoram's army, they were afterwards defeated with great slaughter, and obliged to retire within their intrenchments. After this period, the Edomites remained secure from any attempts against them on the part of the kings of Judah for 60 years. At length they became subject to the king of Babylon; and when the captivity of the Jews commenced, they retaliated upon them, with ample vengeance, the sufferings they had endured in the days of king David, cut off many of them who were endeavouring to make their escape, and consumed with fire the remains of the temple, as soon as the Chaldeans, or Babylonians, had withdrawn. They even attempted to level the whole city with the ground, and insulting the God of Israel with horrid blasphemies, triumphed in the prospect of beholding the utter end of the Jewish nation. For this cruelty, they were threatened by the prophets with a severe retaliation, importing, that, for the devastation they had made in Judah, they should behold their land become desolate, when those of their now-oppressed enemies should flourish. (Ezek. xxx. xxxii. xxxv. xxxvi. Joel, iii. Amos, i. ix.) These predictions were speedily accomplished: for

their

their country was distracted with violent commotions and persecutions; inasmuch, that many of them abandoned it, and settled in the vacant land of Judæa, particularly in the south-western parts; and probably at this time, they made an end of the temple of Jerusalem. Those, who remained in Edom, joined the children of Nebaioth, and were ever afterwards called Nebatzæans; and thus the ancient kingdom of Edom lost its name, which was transferred to that part of the land of Judæa which the refugees occupied, and which had never been part of their old kingdom, but the lot of the tribes of Simeon and Judah. This is the Idumæa, and these are the Idumæans, mentioned by Pliny, Ptolemy, Strabo, and other ancient writers.

Having traced the Edomites from their origin to the downfall of their kingdom, we shall terminate this article with a brief account of those Edomites, who settled in Judæa. Of these it is only known with certainty, that a decree was issued against them by Darius Hystaspes, commanding them to deliver up all they had belonging to the Jews. (1 Esdr. iv. 50.) Upon the decline of the Persian monarchy, and after the days of Alexander, they were under the power of the Seleucids, when their ancient aversion from the Jews being revived, they warred against that nation, under the conduct of Gorgias, their governor, for Antiochus Epiphanes; but they were constantly worsted by Judas Maccabæus, who, at last, took and sacked their chief city Hebron. (1 Maccab. v. 65. 68.) Having lost their strong holds, and many of their number, the survivors fled to two strong towns, whence many of them escaped by bribery and treachery. At length these two strong castles were forced, and 20,000 Idumæans were put to the sword. The Edomites in Idumæa were afterwards agitated by continual broils and wars, till about the year 130 B. C., they were conquered by John Hyrcanus, who reduced them to the necessity of embracing the Jewish religion, or of quitting their country. They chose the former alternative, submitted to be circumcised, and became incorporated with the Jews. Accordingly in the first century after Christ, the name of Idumæan was lost, and quite disused.

EDON, a mountain of Thrace. Plutarch speaks of a town, called *Edonide*, near the river Strymon. Steph. Byz. on the authority of Aristotle, gives this name to *Astandros*, which was situated at the foot of mount Ida.

EDONI, a people of Thrace, who inhabited the banks of the river Strymon; and their country was called Edonis, on the frontiers of Thrace and Macedonia, separated from Odontasia by the Strymon.

EDOSA, a town of Ethiopia, situated W. of the Nile. Pliny.

EDRAL, a town of Palestine, in the tribe of Judah, mentioned in the book of Joshua, and also by Eusebius.—Also, a town of Palestine, near the torrent Jabok, called *Esraci* by Eusebius and Jerom. who say that it is the same with *Adara* in Arabic, 24 miles from Bosra. It was situated in the half-tribe of Manasseh, on the other side of Jordan.

EDRED, in *Biography*, the brother of Edmund I., succeeded to the throne in the year 946. His reign, like that of his predecessor, was disturbed by the rebellions and incursions of the Northumbrian Danes, who, though quelled, were never entirely subdued, nor had ever paid a sincere allegiance to the crown of England. They attempted to shake off the yoke in the early part of Edred's reign, but he was sufficiently powerful to reduce them to submission, and having laid waste their country by fire and sword, and a punishment for their rebellion, he forced them to renew their oaths of allegiance. After this he fixed English garrisons in their most considerable towns, and placed over them an English govern-

nor, who might watch all their motions, and suppress any insurrection on its first appearance. Notwithstanding the energy of this prince's mind in matters of state policy, he was the slave of Dunstan in the superflition of the times, which obtained the name of religion. To the guidance of this priest, whom he advanced to the highest offices, he blindly and implicitly delivered over his conscience, and at length the management of his civil affairs. Through his influence, a set of foreign monks of the Benedictine order were introduced, who affected an extraordinary purity of doctrine and austerity of manners, and proved formidable rivals to the secular clergy of the kingdom. Edred died after a reign of nine years, leaving children too young for the cares of government, and the crown accordingly devolved on Edwy, nephew of the deceased king. Hume.

EDRISITES, the denomination of a dynasty of the Arabian empire, who erected the kingdom and city of Fez, on the shores of the Western ocean. This dynasty was founded by Edris, who died in the year of the Hegira 214 (A. D. 829.) in the prime of manhood, and terminated in the year of the Hegira 307. A. D. 919.

EDRON, a port of Italy, in Venetia, formed by the two rivers Medoacus, according to Pliny, and supposed by Hardouin to be the modern *Chioza*.

EDROS, or HEDROS, a desert isle, placed by Ptolemy on the western coast of Hibernia; named Andros by Pliny; and supposed by Camden to be the isle of Bardsey.

EDSAN, in *Geography*, a river of Russia, which runs into the Lena; 20 miles S.E. of Ziganik.

EDSWOL, a town of Norway; 18 miles S.W. of Berga.

EDUCATION, in a general sense of the term, may be defined the art of bringing up, forming, and instructing children.

Education, in the limited acceptation of the term, may be considered as that regulation of the external impressions by which the development and cultivation of the various faculties and affections of the mind are affected. In this definition very general expressions are used, because the term education is applicable to that direction of the external impressions by which the progress of the mind is checked, by which its faculties are rendered inactive, or its affections deadened or perverted; as well as to that by which its faculties and affections are developed and cultivated. But though general, our definition is scarcely sufficiently comprehensive, for we sometimes hear of the *education of circumstances*, and, *accidental education*; and no sufficient objection presents itself to this application of the term to cases in which there is no direct intentional interference for the purpose of regulating the impressions. To comprehend these cases of the application of the term, we must define education to be, that series of impressions, whether intentional or accidental, by which the development, &c. See above.

We here speak of education in the way in which the term appears to be usually employed, with reference to the effects produced on the mind by external agency, without considering the direct efforts of the individual object of it. But no one who has watched the processes of the mind, particularly where it is vigorous, and its education (in the most limited sense) neglected, can hesitate in the belief, that more is often done by the express voluntary exertion of the individual towards the cultivation of his faculties and affections, than by any external agency. This self-culture ought to be considered as one species of education; and in order to include it under the term, we must once more extend our definition, and state, that education, in the most comprehensive acceptation of the term, is that series of impressions, or

voluntary exertions of the mind, by which the development and cultivation of the various faculties and affections are affected.

Though we allow it to be frequently convenient to apply the term to a series of what are to us casual impressions, yet our concern with education, except merely as a branch of mental philosophy, is limited to the cases in which the interference of man may modify or controul the effects of external circumstances on the mental faculties and affections. But these are much more numerous than would at first be supposed, by those who have had no practical acquaintance with the object; and hence appears the almost incalculable importance of mental philosophy, as a foundation for the *art* of education, that it serves to disclose the effect of external impressions in the culture of the mind, and (where they are under human controul) shews what are to be employed, and what are to be avoided, according to the various differences of ability or disposition, in order to remedy or supply the effects of original constitution on the mental system. It is true, mental philosophy is yet imperfect and limited; but, even in its present state, it renders most important aid in the business of education.

To enter into the subject of education in its widest extent, would be to shew how every class of circumstances, whether casual or intentional, operates in affecting the development and culture of the powers and affections of the mind;—our object is much more limited; and we shall be satisfied if we succeed in laying before our readers a tolerably extensive and accurate view of those means, the employment of which may be expected to assist such development and culture, without attempting to investigate those minutiae which are not of general occurrence.

Without ascertaining whether there can be any clearly defined distinction between the moral and the intellectual powers, it is obvious, that the difference between thoughts and feelings, between the understanding and the affections, and also between the means by which the powers of the understanding are to be developed and improved, and those by which the affections are to be produced and regulated, is sufficiently distinct to allow of our dividing the business of education, according to its object, into *intellectual* and *moral*. In order to bring the system of thought and feeling into its due state of perfection, both as to comprehensiveness and vigour, and to proper direction, the organs of sensation must have vigour and sensibility: much, too, of intellectual improvement and of moral culture depends upon the state of the muscular and nervous system in general. The education of the human being, as far as respects these objects, may be termed *physical*.

Under the article *PHYSICAL EDUCATION*, then, we shall, without encroaching upon the science of pathology, give a view of those means by which the external organs of the mind, the organs of sensation, and the muscular and nervous system, so far as the mind is directly concerned with their operations, are to be preserved in a sound and healthy state, and improved in activity and vigour. In *INTELLECTUAL EDUCATION* we shall enter into the consideration of the cultivation of those powers of the mind which come under the head of understanding. And in *MORAL EDUCATION* we shall consider the methods of cultivating and regulating the affections. Under the topic of intellectual education, the various branches of knowledge, which form the objects of instruction in different departments of education, will of course receive some attention.

As there will be sufficient opportunity, under these three separate articles, to enter as fully as the nature of our work will admit, into all the particular topics connected with the

subject of education, we shall not enlarge much here, and we shall only subjoin a few observations of a general nature, respecting the importance of attention to the object,—what has hitherto been publicly done with a view to the improvement of the art of education, and, the education of the poor. Respecting the second of these topics, we shall have an opportunity of saying more in our separate articles, and shall content ourselves here with a very summary view. Respecting the first, it is unnecessary to enlarge, for we consider it as a prominent and very pleasing feature of the age, that the business of education is pretty generally considered as of primary importance, and is made much more an object of scientific attention, than it has been at any former period. The long agitated question, whether and in what cases public or private education is to be preferred, will be best considered under the separate heads of Intellectual and Moral Education.

The opinion that every thing in the intellectual and moral system is the result of education, has had some ingenious supporters, but it can never stand the test of accurate observation. If every human being could be placed in precisely the same circumstances for the first few months after birth, and could be exposed to exactly similar impressions in every respect, there is no room for reasonable doubt, that still great diversities would be manifest in their dispositions and capacities. We infer this, because the rudiments of disposition and capacity are obviously different when we have first the power of discerning them; and it is inconceivable that the few impressions which are received within two weeks after birth, should of themselves produce all that diversity, which, even then, is, in many instances, clearly perceptible to the accurate observer. In some, even at that early period, it may be distinctly perceived that the sensitive powers are quick and lively; in others, they are dull and sluggish: and this early aptitude to receive sensations with different degrees of vividness, must arise from a difference in the original system, over which education will seldom be found to triumph. Greater or less degrees of physical sensibility, are the foundation of greater or less degrees of mental sensibility; and it is, in a great measure, upon the vigour of our early sensations, that the furniture of the mind, the thoughts and affections, depend for their strength and durability. Besides, suppose what we will with respect to the precise degree in which the mental system depends upon the conformation of the brain, more or less the former must be affected by the latter; and while the external structure, and the external organs of the mind, so essentially differ in different children, as soon as mind is at all perceptible, it is reasonable to suppose that the internal structure, and the more concealed corporeal system on which the offices of the mind depend, must also be essentially different.

But though education cannot do every thing, it can do a great deal. It cannot implant an aptitude to receive vivid and vigorous sensations where it is not, but it can render the sensations actually received more efficacious. It can call into action, or greatly repress, the sensibilities of the frame. It can enliven the powers of the mind, and exercise and strengthen them. It can extend, refine, and invigorate the affections.

Probably the advocates for the opinion that the intellectual and moral system owes its peculiarity entirely to education, do not themselves understand their position in that extent in which it is understood by their opponents: and both, in general, seem almost equally willing to admit the only valuable practical inference from the discussion, *viz.* that an early, well-directed, and persevering attention to the business of education, is of the highest importance, and that it is the duty

Duty of all who have it committed to them, to discharge it fully and faithfully. It must, however, be allowed, that the opinion that there is no original intellectual difference between man and man, though founded upon a very curious examination and incomplete induction, is more likely to stimulate to exertion than that which some of its opponents have maintained, *viz.* that where there are certain inherent natural tendencies, it is in vain to attempt to free the mental constitution from them. The principal practical injury resulting from the former is, that when persons find, as inevitably they must, that their efforts are often unavailing, and that it is totally out of the power of any individual to have under his command all the impressions by which the dispositions and powers of the mind are to be exercised, and their peculiar cast given to them, they are apt to sit down in despair respecting the efficacy of what is in their power. Happily the great work of education can, in the earliest periods of life, go on without the direct interference of man; and if he will only permit the powers of the mind to be unfolded as occasion calls for them, and keep off improper impressions which might debase and pervert the affections, almost every thing will be done well. We are, however, well aware that this cannot be thoroughly done without skilful care and attention; but an excess of care and attention is, in many instances, the bane of both the mental and moral powers. In the early period of education, our business is to watch the opening intellect, and sometimes to present opportunities and excitements for its exertion;—to allow the kindly affections materials for their growth, and to check these which injure the moral system. In the later periods a great deal is of course to be done by the direct methods of instruction. All we wish to maintain is, that one grand secret of education is to temper our direct interference, and to rest satisfied without forcing the progress either of the intellect or of the affections.

The foundation of a true and comprehensive system of education must be laid in right views as to the laws of the human mind. It is true, that in many respects a practical acquaintance with these laws is sufficient to guide us wisely in the business of education; and numbers, possessing nothing but good sense, accurate observation, and right dispositions, have succeeded in conducting the intellectual and moral culture of others beyond what might at first be expected; and partial systems of education may be formed, by those who have only such practical knowledge, which may prove of eminent utility: but a full, comprehensive, and just system of education, can be founded only upon an enlightened and extensive acquaintance with the principles of the human mind, with the characteristic features of intellectual and moral excellence, and with the manner in which the powers of the mind are expanded and perfected, and in which the dispositions are formed and properly directed. In fact, the theory of education is nothing more than the extension of one grand branch of mental philosophy. If any essential change should take place in the condition of men, and the visions of a benevolent philosophy should ever be realized as to the diffusion of knowledge and moral worth, it will only be through the extension of practical knowledge as to the objects of education, and the means by which they are to be effected. It is much to be wished that the results of individual observation, as to the effects of certain discipline or other circumstances, on peculiar dispositions or intellectual biases, were to be more frequently registered for public notice. Perhaps it requires some considerable degree of mental culture, and of acquaintance with the principles of the human mind, to determine these effects with any tolerable precision; but if the object were more attended to, by degrees

a large fund of observations would be collected, from which the more philosophic mind might produce an approximation towards a rational and comprehensive system of education, such as would serve materially to accelerate the progress of the community towards its utmost degree of improvement.

It is earnestly to be wished that a judicious view of the chief practical principles of mental philosophy were accessible to all the thinking part of the public; and that to impart them to the female sex in particular, and familiarize their minds with them, formed an essential branch of their education from the period when their understandings had been prepared by the acquisition of the more usual objects of education, (we speak of course of those cases in which female education has been directed beyond exterior accomplishments,) to that in which they themselves enter upon the business of education. The education of the nursery, at least maternal education, has indisputably the greatest share in the determination of the future character, particularly in a moral point of view.

One female writer, (Miss Hamilton.) has the high praise of rendering accessible to her sex, some of the most important principles of the philosophy of the mind. Her work on education, as far as it respects the affections, is of very great value; and there is reason to hope that it has had, and will have, great influence in judiciously guiding maternal instruction. Her hints respecting the cultivation of the intellect are not equally valuable. They are founded on an erroneous classification, and often are themselves inaccurate and indistinct. But even from this part persons who have paid but little attention to the subject may learn much; and as to the cultivation of the affections, her work is yet unrivalled. As far as respects early education, this point is first in importance; for every one knows that the affections are the grand spring by which the whole system is animated; and where this is active and well-regulated, there is a principle on which the future culture of the intellect may be founded with the best prospect of success.

We do not mention Miss Hamilton as having alone been guided by mental philosophy in her views on education, but simply bring forwards her work as containing more of the philosophy of the mind than is accessible perhaps in any other form, to those who have not received considerable culture of intellect. Her contemporaries, Miss Moore and Miss Edgeworth, have furnished many exceedingly important remarks respecting the principles of education: and, except in the examination, arrangement, and correction of the principles which have already been detailed by them, and their predecessors, Locke, Priestley, &c. and in the accumulation of new facts, little more, probably, will be done, till some one, early impressed with the importance of the object, disciplined to habits of correct observation, and of cautious and accurate induction, and possessed of sound views of the philosophy of the mind, and of the effects of external circumstances upon different dispositions and intellectual biases, and different periods of mental and moral culture, shall devote himself to the undertaking: when it may reasonably be expected, that a system will be produced which may serve as a clear, steady, and secure guide to the well informed parent or preceptor.

It is not probable that in uncivilized states any direct attention can have been paid to education, except so far as relates to instruction in the arts of gaining subsistence and clothing, and in providing means of defence, and to the cultivation of courage and fortitude. In some of the ancient states which had made considerable advances towards civilization, education was made the care of the state. Sparta presents the most complete system. It has been well observed, that all the plans of Lycurgus had in view to keep society

just as it then was: certainly the mode of education adopted by that legislator had this object as its guide and principle. But how ever much we may admire the system of Lycurgus, considered as cultivating a spirit of heroism, and of exclusive patriotism, surmounting alike all regard to the interest of other states, and their own individual interests, it is obvious that it was narrow and confined, and had no tendency to elevate the human intellect, or to stimulate into activity any noble and generous affections which had not the love of their country as their basis. Could the institutions of Lycurgus have been preferred in their vigour and efficacy, the Spartans might have continued precisely the same, destitute of all knowledge of the arts and sciences which adorn and improve society.

Wherever the specific education of the people has been under the guidance of the state, it has hitherto (with little exception) been calculated only to mould them all into one form; to produce habitual submission to the will of one, or to the will of many. No doubt can exist which is to be preferred, the total neglect of education, or that artificial and forced method of which we now speak; but all that the state has to do is, to take care that none shall be without the means of instruction, and to leave every individual to follow the bent of his own inclination, or to the peculiar direction of his employment of them. Further than this, the interference of the state is as injurious to education, as it is to commerce.

It is to be supposed, that where individuals possessed any strong sense of moral, and especially of religious obligation, the attention would be paid to the training up of those habits and dispositions, which are favourable to virtue and religion. In those nations which were first civilized, the power of the parent was considered as absolute; and as implicit submission was, from the first, inculcated upon the young, the labour of education was greatly diminished, and the limited knowledge and sentiments of the parent were very easily communicated to youth. The round of duty was less extensive, and its parts less complicated than at present. Among the Israelites, where moral education appears to have made the greatest advances, the system of duty was completely laid down in the written law; so that all the knowledge which the age and country possessed, was certainly to be gained, and the moral principles certainly to be regulated aright, where the parent employed wisely that authority which the law enforced, and which the customs of the times would otherwise have allowed. One grand object of moral education, so far as it respects rectitude of dispositions and affections, is to cultivate the habit of self-control. Religious people, of all periods, who have possessed the light of revelation, have, in a particular manner, been sensible that this habit lies at the foundation of moral worth; and where the authority of the parent is generally preserved, the cultivation of this habit follows as a matter of course. It requires a wise choice of means to prevent filial submission from being the submission of a slave, rather than of a child; but where it is acquired, and rightly directed, the foundation is laid for submission and obedience to the will of God; and where this principle takes a firm hold on the mind, almost every thing is done that could be wished, to further the progress of the individual towards moral worth. Freedom from improper biases of affection, or the possession of power to correct them, is absolute excellence.

The necessity of a tolerably correct direction of the early propensities, in order to promote domestic comfort, must in a great number of cases have led to such direction of them, without any view to the future advantage of the individual. But with respect to those who were to come forwards in the

employments of the state, or in any other way to be exposed to the notice of their countrymen, the advantages of early instruction in knowledge, and of the early cultivation of those qualities which the wants of the age and country made of great estimation, were so obvious, that they appear to have led, in a great variety of cases, to great attention to the work of education; and though we have not, in any instances, any account of the procedures of the ancients, yet, in the few circumstances which have been recorded, we perceive that, long before any thing like a systematic plan of education was adopted, individuals made education an object of primary concern. The principal systematic work of antiquity, on the subject of education, is indisputably that of Quintilian. This writer was possessed of great good sense, excellence of disposition, and extensive information; and from his work, though it had a particular object in view, much may be learned by the modern instructor, respecting education in general. Various excellent principles are to be found scattered up and down in those general parts, which amply repay our perusal, though we are seldom invited to proceed by elegance of language, or brilliance of imagination. From different facts which he mentions, we have reason to suppose that, in his time, education was in a most degraded state at Rome: and his reflections have, probably, been more useful to the moderns, than to his contemporaries.

In our own country, within the last two centuries, much has been written on the subject of education; and among others, the great Milton produced a work, which had principally as its object to correct the plans of instruction then prevalent. But the first writer who had in view to deliver a system of education in general, was Mr. Locke. One would naturally expect that a man, who had seen so much of the world, and known so much of human nature, would at once advance the business of education to the rank of science. He did a great deal; and though what is excellent is mixed with much that is exceptionable, and though his system, if followed implicitly, would not fully accomplish the objects of education, yet he laid the foundation for national attention to education, in like manner as he first properly developed the mode of examining the faculties and dispositions of the mind.

Since the time of Locke, various writers have come forward to the public notice, with observations and discussions on the subject of education. Several have had in view merely to detail plans of instruction in the different branches of commercial, literary, or philosophical education: others have taken a wider range, and have investigated the principles of education. Some of their peculiarities of opinion will probably come under examination in our separate articles; and we shall only add on this point, that all which detail the results of experience, are in themselves considered valuable; but that there are many writers, who seem to have had in view rather to captivate the imagination with any airy system, and to strike out new and shorter roads of education, than to trace out those plans which alone can lead to satisfactory results, by being founded on just views of human nature.

We shall now conclude our article by a few words respecting the education of the poor. Taken in a religious point of view, no one can reasonably doubt, that it is our duty to afford to the children of the poor the means of knowing their duty; but we shall not enlarge upon the subject in that view, but attend to it as a national consideration, as an object in which national welfare is intimately concerned.

It may be truly said, that there is no direction of benevolence, in which national and individual benefit meet more clearly go hand in hand. And the reason is obvious. Wherever industry,

Industry, frugality, and obedience to the laws form the decided character of the poor, there the rich will have their rights respected, and, at the same time, the poor will be contented and happy. Perhaps, for this purpose, national industry must be principally directed in the channel of agriculture; but however this may be, there can be no doubt that whatever constitutes national wealth, the industry of the poor must have a principal share in the acquisition of it; and that whatever be the true source of national happiness, the good conduct of the poor is essential to it. Few, who have thought closely on the subject, can doubt, that, among all classes of society, the only general and permanent source of good conduct is a good education; that training up of right habits, and instilling of useful knowledge, which, together, may give the individual true views as to duty, and a decided bias towards the practice of it. We would not be understood to mean, that no one who has not had the benefits of a right education, can be expected permanently to possess those qualities which render a man a good member of society, but maintain it, as a certain general principle, that a good education is the only permanent source from which good conduct can be expected. And this is peculiarly the case among the poor, so far as civil and political duties are concerned. The crimes of the rich, against society at least, are usually so much the object of general notoriety, that a man is almost constrained to keep within those limits which the law imposes, and those few additional limits which a sense of honour sometimes sets where better principles are wanting. But among the poor, such a variety of opportunities occur, for the almost unobserved practice of petty fraud and deceit, and the pressure of circumstances is so much felt, that if you can truly say of a poor man, that he is thoroughly and strictly honest, you at once establish his character. And can any one doubt, that the foundation of such honesty, to say nothing of other virtues, is laid in a right education? And is there sufficient reason to believe, that the poor, unaided by the rich, unnoticed, neglected by them, will, as a general case, communicate to their children such habits and knowledge as may render them upright characters, and, in their respective situations, truly worthy members of society. Let us take the great mass of the uneducated poor in large and crowded cities, and consider their situation, and that of their children. "Every child," says the Philanthropic Society, "brought up in the resort of vicious and profligate people, must almost inevitably imbibe the contagion of moral turpitude, and become an enemy to those laws on which the general good depends. Lying is the first lesson of their tongues, and theft of their hands; every object they see is at war with decency, and every impression they receive is a vice." Such a picture, one would hope, cannot often be, in all its parts, correctly drawn out of the metropolis; but of its leading features too many originals may be found in every populous place, among those who have had none of the now common advantages of education. And can any one doubt that such dreadful ignorance of even the common duties of society, is, as far as it extends, a most serious national injury; that every approach to it, is, in its degree, baneful; and that the only general, secure, and permanent preventative, is the putting of the means of instruction in the power of all.

When contemplating the importance of early education in raising the character of society at large, it is highly satisfactory to perceive that we are fully borne out by an appeal to facts; and we shall here bring forwards to the attention or recollection of our readers, some invaluable statements from the writings of the late philosophic and benevolent Dr. Currie, (*Burns's Life and Works*, vol. i. p. 351.) which

we wish to become familiar to every individual who has the power, either by his influence, wealth, or personal exertion, of aiding the highly important cause of the education of the poor. "The influence of the school-establishment of Scotland on the peasantry of that country," says Dr. Currie, "seems to have decided, by experience, a question of legislation of the utmost importance—whether a system of national instruction for the poor be favourable to morals and good government."

In the year 1698, Fletcher of Saltoun declared as follows: "There are at this day in Scotland two hundred thousand people begging from door to door. And though the number of them be perhaps debatable to what it was formerly, by reason of this present great distress," a famine then prevailed, "yet in all times there have been about one hundred thousand of those vagabonds, who have lived without any regard or subjection either to the laws of the land or even to those of God and nature; fathers incestuously accompanying with their own daughters, the son with the mother, and the brother with the sister." He goes on to say, "that no magistrate could discover that they had ever been baptised, or in what way one in a hundred went out of the world." He accuses them as frequently guilty of robbery, and sometimes of murder. "In times of plenty," says he, "many thousands of them meet together in the mountains, where they feast and riot for many days; and at country weddings, markets, burials, and other public occasions, they are to be seen, both men and women, perpetually drunk, cursing, blaspheming, and fighting together." This high minded statesman, of whom it is said by a contemporary, "that he would lose his life readily to save his country, and would not do a base thing to save it," thought the evil so great, that he proposed as a remedy, the revival of domestic slavery, according to the practice of his adored republics in the classic ages! A better remedy has been found, which, in the silent lapse of a century, has proved effectual. The statute of 1696, the noble legacy of the Scottish parliament to their country, began soon after this to operate; and happily, as the minds of the poor received instruction, the union opened new channels of industry, and new fields of action to their view."

"At the present day," continues Dr. Currie, "there is perhaps no country in Europe, in which, in proportion to its population, so small a number of crimes fall under the chastisement of the criminal law, as Scotland. We have the best authority for asserting, that on an average of thirty years preceding the year 1797, the executions in that division of the island did not amount to six annually; and one quarter sessions for the town of Manchester only, has sent, according to Mr. Hume, more felons to the plantations than all the judges of Scotland usually do in the course of a year. It might appear invidious to attempt a calculation of the many thousand individuals in Manchester and its vicinity who can neither read nor write. A majority of those who suffer the punishment of death for their crimes, in every part of England, are, it is believed, in this miserable state of ignorance!"

It is, perhaps, worth while to add to the foregoing view the following statements from Mr. Howard's works, (vol. i. p. 9. and 484.) He informs us, that the number of executions in London, for twenty-three years preceding 1772, amounted to 678, or between 29 and 30 annually: that in the twelve following years, including 1783, there were 467 executed in London, on an average of 39 annually; and in the four last years preceding 1784, the average of the London executions was 49 nearly each year. In Scotland, during

thirteen years and a half, preceding 1782, only 76 were capitally condemned, of them 54 only were executed.

Dr. Currie goes on to inform us, that schools have long been established and supported for the education of the poor in New England, in the Protestant cantons of Switzerland, and in certain districts in England, particularly in the northern parts of Yorkshire and Lancashire, and in the counties of Westmoreland and Cumberland. "The similarity of character between the Swiss and the Scotch, and between the Scotch and the people of New England, can scarcely be overlooked. That it arises in a great measure from the similarity of their institutions for instruction cannot be questioned." Dr. Currie admits, however, that it is increased by physical causes, on which he makes some judicious remarks, and thus concludes: "how much superior in morals, in intellect, and in happiness, the peasantry of these parts of England are, who have opportunities of instruction, to the same class in other situations, those who inquire into the subject will speedily discover. The peasantry of Westmoreland, and of the other districts mentioned above, if their physical and moral qualities be taken together, are, in the opinion of the editor, superior to the peasantry of any other part of the island."

Happy had it been for Britain, if the "warning counsels, the prophetic page" of Currie, had been listened to and followed by her statesmen. As far as our relation with other nations is concerned, the time is past; but we may yet profit by those representations which shew us what is to be done in order to raise the intellectual and moral character of the nation at large. It is not improbable that rational reformation will begin with national distress; but it is not too much to say, that a permanent reformation in the condition and character of the poor, can only be brought about by well-directed attention to their education, in connection with a proper regulation of the laws relative to the indigent poor. Whether in the counsels of an all-wise Providence it is decreed that Britain should be thrown from that lofty pinnacle to which she has elevated herself, time only can determine; but it appears clear, that the surest way of avoiding national judgments is by endeavouring, each in his station, to reform those evils which affect our conduct and character as a nation; and in this point of view also, the communication of knowledge to the poor, may be considered as a national benefit, and as a probable means of lessening national punishment. We shall close this article with the following general observations.

The plan of education, whether it be domestic or collegiate, should be suited to the station and views of parents, and to the genius of their children; and it is also right to consult their constitution and inclination. It is of great importance, that those who are destined to occupy superior stations in society, should enjoy the benefits of an enlarged and liberal education; that they should be furnished with every substantial and ornamental accomplishment; and those that are intended for any particular profession or employment should be principally directed to those studies which are appropriated to their respective views; and in every rank of life, an attention to the morals of youth should be a primary object. Though the municipal laws of most countries have made no provision for restraining a parent to bestow a proper education on his children; yet in the case of religion they are under peculiar restrictions in our country. Some of these restrictions, as they affect those who dissent from the religion of the state, may be thought both impolitic and injurious; and have, therefore, lately been considerably relaxed; and there is room for farther enlargement. See **DISSENTERS, PAPISTS, and TOLERATION.**

EDULCORATION. This term is applied, in *Chemistry*, to the process of freeing a difficultly soluble substance from one that is easily soluble, by means of distilled water. In fact, it differs little from lixiviation, except that the former term respects the insoluble residue, and the latter the soluble portion. Thus we say, to lixiviate wood ashes, because the object of the process is to procure the soluble alkaline ingredient separate from the earth and other impurities with which it is mixed; and on the other hand we say, to edulcorate the precipitate from alum, when the intention of the operation is to obtain the earth quite pure from soluble matter. Hence arises a practical difference between the two processes; lixiviation is carried on no longer than the water runs off charged with a sufficient quantity of soluble matter to defray the expence of boiling down, and hence a minute portion of soluble matter is always left in the insoluble residue. Edulcoration is not reckoned complete till the water returns as pure as when it was first added; hence the latter runnings are never sufficiently charged with soluble matter, to make it worth while to boil them down.

The usual method of edulcorating, is to place the substance on a filter, and continue to add successive portions of hot or cold water, till the runnings indicate, by the common tests, that they hold nothing in solution. This, however, is always tedious, and often not perfectly effectual, as the contents of the filter are in many cases very apt to clot together, so as to obstruct the thorough percolation of the water. It will be found, on the whole, a much more expeditious and satisfactory process, to place the precipitate in a large silver crucible with abundance of water, and heat it more or less according to circumstances; then withdraw it from the fire, allow it to settle for a few minutes, and pour off the clear supernatant liquor; then add fresh water to the residue, and proceed as before, till all soluble impurities are got rid of. A single hour thus employed will finish more work than a whole day in the common method; and the necessary loss on the precipitate is considerably less, which is a circumstance of no small importance to the accuracy of an analysis.

EDULCORATION, of *edulco, I sweeten*, in *Pharmacy*, is the dulcifying or sweetening of any food, or remedy, by means of honey, sugar, or syrups.

EDULIUS, in *Ancient Geography*, a mountain of Spain, in the Tarragona territory, supposed to be the modern Montserrat in Catalonia.

EDUS, a small river of Italy, in Liguria, said to be the present Sadocela.

EDWARD, in *Biography*, surnamed the Elder, king of England, was son of Alfred, whom he succeeded in the year 901. The reign of this prince was disturbed by an insurrection, at the head of which was Ethelwold, son to king Ethelbert, Alfred's elder brother, who claimed the crown as his right. Edward, after much contention, subdued his enemies, and reduced them to submission. He afterwards repelled an incursion of the Northumbrians, and completely defeated them at Teterhall in Staffordshire. During the remainder of his life, he was engaged in many conflicts, but was usually successful. He fortified many of the inland towns of England; vanquished Thurketil, a Danish chieftain, and obliged him to retire with his followers into France. He subdued several tribes of Britons, and by his activity proved himself, in some respects, worthy of his descent from the immortal Alfred. On the death of his sister Ethelsteda, he assumed the government of Mercia, which had been before independent of the crown. He died in the year 925, and was succeeded by his natural son Athelstan. Hume.

E D W A R D.

EDWARD, king of England, and surnamed the Martyr, was about fifteen years of age when he succeeded his father Edgar, A. D. 975. Though the eldest, he was opposed in his claims by his mother-in-law Elfrida, who wished to raise her own son Ethelred to the throne. Edward was supported by Danstan, who overcame every obstacle, caused the young king to be crowned, and then obtained the submission of the whole kingdom. Edward appears to have possessed little energy of mind, and to have chiefly employed himself in the amusements of the chase, and in this sort of pastime he spent four years very innocently. Incapable of any treacherous intention himself, he was suspicious of others, of whom he ought to have been perpetually on his guard. His mother-in-law had vehemently opposed his succession, yet Edward soon forgot her conduct, and behaved towards her with the greatest respect, and on all occasions expressed for his brother Ethelred a true affection; but being hunting in Dorsetshire, and fatigued with the sport, he left his attendants and rode to Corfe castle, the residence of Elfrida, with a view, perhaps, of shewing respect to his relation, and of obtaining some refreshment. He requested, while on horseback, something to assuage his thirst; the liquor was brought, but while he was in the act of drinking, a servant of the infamous Elfrida gave him a deep stab from behind. He set spurs to his horse, but becoming faint with the loss of blood, he fell, and was dragged in the stirrup till death put an end to his sufferings. He was buried at Wareham, and the tragical fate to which he had been exposed obtained for him the title of Martyr. Hume.

EDWARD, the Confessor, younger son of Ethelred II. succeeded to the crown of England in 1041; though not the true heir, he was called to the throne in preference to the sons of Edmund Ironside, who happened to be on the continent at the death of Hardicanute, the former king. The impatience of the English to free themselves from the Danish yoke, caused them to unite in favour of Edward, and the Danes in the island acquiesced in the choice. It was feared that this succession to the crown would be opposed by earl Godwin, the most powerful nobleman in the kingdom, who was on ill terms with Edward; but a reconciliation was brought about, and Godwin agreed to acknowledge the king, on condition that he would marry his daughter Editha. The external forms of marriage the king readily complied with, but either through an aversion to the person who was forced on him as queen, or through some superstitious notions that cannot be justified, he obtained from all nuptial commerce, a circumstance which obtained for him the applause of the monks, and contributed not a little to his acquiring the title of saint and confessor. Having been educated in Normandy, he introduced many of the natives of that country to his court, and French language and manners prevailed throughout the country. Godwin made use of this as a popular reason for exciting discontent among the people, though the usage of his daughter was probably the real cause of his enmity. The rebellion of Godwin was unsuccessful, and he was obliged to seek refuge in Flanders, where, however, he recruited his force, and returned with a powerful fleet, with which he sailed to London. Edward was now glad to enter into a compromise with him, and banish the Normans. By this treaty the danger of a civil war was for the present averted, but the authority of the crown was considerably impaired, or nearly annihilated. Godwin, indeed, shortly after died, but he was succeeded by his son Harold, who in the end became a more dangerous enemy to the king than even his father. About the year 1055 Edward restored to the throne of Scotland Malcolm, the son of Duncan, by the defeat and death of the usurper

Macbeth. Edward was now fast advancing in years, and was anxious to appoint a successor; with this view he sent for his nephew Edward, son of Edmund Ironside, who died in a short time after his arrival in England. He next, with the hope of depriving the family of Godwin of all hopes, turned his attention to William, duke of Normandy, and took some measures to secure his succession, but he was incapable of acting with that decision which the nature of the case required, and while he was considering what should be done, he died on the 5th of January, 1066, in the sixty-fifth year of his age, and the twenty-fifth of his reign. He was the last of the Saxon line that ruled in England. His reign was on the whole peaceable and fortunate, but he was more indebted for the prosperity which he enjoyed, to the conjunctures of the times, than to his own abilities. The Danes gave him little trouble, and the mildness of his own disposition, with a love of peace, led him to acquiesce in the power assumed by Godwin and Harold. The talents and power of these noblemen enabled them, while they were entrusted with authority, to preserve domestic peace and tranquillity. Edward is deserving of high commendation for his attention to the administration of justice, and his compiling for that purpose a body of laws, which he collected from those of Ethelbert, Ina, and Alfred. The compilation, though now lost, was long an object of affection to the English. This prince, who, on account of his piety, obtained the reputation of being able to cure diseases, was the first who touched for the king's evil; and "his successors," says Hume, "regarded it as a part of their state and grandeur to uphold the same opinion. It has continued down to our time, and the practice was first dropped by the present royal family, who observed, that it could no longer give amazement even to the populace, and was attended with ridicule in the eyes of all men of understanding." Hume, vol. 1.

EDWARD I. so denominated as being the first of that name of the Norman line, was eldest son of Henry III. and born at Winchester in 1239. He was called early into active life, and his talents were of the greatest service to his country in the contests between his father and the discontented barons. At the battle of Lewes he routed the Londoners, but pursuing them too far, he found, on his return, that the royal army had been defeated, and the king made prisoner. He himself fell into the power of the earl of Leicester, but obtaining a release, he became in his turn victorious, and put an end to all further resistance to the royal authority. In 1270 he made an expedition against the Saracens, but on his arrival at Tunis he found the French king dead, at whose desire he undertook the project, and was obliged to proceed with his forces to the holy land, where he performed many exploits of valour, and rendered himself illustrious by his heroism. So much terror did he excite among the Saracens, that they bribed an assassin to murder him, who missing his blow, only wounded the prince in the arm, and fell himself a sacrifice to the love of gain. This absence of the prince from his native country was attended with the most disastrous consequences. The laws were not executed; the barons oppressed the common people with impunity, and the populace of London returned to the practices of licentiousness, common in those times. The old king, unequal to the affairs of government, called aloud for his gallant son to return, to assist him in swaying the sceptre which was ready to drop from his feeble and irresolute hands. Edward returned, but before he could reach his native land his father was dead, and himself, without opposition, proclaimed successor. His first acts, after he ascended the throne, were to restore order, and re-animate justice in the execu-

cution of her decrees. He repressed the violence of the great, and punished corrupt judges; but his motives have been much questioned, inasmuch as he scrupled not to fill his own coffers by the fines which he exacted upon the guilty. The Jews felt the weight of his anger, and under the pretence of punishing usury he executed multitudes of that unfortunate race, and banished the others from his realm. He next began to inquire by what title the nobility held their estates; the question was first put to earl Warenne, a man of as much courage as himself, who replied, "By this," drawing his sword at the same moment; and he added, in a tone not to be trifled with, "that William the bastard had not conquered the kingdom for himself alone; his ancestor was a joint adventurer in the enterprise; and he himself was determined to maintain what had from that period remained unquestioned in his family." The king, feeling his danger, desisted from all farther inquiries of this nature. He next summoned Llewellyn, native prince of Wales, to do him homage, which demand being refused, the king prepared to compel him to submission by the terror of his arms, and in 1283 he completely destroyed the independence of that country. It was thenceforward annexed to the English crown, by a community of laws and government; "an important and mutually useful acquisition, which has conferred glory on the king, though sullied by his barbarous massacre of the Welsh bards, of the effect of whose animating strains in reviving the national spirit he was jealous." According to historical tradition, Edward assembled the leaders of the Welsh, promised to give them a prince of unexceptionable manners, a Welshman by birth, and one who could speak no other language. Captivated with the description, they poured forth violent acclamations of joy, and promises of the most implicit obedience; the king accordingly invested in the principality his second son Edward, then an infant, who had been lately born at Carnarvon. The death of his eldest son soon after, made young Edward heir of the monarchy. The principality of Wales was fully annexed to the crown, and henceforth gives a title to the eldest son of the kings of England.

Edward then spent three years abroad, endeavouring to mediate a peace between the kings of France and Arragon. Having succeeded he returned, and avenged himself on all those who had been guilty of high crimes during his absence. He soon after began his attempt to destroy the independency of Scotland; with this view he projected a marriage between Margaret, on whom the Scottish crown devolved, and his eldest son Edward, which he would probably have accomplished but for the untimely death of the young queen. Several competitors now arose, but the claims of John Baliol and Robert Bruce were considered as the most valid, and upon these it was agreed that Edward should decide. In 1292 he decreed in favour of Baliol, and caused him to be proclaimed king of Scotland. A war now broke out between England and France, and during the contest Baliol formed a secret alliance with the French, which was the commencement of that union between the two countries, which so long prevailed to the disadvantage of England. Edward found great difficulties in raising supplies, and was forced to the expedient of summoning to parliament representatives from all the boroughs in the kingdom, an event which is thought to be the true foundation of a house of commons in England. When he had obtained the money which he required, he marched with a powerful army into Scotland and obliged the king to resign his crown: he then returned, taking with him the famous stone of inauguration, kept at Scone, as the palladium of the Scottish monarchy. Not contented with this, he ordered all the records and mo-

numents of antiquity to be destroyed, broke the seal of Baliol, and carried him away as his prisoner. When they arrived in London Baliol was committed to the Tower, and kept prisoner two years, and then banished to France, where he died in a private station. Edward was next involved in a quarrel with the clergy, who refused to submit to a tax imposed upon them, but were afterwards glad to agree to the terms which the sovereign exacted. Foreign wars and domestic troubles kept the king always poor, and to supply his wants he was forced to grant to the people a solemn confirmation of the great charter, and the charter of the forests, and to make other concessions in favour of public liberty. Edward died of a dysentery at Carlisle, on the 7th of July, 1307, as he was leading a very large army into Scotland, against the inhabitants of which he had vowed the most dreadful vengeance on account of new disturbances which the oppressions of the English probably excited. He was succeeded by his son Edward II. whom he charged, with his dying breath, to prosecute the war against Scotland, and never to desist till he had finally subdued that kingdom.

The enterprises finished by this prince, and the projects which he formed, were more prudent, more regularly conducted, and more advantageous to the solid interests of the kingdom, than those which were undertaken in any reign, either of his ancestors or his successors. He restored authority to the government: he maintained the laws against the efforts of his turbulent barons: he fully annexed to his crown the principality of Wales, and he took vigorous measures for reducing Scotland to a like condition. Nor was he less attentive to the internal improvement of his kingdom, than to promote its consequence among its neighbours. The laws of the realm obtained so much additional order and precision during his reign, that he has been called the English Justinian. He first instituted the office of justice of the peace, and he made various alterations in the executive part of the law, which have continued to modern times. He was inclined to arbitrary measures himself, but took care that his subjects should not act unjustly towards each other. He prevented all clerical usurpations as much as possible, and is reckoned the first Christian prince who passed an act of mortmain. He protected and encouraged commerce, and from him the society denominated "Merchant Adventurers" had its origin, which was instituted for the improvement of the woollen manufacture, and the vending of the cloth abroad, particularly at Antwerp. He granted protection and privileges to foreign merchants, and also ascertained the customs and duties which those merchants were, in return, to pay on merchandize imported and exported. He promised them security, and on all trials respecting them or their property a jury was allowed, consisting half of natives and half of foreigners. The manners of this prince were courteous: his person was majestic, though the length and smallness of his legs gave him the appellation of "Longshanks." Edward had by his first wife Eleanor, four sons and eleven daughters; three of the sons and most of the daughters died before him. He was married a second time to Margaret of France, by whom he had three children. For queen Eleanor he left many durable tokens of his gratitude and affection, by erecting at every stage where her body rested, in its way from Lincolnshire to Westminster, a stone cross of elegant Gothic architecture. Of these a fine one, in perfect preservation, is still extant near Northampton; and another in a less complete condition exists at Waltham Cross, a village eleven miles north of the metropolis. Hume. See Cross.

EDWARD II. succeeded his father in 1307, but was little inclined to follow the advice given him on his death bed: he was indolent and inclined to pleasure rather than to the serious

rious cares of government. One of his first acts was to recall to his court *Piers Gaveston*, a licentious young man whom his father had banished, but who by him was made earl of Cornwall, and married to his niece. He next went to France to marry the princess *Isabella*, to whom he had been some time contracted, but who was ill calculated to render him happy. His barons were exasperated at his conduct with respect to *Gaveston*: they remonstrated, and he promised to dismiss him for ever from his councils; but in a short time he broke his engagement, which excited an open rebellion. *Gaveston* fell into the hands of his enemies, and was executed as a public enemy. After the death of *Gaveston*, he adopted, as a favourite, *Hugh Spencer*, who was soon as much the object of popular displeasure as *Gaveston* had been, and the king was compelled to sign against him a sentence of attainder, and perpetual exile. *Edward*, however, recovered from the confinement into which he had been thrown, and immediately prepared to attack the barons, who were led on by *Thomas*, earl of Lancaster, his near relation. He obtained over them a signal victory, and Lancaster, who had fled into the north, was taken prisoner and executed at *Penrith* in 1322. Many others suffered, and *Spencer* was enriched with their spoils. In 1324 queen *Isabella* went over to Paris, where she connected herself with several English fugitives, who agreed with her in hatred of *Spencer*, and, among the rest, with *Mortimer*, a baron in the Welsh marches. Here a conspiracy was formed against *Edward*, and *Isabella* returned in the character of an open enemy of her sovereign and husband. She landed on the coast of *Wessex*, and was soon joined by many persons of rank and distinction. Their party became in a short time irresistible: they gained possession of the tower of London and other strong fortresses, seized and put to death, without trial, both the *Spencers*, and at length made the king prisoner. He was at first confined in *Kensilworth* castle: he was then disposed by a vote of parliament, and compelled to sign an instrument of resignation. This was not sufficient: his enemies sent him to *Berkeley* castle, where he was inhumanly murdered, by thrusting up a red-hot iron into his bowels, in such a way as to prevent any marks of external violence from being seen. His friends, however, betrayed the bloody deed to the guards and other attendants in the castle. He died September 21, 1327, having reigned twenty years, and lived forty-three; and was succeeded by

EDWARD III. who was then only in his fourteenth year, and was proclaimed king under a council of regency, while *Mortimer* really possessed the principal power of the state. After some fruitless attempts made on the liberties of Scotland, *Robert Bruce* was acknowledged lawful king, and his son and heir *David* was contracted to *Edward's* sister *Jane*. *Mortimer* by this act became very unpopular in England, and after enriching himself by fines and confiscations levied on his enemies, he was seized and hanged in the castle at *Nottingham*. After this, *Isabella* was confined to her house, with a reduced allowance, and though treated with decency never recovered any degree of authority. *Edward* now assumed the reins of government, and his first concern was to restore order and submission to the laws. He then undertook the assistance of *Baliol* king of Scotland, and levying a well appointed army, marched to the borders and took *Berwick* from those who had got possession of the greater part of the kingdom, and who had driven *Baliol* to England.

By a bloody battle at *Halidown* hill, July 19, 1333, in which the Scots were defeated with the loss of 30,000 men, *Baliol* was restored, who, in gratitude to *Edward*, recognised the superiority of the English crown, and put into *Edward's* hands several important fortresses, with all the south-east

counties of Scotland. *Edward* now, owing to an interruption in the lineal succession to the crown of France, which had fallen to *Philip de Valois*, put in his claim to that crown, in right of his mother *Isabella*, sister of the late king *Charles* of France, and prepared to justify his claims by force of arms. With this view, in 1339, he appeared on the north-east frontiers of France, with an army of 30,000 men chiefly foreigners. *Philip* was not less active, and met him with one double that number, and after some time spent in mutual defiance, *Edward* wisely withdrew into Flanders, and disbanded his troops. Next year he renewed his attempts, but was obliged to call his parliament together for new aids, who demanded of him certain concessions, which he readily granted to obtain his object. To prevent the attack *Philip* fitted out a large fleet of 400 sail, manned with 40,000 men, which he stationed off *Sluys*, in order to intercept the king in his passage. The English navy consisted of only 240 ships, but was completely victorious, destroying the greater part of the French fleet, and their crews. The king himself commanded in person, and it has been said, that this naval fight may contend in glory with any of the most celebrated triumphs in the maritime records of England. Notwithstanding the victory, *Edward* returned, without attaining the object of his ambition, deeply in debt, and much disconcerted; and to obtain further supplies, he was obliged to make more concessions to parliament. In 1342, new prospects opened upon him, and he again attacked France, but shortly after agreed to a truce for three years. In 1346, the king himself, with all his chief nobility, his eldest son *Edward* (the famous black prince) and an army of 30,000 men landed at *La Hogue* in Normandy. He over-ran and ravaged great part of the province, took and pillaged *Caen*, struck an alarm even into Paris, and then proceeded into *Picardy* followed by the king of France with 100,000 men. He forded the *Somme*, and arrived at the village of *Crecy*. Here he drew up his army in three lines, and awaited the attack of the enemy. *Edward*, the prince, was then only 16 years of age, yet to him did the king leave the honour of obtaining the first part of the victory with his line unassisted. The rout was afterwards completed with the slaughter of 36,000 of the enemy, though the loss of the English was incredibly small. This victory was followed by the siege of *Calais*, which occupied the English arms nearly a year. During this period, the Scots under *David Bruce* made an incursion into England, and penetrated as far as *Durham*. Here he was met by an inferior force, raised by queen *Philippa*, and commanded by lord *Percy*, which gave him a total and signal defeat. *David* was taken prisoner with many of his principal nobles. *Philippa* having achieved this noble act, went over to her royal spouse, where she was received with deserved triumph. *Calais* was now reduced to the greatest difficulties, and the governor offered to capitulate, but *Edward* would listen to no terms, unless six of its principal citizens were delivered to him with cords about their necks, as sacrifices to his rage. *Eustace de St. Pierre* and five others offered themselves as voluntary victims. They were led to the English camp, and the entreaties of the queen alone prevented the king from putting to death, men, whose only crime was love to their country and fidelity to their sovereign. *Edward* caused all the French inhabitants to quit *Calais*, and substituted an English colony which long possessed it, as one of the keys of France. In 1348, a truce was concluded, but during the truce, the French made an attempt to recover *Calais* by surprize, which proved unsuccessful. On this occasion, the king himself fought on foot as a private soldier, and engaging in combat with a French knight, took him prisoner, whom he almost instantly

liberated without a ransom, throwing, at the same time, with much courtesy, a string of pearls about his neck. In the year 1349, Edward instituted the noble order of the Garter, which soon became one of the most illustrious orders of knighthood in Europe. See GARTER, KNIGHT, &c. In 1355, Edward invaded France on the side of Calais, while the black prince did the same from Gascony, but after much plunder and devastation, the king was recalled by a threatened invasion of the Scots, which he not only repelled, but carried the war into their own country from Berwick to Edinburgh. In the year 1356, was the famous battle of Poitiers, and in a short time Edward had the good fortune to possess as prisoners, his two most inveterate enemies the kings of France and Scotland. In 1359, Edward passed over to Calais with an army of 100,000 men. He desolated the provinces of Picardy and Champagne, and appeared before the gates of Paris; but notwithstanding all his successes, he seemed to have no chance of obtaining the crown of France, and consented to a peace, which was concluded in the year 1360, highly in favour of Edward. In the reign of Charles V. he had the mortification to witness the loss of all his ancient French provinces except Bayonne and Bourdeaux, and all his conquests except Calais. But he had to experience still greater afflictions, by the death of his heroic son Edward, and by the diminished attachment of his people. He died June 21, 1377, in the 65th year of his age, and fifty-first of his reign, and the people were then sensible, though too late, of the irreparable loss which they had sustained. The reign of Edward has been esteemed not only one of the longest, but also one of the most glorious that occurs in the annals of our nation. Edward was great as a warrior, but the domestic government of this prince is more admirable than his foreign victories, and England enjoyed, by the prudence and vigour of his administration, a longer interval of domestic peace and tranquillity than he had been blessed with in any former period, or than he experienced for many ages after. He gained the affections of the great, yet curbed their licentiousness. He made them feel his power, without their daring, or even being inclined to murmur at it. His affable and obliging behaviour, his munificence and generosity made them submit with pleasure to his dominion; his valour and conduct made them successful in most of their enterprizes, and their unquiet spirits, directed against a public enemy, had no leisure to breed those disturbances to which they were naturally so much inclined, and which the frame of the government seemed so much to authorize.

Edward left behind him a numerous posterity by his queen Philippa. The line of his eldest son ceased in his unfortunate successor Richard II. The two rival houses of Lancaster and York were derived from John of Gaunt duke of Lancaster, the third son of Edward, and from Edmund earl of Cambridge, afterwards duke of York, the fourth son of Edward.

One of the most popular laws enacted by any prince, was the statute which passed in the twenty-fifth year of this reign, and which limited the cases of high treason, before vague and uncertain, to three principal heads, *viz.* conspiring the death of the king; levying war against him, and adhering to his enemies; and the judges were prohibited, if any other cases should occur, from inflicting the penalty of treason without an application to parliament. It was also ordained, that a parliament should be held once a year, or oftener, if need be; "A law," says Mr. Hume, "which like many others, was never observed, and lost its authority by disuse." Edward granted above twenty parliamentary confirmations of the Great Charter, which is strong presump-

tive evidence, that he occasionally made no scruple in violating it. The use of the French language in law proceedings was laid aside in this reign, as a badge of the conquest which it was time to abolish. Legislation and the laws of police were much improved in this reign; and though commerce still lay under many impolitic restrictions, yet the staple of the nation, the woollen manufacture, was promoted by encouragement given to foreign weavers, and by enacting a law which prohibited every one from wearing any cloth but of English fabric.

Edward was a prince of great capacity, and desirous of keeping on good terms with his people; "yet on the whole," says the historian, "it appears that the government, at best, was only a barbarous monarchy, not regulated by any fixed maxims, or bounded by any certain undisputed rights, which in practice were regularly observed. The king himself governed by one set of principles, the barons by another, the commons by a third, the clergy by a fourth. All these systems of government were opposite and incompatible: each of them prevailed in its turn, as incidents were favourable to it." Hume.

EDWARD IV. was born in 1441. His father, Richard, duke of York, was grandson of Edmund, earl of Cambridge and duke of York, to whom we have already, in the preceding article, referred. He succeeded his father, in the title of York, slain at the battle of Wakefield in 1460; and after the battle of St. Alban's, gained by queen Margaret over the earl of Warwick, Edward, collecting the relics of Warwick's forces, advanced, and obliged the queen to retire to the north. He then entered London, where, by popular acclamation, he was declared king, in March, 1461, but he did not succeed without a struggle; he had to fight for his crown against an army of 60,000 Lancastrians, assembled in Yorkshire; a decisive victory confirmed his title. After this he lost no time in assembling a parliament which recognized his right, and passed the severest laws against his opponents. Margaret, however, was not subdued, she appeared again in arms; but, being defeated, was obliged to take refuge in Flanders, while her husband, Henry VI. fell into the hands of his enemies, and was committed to the Tower. Edward was now early on the score of a rival, and began to indulge himself in pleasures that seemed suited to his age; but a marriage of love, which he contracted with Elizabeth Woodville, widow of a Lancastrian, whose estate had been confiscated, produced very serious consequences. This lady took the opportunity of an accidental visit at her father's house, to throw herself at the king's feet, and implore compassion for her ruined children. The sight of her beauty won the heart of Edward, who privately married her. This circumstance gave so great offence to some foreign courts, and to the powerful lords of England, that Edward was at length driven from his own country, and the Lancastrians became again triumphant. Henry was once more acknowledged king, and all the attainders of his party were taken off and transferred to the Yorkists. Warwick and Clarence were declared regents of the kingdom under Henry, and Margaret, with all the exiles, prepared to return. In 1471, Edward was enabled, by the assistance of the duke of Burgundy, to land with 2000 men, and to these were soon added great numbers who flocked to his standard. He marched to London, obtained entrance, and Henry was again made prisoner. Warwick advanced against him as far as Barnet, where, on April 14th, a great battle was fought, which terminated in a complete victory to Edward. On the same day, queen Margaret and her son landed at Weymouth. She advanced as far as Tewkesbury, was defeated, and, with her son, made prisoners. The king ordered them

to be brought before him, and asking the prince how he dared to invade his dominions, received a very spirited reply, for which Edward basely struck him in the face with his gauntlet. At this signal, the creatures of the king dragged the heroic young man into an adjoining apartment, and infamously murdered him. Margaret was thrown into the Tower, where she witnessed the death of her husband. Edward, now secure by the destruction of his foes, resigned himself to those pleasures to which he had been ever addicted: in 1475, he made an attempt at French conquests, but was bought off by a present payment of money, and a promised pension, and from this period he ceased to interfere in continental politics. He was chiefly engaged with examining into some charges brought against his brother Clarence, who was, at length, capitally arraigned before the house of peers, and convicted. The commons concurred in a bill of attainder against him; and, finding that his life must be sacrificed, he begged to be drowned in a butt of Malmsey wine, a request in which he was indulged. An expedition of the duke of Gloucester to the borders of Scotland, in which he took Berwick, and forced the Scots to make peace, was the remaining event of this reign. This success encouraged the king to think more seriously of a French war; but while he was making preparations for that enterprise, he was seized with an illness that put an end to his life, in the forty-second year of his age, and the twenty-third of his reign. He left two sons and five daughters. He was, according to Hume, "A prince more splendid and showy, than either prudent or virtuous; brave though cruel; addicted to pleasure, though capable of activity in great emergencies; and less fitted to prevent ills by wise precautions, than to remedy them after they took place, by his vigour and enterprise." Hist. Eng. vol. iii.

EDWARD V. succeeded the father, Edward IV. when he was only in his 13th year; and scarcely had he reigned two months, when, by the ambition of his uncle, the duke of Gloucester, he and his brother Richard were lodged in the Tower, where they were presently murdered, and privately interred at the foot of the stairs of the apartments which they inhabited. (See RICHARD III.) In the reign of Charles II. when some bones were removed, and the spot dug up which was mentioned as the place of their burial, the bones of two persons were found, which, by their size, exactly corresponded to the age of Edward and his brother. They were, of course, concluded to be the remains of those princes, and were interred under a marble monument by order of the king.

EDWARD VI., son of Henry VIII., by queen Jane Seymour, was born in 1538. When Henry died, he was but nine years old, and as he lived only till he was sixteen, two years before his father's will allowed him to govern for himself, his acts are to be regarded as those of the counsellors appointed to superintend the affairs of government during the minority, and as such, will require but a short notice in this place. He was celebrated for an amiable disposition, and for considerable talents in the acquirement of learning. His maternal uncle, the earl of Hertford, afterwards duke of Somerset, notwithstanding the will of Henry, (see HENRY VIII.) assumed the title of protector, and under him great care was taken to inspire the young king with just principles, with regard to the Protestant religion, by which he was induced to favour the reformation. One of the earliest public events that happened in this reign, was a quarrel with Scotland, respecting a projected marriage between Edward and the young queen Mary. The protector marched an army into the country, and gained a decided

battle, which, however, proved of no use to his main purpose; Mary was sent to France, where she was contracted to the dauphin. During the absence of the protector, his own brother plotted against him, of which he was afterwards convicted and executed. This was but the commencement of troubles; insurrections broke out in various parts of the kingdom, which were not suppressed without much bloodshed, and which raised up so many enemies to the administration of Somerset, that he was at length brought to the scaffold. These severities must have been very repugnant to the mild and benevolent spirit of Edward, who could scarcely be brought to sign the death-warrant of a worthy woman accused of heresy. (See CRANMER.) After the death of Somerset, Dudley, duke of Northumberland, became all-powerful, and governed the king and kingdom with equal despotism. (See DUDLEY.) Through the influence of this nobleman, Edward was induced to set aside from the succession his sisters Mary and Elizabeth, and to settle the crown upon lady Jane Grey. The young king had in the course of one year, been seized with the measles, and afterwards with the small-pox, the effects of which he probably never quite recovered; and as he was making a progress through some parts of the kingdom, he was afflicted with a cough, which proved obstinate, and which gave way neither to regimen nor medicines. Several fatal symptoms of a consumption appeared, and though it was hoped, that as the season advanced, his youth and temperance might get the better of the malady, his subjects saw, with great concern, his bloom and vigour sensibly decay. After the settlement of the crown, which had been effected with the greatest difficulty, his health rapidly declined, and scarcely a hope was entertained of his recovery. His physicians were dismissed by Northumberland's advice, and the young king was entrusted to the hands of an ignorant woman, who undertook to restore him to health in a very short time. Death had, however, pronounced his irreversible decree: the medicines prescribed were found useless; violent symptoms were greatly aggravated; and on the 6th of July he expired at Greenwich, in the sixteenth year of his age, and the seventh of his reign. The excellent disposition of this young prince, and the blow followed by the Protestant cause, have rendered his memory dear to the nation. He possessed mildness of disposition, application to study and business, a capacity to learn and judge, and an attachment to equity and justice. He is also advantageously remembered as the founder of some of the most splendid charities in the metropolis. Hume's Hist. vol. iv.

EDWARD, prince of Wales, denominated, from the colour of his armour, the Black Prince, one of the greatest military heroes of his age, eldest son of Edward III., was born in 1330. He accompanied his father on his invasion of France when he was but fifteen years of age; and in 1346, at the battle of Crecy, this young man fought with so much intrepidity, united to the most exact skill, that he was deservedly held up as an example to the bravest men in the army. Being, however, very hardly pressed, a message was sent to the king, who was posted on an adjacent hill, desiring succour, to which his father replied, "I referre to my lion the honour of this day's victory; I am confident that he will prove himself worthy of the trust reposed in him." Animated by the king's expectations, he redoubled his efforts, routed the French, and decided the contest. When the battle was won, the king flew to his arms, and rendered him all the praise and honour which his prowess merited. On this occasion the prince of Wales assumed the crest of British fathers, and the motto "Ich dien." (I serve) belonging to the king of Bohemia, who fell in the battle, which all his successors have

since borne. In 1355, and following year, he penetrated into the heart of France, till he was at length opposed by John the king of the country, at the head of 60,000 men, and was reduced to a situation that would have obliged him to surrender for want of provisions, had not the French king resolved upon an attack. This battle, which was fatal to the French army and their king, who was taken prisoner, was fought Sept. 19, 1356, near Poitiers. The monarch, when led to the victor's tent, was met by the prince with every expression of sympathy and respect. So great was the conduct of Edward in this instance, that he not only caused a noble repast to be prepared for the fallen king, but waited upon him in person, and in every instance treated him as a superior rather than a captive. "Here," says the historian, "commences the real and truly admirable heroism of Edward: for victories are vulgar things in comparison of that moderation and humanity displayed by a young prince only twenty-seven years of age, not yet cooled from the fury of battle, and elated by as extraordinary and as unexpected success as had ever crowned the arms of any commander. He came forth to meet the captive king with all the marks of regard and sympathy, and administered comfort to him amidst his misfortunes; paid him the tribute of praise due to his valour, and ascribed his own victory merely to the blind chance of war, or to a superior providence, which controls all the efforts of human force and prudence. All his father's pretensions to the crown of France were now buried in oblivion: John, in captivity, received the honours of a king, which were refused him when seated on the throne. His misfortunes, not his title, were respected; and the French prisoners, conquered by this elevation of mind, more than by their late discomfiture, burst into tears of admiration, which were only checked by the reflection, that such genuine and unaltered heroism in an enemy must certainly in the issue prove more dangerous to their native country."

Edward conducted his prisoner to Bourdeaux, concluded a truce with France for two years, and then conducted the captive monarch to England. He landed at Southwark, and was met by a vast concourse of people of all ranks and stations. The king was clad in royal apparel, and mounted on a white steed, distinguished as well for its beauty as for the richness of its furniture. The conqueror rode by his side in a meaner attire, and was carried by a black palfrey. In this situation he passed through the streets of London, and presented the king of France to his father, who advanced to meet him, and received him with the same courtesy as if he had been a neighbouring potentate that had voluntarily come to pay him a visit. In 1361 the prince married Joan, daughter of Edmund, earl of Kent, his father's uncle; and he then took up his residence in France, where his father had many conquered provinces which he had formed for his son, under the title of the principality of Aquitaine. Here he undertook the defence of Peter the Cruel, king of Castile, in opposition to Henry, count of Trastamare, whom he entirely defeated. Peter, in justification of the bloody character for which he was famed, would have massacred in cold blood all the prisoners, but was restrained from the savage act by the noble-minded Edward. Peter, when placed on the throne by the Black Prince, refused the stipulated reward to the English troops, and Edward returned with the glory of having successfully accomplished his enterprise, but with a ruined constitution. The government of this prince, notwithstanding his noble qualities, became unpopular, owing to the taxes which he was obliged to levy to pay the expenses of his wars. Appeals were made by the nobles to Charles, their superior lord, the

new king of France, who summoned Edward, as his vassal, to appear before him at Paris. "I will come," said the prince, "but it shall be at the head of 60,000 men." The state of his health was become too delicate to admit of any farther exploits: and after a lingering illness he died in the forty-sixth year of his age, leaving behind him a character illustrious for every eminent virtue, and from his earliest youth, till the hour in which he expired, unflinched by any blemish. His valour and military talents formed the smallest part of his merit. His generosity, humanity, affability, and moderation, gained him the affections of all men, and he was qualified to throw a lustre, not only on that rude age in which he lived, and which nowise infected him with its vices, but on the most shining periods of ancient or modern history. *Hume's Hist.* vol. ii.

EDWARDS, in *Geography*, a fort in Nova Scotia, in the town of Windsor, in Hants county, large enough, as it is said, to contain 200 men. It is situated on the river Avon, navigable to this place for vessels of 400 tons: those of 60 tons can proceed two miles further.

EDWARDS, GEORGE, in *Biography*, celebrated for his knowledge in natural history, was born at Westham, in Essex, about the year 1693. He was designed for trade, but the access which he had, while he was pursuing the elementary parts of a commercial education, to the library of a deceased physician, gave him a turn to literature and scientific pursuits, which detached him from the course for which he was originally intended. Having spent some years in foreign travel, he returned to his native country, and applied himself to the study of natural history. He practised the art of drawing and colouring birds from nature, and obtained, by the sale of his works, a good subsistence. He was, in the year 1733, appointed librarian to the college of physicians, a situation which afforded him ample opportunity for pursuing his favourite studies. Between the years 1743 and 1751, he published his "History of Birds," in 4to. with coloured plates and descriptions in English and French. In addition to his history of birds were given some plates of serpents, fishes, and insects. The last volume, as a testimony of pity and gratitude to his maker, who had enabled him to complete his work, he dedicated "To God." As a supplement, he published, in parts, his "Gleanings of Natural History," consisting of coloured plates of birds, fishes, insects, and plants. His reputation as a naturalist gained him the acquaintance of the celebrated Linnæus, who kept up a constant correspondence with him, and completed the general index to his works according to his own system. He received, for his history of birds, from Godfrey Copley's medal, voted to him by the Royal Society, of which body he became a member in the year 1757. He was also elected a member of several of the learned societies in Europe. In the year 1769, he resigned his office at the College of Physicians, having sold his collections of drawings to Lord Bute, and retired to a small house at Plaistow in Essex. In the course of the following year, he published his "Essays," in 8vo. which were chiefly collected from the prefaces or introductions of his former works, to which were added instructions for drawing, painting, and etching. The remainder of his life was spent in privacy among his friends, towards the close of which he was grievously afflicted with the stone and a cancer in his eye. He bore his sufferings with manly fortitude and patience, and died at the age of eighty, in July 1773. His temper was cheerful, open, and benevolent; his diffidence and humility prevented him from shining in mixed company, but he was entertaining and very instructive in a small and private circle. *Biog. Brit.*

EDWARDS, JONATHAN, an American divine of considerable

able celebrity, was born at Windsor, in Connecticut, in the year 1703, and was educated at Yale college, where he took his degree of B. A. before he was quite 17 years of age. He made a rapid progress in the natural sciences, but was particularly attached to moral philosophy and theology, as connected with the profession for which he was designed. Having continued at his college two years after he took his first degree, he was examined, and licensed to preach the gospel as a candidate. In the year 1722, he went to New York, and preached among the English Presbyterians for about eight months with considerable success, but not thinking the circumstances of the society such as to justify him in making choice of this situation for a settlement, he returned to his father's house, where he pursued his studies with much diligence. In 1723, he was admitted to the degree of M. A. and in the following year was chosen tutor of the college in which he had been educated. In the year 1726 he resigned his situation as tutor, and was ordained pastor of a congregation at Northampton, which he continued to serve with much success till the year 1744, when, from some disputes occasioned, perhaps, by the assumption of too much authority on the part of the minister, he fell into disrepute. His usefulness and his comfort were now nearly at an end, but he continued in this connection till the year 1750, when he was formally dismissed by a vote of the congregation, having only twenty persons in his favour, and more than two hundred against him. In 1751, he became Indian missionary at the town of Stockbridge, in the province of Massachusetts, where he discharged the duties of the office devolved upon him to the entire satisfaction of all concerned, and was honourably supported by the commissioners of the society in London for propagating the gospel in foreign parts. He was, in the year 1757, induced to decline this business, on his election to the presidency of the college of New Jersey. Scarcely, however, had he entered upon this honourable office, when he was advised to be inoculated for the small-pox, on account of the ravages that the natural disease was then making all around him; to the effects of this disorder he fell a victim in the month of March 1758, being in the 55th year of his age. Mr. Edwards was author of many works, but of these the most important, and that by which he is most known, is his "Careful Enquiry into the modern prevailing Notion of that Freedom of Will which is supposed to be essential to moral agency." This was published in the year 1754, and has obtained a high character as a most able and acute justification of the doctrine of philosophical necessity. Mr. Edwards was allowed, by all capable of appreciating his talents, to be a man of considerable and deep learning, extensive reading, and sound judgment. He was eager for the acquisition of knowledge, and diligent in the pursuit of it. His piety towards God was ardent, and his benevolence towards his fellow-creature was extensive and liberal. He was a Calvinist in principle, and an able defender of the doctrines which he espoused. Gen. Biog.

EDWARDS, THOMAS, a zealous divine, according to the principles of Presbyterian church discipline, was born towards the close of the 16th century, and was educated at Trinity college, Cambridge, where he took his degree in 1609. He entered into the established church, though he was a puritan in principle. He wrote against toleration, and yet, from his own account of his conduct and character, no one required the latitude granted by toleration more than himself. He never properly conformed to the manners and habits of the church of which he was a member, and speaking of a sermon which he preached on a fast day in July 1640, at Mercer's chapel, he says, he preached "against the bishops and their faction, such a free sermon, as I believe never a

sectary in England durst have preached in such a place and at such a time." He chiefly officiated at Hertford as lecturer, and also in some places in London, and more than once incurred the rebukes of his superiors, for the puritanical style of preaching which he adopted, and the offences which he committed against the rules and orders of the church. When the long parliament declared against king Charles I., he became a zealous advocate for the changes in civil and ecclesiastical matters which were gradually introduced, and supported, by every method in his power, the views of the ruling party against the favourers of episcopacy and royalty. He was author of many pieces, which are now well nigh forgotten, and which do not merit a mere enumeration. They display much violence and bitterness as well in the matter as in their manner, and there can be no doubt, but that if Mr. Edwards had possessed the power he would not have wanted the will of being a rigid persecutor of those who thought and acted differently from himself. He died in 1647 in Holland, whither he fled to avoid the resentment of the independents, after Cromwell had overturned the power of parliament. Biog. Brit.

EDWARDS, JOHN, was son of the preceding, and born at Hertford in the year 1637. He received his grammatical learning at Merchant Taylors' school, and pursued the more advanced studies at St. John's college, Cambridge. He distinguished himself for his diligence and superior talents. In 1661, he took the degree of M. A. and was soon after ordained deacon and then priest, by Dr. Sanderfon, bishop of Lincoln. In 1664 he undertook the duty of Trinity church, in Cambridge, and greatly distinguished himself as an eloquent and popular preacher; but in the following year, when the plague raged at Cambridge, he removed from the college into the town, that he might devote his whole time to the consolation of his parishioners in the time of their calamity. After this, he refused a good living in Gloucestershire, and chose to continue in his station at Cambridge. About 1688, he was admitted to the degree of bachelor in divinity, and about the same period was chosen one of the lecturers of Bury St. Edmund's, whither he removed, but returned to college in about a year after. He went through many changes, and obtained preferment in Norfolk and Essex. In 1699, he was admitted to the degree of doctor in divinity, and after this, he spent his life in studious retirement. Though a diligent student, and the author of many publications, he never possessed a library, and had indeed few books except bibles, lexicons, dictionaries, and works of a similar nature. He borrowed books from the university libraries; and from booksellers to whom he paid a stipulated sum for the loan. He died in 1716, having attained to his seventy-ninth year. His works are very numerous and very voluminous, mostly on theological subjects; in defence of Christianity, and of the established church of which he was a zealous member. Dr. Edwards was a man of extensive learning, of ardent piety, and exemplary moral conduct. Biog. Brit.

EDWARDS, THOMAS, a divine of the church of England, was born at Coventry in the year 1720, where he received the early parts of his education. In 1747, he was entered at Clare Hall, Cambridge, where he graduated in 1750 and 1754, and was at length chosen fellow of his college. He was ordained to priests' orders in the year 1755, and about this period he published "A new English Translation of the Psalms from the original Hebrew, reduced to metre by the late Bishop Hare, with Notes critical and explanatory; illustrations of many Passages drawn from the Classics, &c." His object was to make Bishop Hare's system of Hebrew metre better known, and to show the utility of a judicious applica-

tion of it in elucidating the poetical parts of the Hebrew scriptures. He was, in 1758, appointed master of the free school at Coventry, and presented to the rectory of St. John the Baptist; soon after this, he published a work, entitled "The doctrine of irreflexible grace proved to have no foundation in the writings of the New Testament." He then engaged in a controversy, respecting Hebrew metre, with Dr. Lowth, which was carried on till the year 1766. It was in this year that Mr. Edwards was admitted to the degree of doctor in divinity. He continued to write on useful and important subjects, till almost the close of his life. In 1770, Dr. Edwards was presented by the crown with the valuable vicarage of Nuneaton in Warwickshire, to which he went in the year 1770, having resigned his school and rectory at Coventry. His last publication was entitled "Selecta quedam Theocriti Idyllia recensuit, variorum notas adiecit, suasque animadversiones, partim Latine, partim Anglice, scriptas immixcit Thomas Edwards, S. T. P. 8vo. 1770." He died at Nuneaton in 1785, in the fifty-sixth year of his age, having been some time incapacitated from performing the duties of his station by a paralytic stroke. He was a man of much mildness in his manners; benevolent and humane. He was particularly noted for inflexible integrity. As an instructor of youth he obtained a high reputation. He was fond of retirement, and his connection with the learned world was maintained more by correspondence, than by personal intimacy with its members. *Biog. Brit.*

EDWARDS, THOMAS, was born in London in the year 1699, and educated for the bar. A hesitation in his speech prevented him from ever engaging much in professional practice. He was, besides, too much attached to poetry, and the belles lettres to find amusement in the study of the law. Shakspeare was his favourite author, and on the appearance of Warburton's edition of that dramatist, Mr. Edwards published "A letter to the Author of a late Epistolary Dedication, addressed to Mr. Warburton." This came out in 1744, and in 1747 he followed it by "A supplement to Mr. Warburton's edition of Shakspeare," a work which passed through many editions, and became famous under the title of "The Canons of Criticism." The idea of this work was derived from a hint given by Warburton, that he had once intended to draw up a body of canons for literary criticism. Mr. Edwards pretends to take up the design, and has framed a set of canons drawn from Warburton's notes upon Shakspeare and illustrated by the examples they afford. "The canons," says a good writer, "in the last edition amount to 25 in number; and it is impossible to read them and their illustrations without extraordinary mirth at the expense of the reverend annotator, who, as a critic, has perhaps contrived to be more ingeniously and singularly in the wrong than any other of the profession." An "Essay towards a Glossary," another of Warburton's designs, is annexed and drawn up in the same ironical style. The work has much value, as tending to discredit the rash and fanciful mode of correcting and explaining authors, which has been countenanced by critics of reputation. Mr. Edwards was distinguished as a poet, and printed about 50 sonnets in Dodds's and Pearch's collections. He was a skilful critic in the English language. He passed his life in literary leisure, and was respected by many of the most respectable characters of his time. He died in the year 1757. The edition of his canons of "Criticism," published in 1765, contained his sonnets; and an "Account of the Trial of the letter γ , alias γ ," in which are discussed the principles of English orthography. These he founds on etymology. A work on predestination was published after his death.

EDWARD'S, *Prince, Island*, in *Geography*, a British North

American island, near the coast of Nova Scotia, in the gulf of St. Lawrence remarkable for a colony of highland emigrants from Scotland, settled there by the earl of Selkirk, in 1803.

The settlers, to the number of 800 persons of all ages, reached the island in August, 1803. The spot selected upon the coast was almost desert, being separated by an arm of the sea, and an interval of several miles from any other settlement. Before the middle of September, the people were dispersed upon their separate lots, which were laid out in such a manner, that four or five families built their hamlets in a little knot together. This social plan of settlement resembled their style of living in their native country. They were allowed to purchase in fee-simple, and to a certain extent on credit. From 50 to 100 acres were allowed to each family, at a moderate price, which they were not required to pay in full before the third or fourth year of their possession. Every assistance in provisions was likewise a loan under strict obligations of repayment with interest. They constructed their first houses upon the model of those of the American woodmen. Lord Selkirk returned to the settlement twelve months after. He found the settlers engaged in securing their harvest; their crop of potatoes would alone have been sufficient for their entire support. Round the different hamlets, the extent of land in cultivation was, at an average, in the proportion of two acres to each able working hand: and several boats had been built, by means of which a considerable supply of fish had been obtained. The further progress of the colonists was left to their own guidance. Observations on the present State of the Highlands of Scotland, with a View of the Causes and probable Consequences of Emigration, by the Earl of Selkirk, 1807.

EDWARD'S, *Prince, Islands*, two islands in the southern Indian ocean, S.E. of the Cape of Good Hope. E. long. $37^{\circ} 45'$. N. lat. $46^{\circ} 53'$. The largest and most southerly is about 15 leagues in circuit, the other nine; they are about five leagues distant from each other, and there is a passage between them at mid-channel.

EDWARDSBURGH, a township of Upper Canada, in the county of Grenville, being the seventh township in ascending the river St. Lawrence.

EDWARDSIA, in *Botany*, so named after Mr. Sydenham Edwards, a highly deserving botanical draughtsman, whose merits are conspicuous in the numerous plates marked with his name in Curtis's Magazine, and whose skill and scientific knowledge extend no less to zoological subjects. This genus is founded by Mr. Salisbury in the Transactions of the Linnæan Society, v. 9. 296, on the *Sopobra microphylla*, *tetraptera*, and a third species, likewise from the South Seas, all which we hesitate to separate from the original and genuine genus *Sopobra* of Linneus and Jusseu, though aware of the heterogeneous assemblage subsequently referred to it, which we have long since taken some pains to reform. S.

EDWAY, in *Geography*, a river of South Wales, which runs into the Wye, 4 miles S.E. of Builth, in the county of Radnor.

EDWORTH, a river of Wales, in the county of Monmouth, which joins the Usk, at its mouth.

EDWY, in *Biography*, king of England, son of Edmund I., succeeded, at the age of 16, his uncle Edred, in the year 955. He was, at this period, possessed of an amiable figure, and endowed with the most promising virtues. He would have been a favourite of the people, had he not unhappily, at the commencement of his reign, been engaged in a controversy with the monks, who pursued him with unrelenting

unrelenting vengeance during his short reign. His marriage with Elgiva, a beautiful princess of the royal blood, and within the prohibited degrees of kindred by the canon law, was a source of misfortune that only terminated with his life. The savage Dunstan was his principal enemy, who, at the head of the monks, declared war against the king. On the day of his coronation, when the nobles were assembled at a feast, Edwy withdrew from the company to his queen's apartment, where he indulged his fondness for his wife, which was only checked by the presence of her mother. Dunstan, suspecting the cause of the king's absence, burst into the chamber, rudely upbraiding the young couple, and forcibly dragged the sovereign to the banquet. Edwy could not forget the affront; he challenged Dunstan with a mal-administration of public affairs: the haughty monk refused to answer the accusation, and was banished. (See DUNSTAN.) His party excited disaffection against the king: they seized the queen, and, by the order of archbishop Odo, branded her in the face with a red hot iron, hoping thereby to destroy her beauty: they then carried her away by force into Ireland, there to remain in perpetual exile, and Edwy consented to a divorce, which was pronounced by the infamous Odo. Elgiva having completely recovered of her wounds, and time having almost obliterated the scars, was hastening to the arms of her husband, when she fell into the hands of her blood-thirsty enemies, and was by them barbarously murdered. The torments which she endured could only have been inflicted by demons in the shape of priests. These deeds were, however, sanctioned by a barbarous and superstitious people, who rose against Edwy, drove him from the throne, and placed on it his brother Elgar in his stead. The fallen monarch was obliged to take refuge in the southern part of the kingdom, when he was excommunicated, and pursued with unrelenting hatred, till death terminated his calamities, in the year 959. Hume, vol. i.

EDYLIUM, in *Ancient Geography*, a mountain of Greece, in Bœotia, called *Hadylius* by Pliny.

EDYMA, a town of Asia, in Caria. Steph. Byz.

EDYSTONE, in *Geography*. See EDDYSTONE.

EECLOO, a small town of France, in the department of l'Écfaux, (the Scheldt,) chief place of a canton, in the district of Gand, with a population of 5827 individuals. The canton contains five communes, with 15,153 inhabitants, on a territorial extent of 112 kilometres and a half.

EED, a town of Norway, 24 miles N.N.W. of Drontheim.

EEDT, a town of Germany, in the archduchy of Austria; 14 miles E.S.E. of Ens.

EEL, a lake of North America. N. lat. 49°. W. long. 98° 50°.

EEL-Town. See KENAPACOMAQUA.

EEL Cove and River, lie on the fourth side of Chaleur-bay, in Lower Canada, about three leagues W. from Maligash. The cove abounds with salmon, which are taken annually in great quantities by the inhabitants who are settled near it.

EEL River Indians, are those who occupy the lands on Eel river, a head branch of Wabash river. (See WABASH.) These Indians, at the treaty of Grenville, in 1795, ceded some land at the mouth of the river to the United States; the government paying them a sum of money, and engaging to pay them in goods to the value of 500 dollars annually for ever.

EEL, *Anguilla*, in *Ichthyology*, a species of the *Murena*; which see.

EEL fishing. See FISHING.

EEL, *Electrical*. See GYMNOTUS,

EEL, *Indian*, a species of *Trichivurus*; which see.

EELS, *Microscopic*, in four parts. The long-bodied animalcules, discovered by the microscope in vinegar, four parts, and many other subjects, have, from their figure, been generally distinguished from the rest of the microscopic animalcules, by the name of eels. These, and the other kinds, have been, by the most judicious naturalists, supposed to be produced of the eggs of other animalcules of the fly kind, floating in the air. But those in paste are discovered to be viviparous animals, producing living creatures of their own shape. In order to be always furnished with these minute eels ready for the microscope, take fresh paste as book-binders commonly use, of a moderate consistence, and expose it to the air in an open vessel, and prevent its becoming hard, or mouldy, by occasionally stirring it. After some days, it will turn sour; and, if examined attentively, you may discern multitudes of exceedingly small, long, slender, wriggling animalcules, which grow larger daily, till you will be able to see them with the naked eye. In order to promote their coming forward, pour now and then a drop of vinegar on the paste, and then they may be preserved all the year; the continual motion of these animalcules will contribute to prevent any mouldiness in the paste, which is best kept in some glass vessel. Apply them to the microscope on a single tele, or singlass, after having first put upon it a small spot of water for them to swim about in, the internal motion of their bowels may be plainly perceived; and when the water is almost dried away, and they are nearly expiring, their mouths may be seen opening to a considerable width. On cutting one of these paste-eels in two across the middle, a long and slender tube is seen to shoot out from each of the divided ends, and a number of seeming ova issue from this; but these, examined strictly, appear to be living eels of different growths, and all included in their proper membranes; some move themselves but slowly, while others coil and uncoil themselves pretty briskly; and the most mature are seen to make strong efforts towards the disengaging themselves of their enveloping membranes, and at length succeed, and swim at liberty like their parent animal. The tube thrust out each way, on dividing the body, is properly the uterus of the animal, which, in the larger eels, is seen to be full of dark spots that are the embryo eels; and these dark spots are also to be observed in the young ones, as soon as produced. Phil. Trans. N° 478. § 13, and vol. xlv. p. 67, and Baker's Microf. 1743. p. 81, &c. See ANIMALCULE.

EEL-fares is used for the fry, or brood of eels. Stat. 25 Hen. VIII.

EEL-pout, in *Ichthyology*, the English name of the mussela fluviatilis, a fish of the *Gadus* kind. See GADUS.

The name is derived from the German *ael puit*, which is, in that language, the name of the same fish, and is compounded of the words *ael*, an eel, and *puit*, or *pud*, a frog; so that the English word should properly be the *eel-frog*. It is commonly, when full grown, about fourteen inches long, and is slender in proportion to its length, and something of the eel-shape, but too short for its thickness, to be truly so. It is very soft and slippery to the touch, like the eel, and is covered either merely with a slimy matter, or else with extremely minute scales. It is of the colour of a tench; its head is large and flat, its nostrils small and round, and its jaws beset with very small teeth, which make them feel rough like a file; and there is, beside these, a semi-circular spot in the palate, rough in the same manner. There are two fins on the back, and one on the belly, reaching from the anus to the tail; and it has a little beard from the extremity of the lower jaw, and between the nostrils and end of the snout, two others, and seven gills. Willughby's Hist. Pisc.

p. 125. There is another variety of eel pout, which Linnaeus has made a species of *Blennius*; these are viviparous, and bring forth two or three hundred young at a time, a little after the depth of winter. They are common in the Eik, at Whitby, in Yorkshire, and are a coarse fish.

EEL spear, a forked instrument with three or four jagged teeth, used for catching eels; that with four teeth is the best. This is struck into the mud at the bottom of the river; where, if it strikes against eels, it is sure to bring them up.

EEL-backed, a term used by the dealers in horses, for such as have black lists along their back.

EELWYCK, in *Geography*, a town of Norway; 20 miles W. of Romfald.

EEMBARG, or **EMBARC**, a town of Utrecht, seated on the Ems; 5 miles N.N.W. of Amersfort.

EEMS, a river of Holland, which runs into the Zuyder sea, below Eembarg, in the state of Utrecht.

EERSEL, a town of Brabant; 6 miles S.W. of Eindhoven.

EERSTE RIVER, a river of Southern Africa, which forms one of the divisions of the Droody, or district of Stellenbosch, lying between it and False bay.

EFESE, a town of Asiatic Turkey, in the province of Natolia; 32 miles S.E. of Smyrna.

EFFAIRE, or **EFFRAYE**, in *Heraldry*, a term applied to a beast, when rearing on its hind legs, as if it were frightened.

EFFECT, the result, or consequence, of the application of a cause, or agent, on some subject.

It is one of the great axioms of philosophy, that full, or adequate effects, are always proportionable to the powers of their causes.

EFFECT, in the *Manege*, is applied to the motions of the hand which direct the horse.

They distinguish four effects of the hand, *viz.* in using the bridle to put a horse forwards, draw him backwards, and shifting it out of the right hand into the left, or *vice versa*.

EFFECT, in *Musick*. This word became technical in England about the middle of the last century; and we believe that it was Abel who brought it thither.

The great bands of sovereign princes in Germany, before the revolution, such as those of Manheim, Dresden, Wirtenberg, Esterhazy, &c. inseparably attached to the same orchestra, under the immediate direction of the composer, had leisure to try effects; and it was at the beginning of the cultivation of symphonies on the new plan of Stamitz, Hülzbaer, Canabich, Ditters, Vanmaldere, Toeschi, and Filtz, different from the light opera overture, which had superseded those of Lulli and Handel, that experiments of this kind were tried. The effects of *crescendo* and *diminuendo* were successfully produced in theatrical orchestras, even in songs; and we remember the first air in which we noticed this effect, was composed by Jno. Christ. Bach, and sung by Ciprardi: *Non so donde vieni*, &c.

To produce an effect, is to cause an agreeable and powerful impression in the ear and the mind of the hearer, by unusual musical combinations: so that the word *effect*, in music, means something uncommonly excellent; and effect is not only applied to a single passage, but to such whole movements or works, as are full of effects which produce sensations that appear superior to the means employed to excite them.

Long practice and observation may teach a musical student how to discover passages of effect upon paper; but genius alone inspires them. It is the defect of bad composers, and

of all beginners, to heap parts on parts, and crowd instruments on instruments to produce that effect which flies their grasp; and as an ancient said, "to open a wide mouth to blow a small flute." You would expect, in seeing their crowded and labouring scores, that you should be surprized by prodigious effects, but if you are surprized at all, it will be at hearing so meagre, mean, and confused a composition, without effect, and more like y to than than delight good ears. On the contrary, the eye seeks in the scores of great masters, those sublime and ravishing effects which their music is sure to produce when well executed. Frivolous fillings up are either unknown, or despised by men of fine genius, who never call our attention to a crowd of small and puerile objects, but move us with great effects, the result of that force and simplicity united, which always constitute their character.

EFFECT, in *Painting*, is, properly speaking, the name of that impression which the first momentary glance of a picture produces on the eye and the mind of an observer: but artists have adopted it as indicative of the *cause* of that impression, and hence, with them, it becomes a technical term, signifying the arrangement of the component parts of a picture.

In its most extensive sense, thus employed, it designates the *mode of relief* in which the objects of a picture are wrought. Its greatest excellence consists in making the subject of a picture at once familiar to the understanding in an interesting and pleasing manner; and when produced by the hand of taste and skill, it leads irresistibly the imagination of the observer, and enforces a more close inspection of the work.

Very many are the masters whose pictures possess excellent qualities, such as drawing, composition, and expression; yet they remain unattractive for want of union and harmony in their various parts; they are, therefore, passed by unnoticed, till accident renders their beauties observable: while works of less intrinsic merit, but possessing a better arrangement, or in other words, a better general effect, are constantly imposing themselves on the eye; and it is only when these qualities unite, that a perfect work can be produced.

Effect depends entirely upon the management of chiaro-scuro and colour: that is, the mode in which they are arranged, and the degree of opposition in which they are applied. It has little or no relation to the execution or finishing of the work; the slightest sketches, wrought in the enthusiasm of feeling, generally possess this quality in a more perfect degree than highly finished works.

The effects of pictures are denominated according to their different kinds; vigorous, powerful, weak, rich, or mean, bright, gloomy, pleasing, &c. &c. but no positive rules for producing effect can embrace the infinite varieties under which it pleases. Rubens in many of his pictures gratifies us with the brilliancy and breadth of effect of broad daylight spread almost equally over every part of them; the local colours alone producing the chiaro-scuro; whilst, on the contrary, we behold with pleasure many works of Rembrandt, whose surfaces bear the representation of light upon only $\frac{1}{10}$ th or even $\frac{1}{20}$ th part of them, and have very little local colour of course, and between these two extremes all the intermediate degrees may be made attractive.

A *vigorous*, or *powerful* effect, is produced by using bright lights and colours with strong dark oppositions to them; in whatever degree as to quantity they may be employed. In general a small portion of light, with broad and strong dark shadows, is the most certain mode of obtaining it. Of this class are most of the works of Rembrandt: those of Rubens sometimes; particularly in his candle-light pieces.

Michael

Michael Angelo Caravaggio generally employed it, and fo also did Spagnoletto, and many painters who have followed them. Correggio, however, appears to have been the father of this style of effect most observable in his pictures of the Birth of Christ, called "La Notte;" which was in the gallery at Dresden, and in his small picture of the Magdalen, also in the same place; in both these pictures it is managed with the utmost sweetness of tone, much more than any of the above-mentioned masters have ever arrived at; though, perhaps, not with so much brilliancy as Rembrandt has sometimes obtained.

The works of the late professor of painting in our Royal Academy, J. Opie, &c. are also excellent examples of power and vigour of effect, gained by strength of opposition in the chiaro-oscuro and colour. In the more confined sense of the word (of which we shall presently speak) viz. the degree of relieve of the individual objects of the picture, no artist ever surpassed him. Many of his figures appear absolutely round, and fully to project from the canvas.

A more pleasing, though less powerful kind of effect, is produced, by making use of less violence of opposition; less sudden transition from light to dark, and from colour to colour; by blending the lights and shades with a greater breadth of half-tint; and instead of giving the shadows a great depth of tone, allowing them to partake of reflections from the atmosphere, as well as from surrounding objects.

It is also necessary to take care that no colours, which violently oppose each other (such as bright reds and blues,) should come in close contact; but that they should be united by the help of some intermediate tint, or their tones should be blended with each other, and each participate of the general hue of the picture; of this class are the greater part of the works of Correggio; those of Guido Rheni in his best style; Murillio, Vandyke, Sir Joshua Reynolds, and almost all the painters of the Dutch and Flemish schools; who, after Correggio, are the most perfect masters of this kind of effect.

Rubens united very much of it with the style of Venetian composition; but the range of his genius is so large, and his works of course so various, that it is difficult to assign him as an exemplar of effect in any particular branch: he displays in his works all its different species. His picture of the "Descent from the Cross," now in the gallery of the Louvre, at Paris, is an instance of the grave and serious, wrought with great strength and brilliancy; and it is obtained by using one light only, and that about one-third of the picture. His series of pictures, known as those of the gallery of the Luxemburgh palace, are specimens of the gay and luxurious effect of broad lights and bright colours; and his portraits are a medium between these different degrees.

Among the Venetians, Titian may almost alone be said to have possessed (and that not till his later time) the magic power of producing (without the appearance of art) the true effect of nature in its happiest combinations, by so admirable a management of the chiaro-oscuro and colours, as immediately to lead the eye to the principal object, and yet maintain the whole surface of his picture rich and brilliant; as in his "Diana and Acteon," at the marquis of Stafford's. Sir J. Reynolds has admirably followed him in this particular, but too often with an admixture of the style of effect used by Rembrandt, wherein the artifice, being more apparent, weakens the claim to ingenuity in the artist.

An effect, termed classical, is obtained by the adoption of lines and forms similar to those found in the works of the ancient painters and sculptors; by working upon the same series of thought which appears to have engaged their attention, and also by selecting for representation, the grand fea-

tures of nature, as N. Pouffin has done in his landscapes, and leaving out the more minute parts. The adoption of the reverse, selecting the ordinary forms and scenes of nature; and representing them in a laboured and coarse manner, produces an effect justly denominated *vulgar*.

It has been said before, that the effect of a picture should convey an impression of the nature of its subject; that correspondence is the best test of the merit of the painter, as it proves a comprehension of mind not confined to detail, but exerting itself on the whole together. A picture, the subject of which is grand, should have an effect at once imposing and sublime, by its simplicity and power. "The Death of St. Peter, Martyr," by Titian, now at Paris, is a beautiful instance of this happy adaptation of effect to subject. The first impression made on seeing it is awful, and creates in the mind of the beholder somewhat of horror. The parts are large, the tone of colour is deep and sombrous, something like that of twilight, and produces a seriousness of mind instantly on observation, and notwithstanding every part is found; by continued examination, to be wrought with great finish, yet the whole only strikes at first sight.

The portrait of Leo X., by Raphael, with the cardinals de Medici and Rossi attending him, is another instance of this: the character of the personage is grand; the effect of the picture is serious; and to produce this, the actions of the figures are simple, and the tone of colouring is low.

If a pleasing subject be chosen for representation the effect should be gay. Great variety of tints, a bright tone of colour, and sparkling lights and darks, amongst a broad general mass of light, are the requisites for producing this. The best examples of it are the works of Rubens and Watteau; and Paul Veronese among the Venetians adopted it. The French school have generally wrought upon this principle, till, in fact, they have proved that it is as dangerous to push a system too far, as to proceed entirely without one.

Sir Joshua Reynolds, in one of his discourses, has said, (and every painter pursuing anxiously the higher qualities of his art acknowledges the truth of his remark,) that the production of a good *general effect*, that is, a complete combination of all the parts of a picture in such a manner as pleasingly to attract the eye of the observer, and at once to convey the full interest and nature of the subject; is, when the work is composed of many parts, the most difficult branch of the art of painting. It becomes so, from the necessity of maintaining vigour and brilliancy in every part; yet, under the obligation of subduing some, in order to give more relief or more interest to the main point of the work, and by that means attracting and fixing the attention of those who regard it.

In a more confined sense, *effect in painting* is used to signify the degree of relieve of the objects of a picture, and the absolute truth of representation of nature in its individual parts. A painting is said to be wrought to great effect when every object appears to project strongly from the canvas; being rounded up with great care, and close imitations of the thing itself, whatever it may be; and thus effecting a degree of deception in the relieve. This kind of effect, however esteemed by some, is a great enemy to that more extended sense of it, in which it has been already described; as it is extremely difficult, if not impossible, to make every object to relieve, and yet maintain but one principal.

This inferior use of the word extends only to positive imitation, within the compass of an ordinary mind by diligent study to obtain. The other is in great measure ideal; and the painter is obliged, in order to produce it, to assist nature by art. It requires great science in the nature and effect of

colours, of forms and the chiaro-oscuro; so to arrange them that as little recourse as possible may be had to artificial or ideal shadows; and, when necessary to introduce them, to give them their proper places. So as to make the principal mass of a pleasing form, and more agreeably to exemplify the subject of the work, and cause the observer to dwell with more confidence on those parts that are immediately necessary for that purpose: thus, acting on that difficult, though requisite principle of art, that of sacrificing a part for the good of the whole.

Many painters are fully adequate to this latter and more confined sense in which effect is understood, who are totally unequal to the production of works possessing that quality in its more general application. For instance, those who paint dead game hanging against a deal board, may, and do, represent almost to deception those objects of their study; but set them to produce a picture containing many groups of these same objects, and still representing the individual parts truly, with their usual force and spirit; yet, for want of taste and knowledge in the due subordination of parts requisite to produce a perfect whole, they must of course present only a heap of confusion, on which the eye finds no resting place, but wanders from part to part, each having as much power to detain it as its neighbour; till at last the observer retires with fatigue and disgust, instead of dwelling on the work with pleasure, as it does when a more skilful attention to general effects, instead of that of individual objects, takes place, and gives it repose by an union of harmony and propriety.

This absolutely necessary quality in a perfect picture, taken in the sense in which we first considered it, there is little or no reason to conclude, was ever in the contemplation of the ancient painters. The descriptions remaining of their works convey no idea of it, unless what Pliny says of the union and harmony of those of Apelles may lead us to imagine they participated of it. But it is probable that he alludes only to the colouring, which, though a necessary part of a good effect, yet to be complete, it must have a sufficient portion of judicious management of the chiaro-oscuro united with it. In general, those descriptions alluded to lead us to conclude, that their study was rather to give each figure its appropriate action and character in its full force, and that they generally produced something more like the imitation of a bas-relief in sculpture, than that of a picture possessing a good general effect, as at present understood.

On the revival of the art of painting, in the 13th century, it was quite as little, most probably still less understood; till Fra. Bartolomeo and Lionardo da Vinci laid the foundation of the future attention to justly bestowed on this valuable part of the art, as they were also, in fact, those to whom we owe the first advancement of all that is valuable in it. Michael Angelo and Raffaello caught somewhat of the feeling of effect from them, but not happily, and it never flourished in the Roman or Florentine schools. The Carracci obtained more of it; and the Venetians improve upon it, particularly Giorgione and Titian, who raised highly the taste for its beauties, by the truth and propriety of their works. The latter in a more super-eminent degree, as the short life of the former prevented him from carrying the great abilities he possessed so far as they appear to have been fully equal to, had he been longer spared to please and inform mankind.

The large work of Titian, the "Death of St. Peter, Martyr," has already been mentioned as an instance of grandeur and sublimity of effect, which, in a greater or less degree, is the general characteristic of his pictures; but he sometimes chose the gay and luxuriant class of subjects, and in managing

them produces, by his brilliancy of colour, by his clearness and brightness of chiaro-oscuro, and the excelling power of his pencil in expressing his thoughts, great perfection in this branch also: a beautiful instance of which is the large picture of "Bacchus and Ariadne," now in possession of the earl of Kinnaird.

It, however, was Correggio who carried the artifice of effect to its ultimate point. He had not the strength of opposition of Titian, but his effects are more sweet, more chaste, more inviting, than those of the latter. One general hue more absolutely prevails, and the eye is more determinately led to the subject, not having that confusion to contend with, which it necessarily finds where there is a greater variety of tones to disturb its enjoyment. The artifice of Correggio is, however, more apparent than Titian's in his best works.

The Carracci, and their followers, by endeavouring to unite the valuable parts of both with the style of design of the Roman school, fell gradually from good, to indifferent and bad; and it was with the Flemings and Dutch that effect was retrieved from the disgrace the Italians were unable to prevent its falling into. Rubens, after several others who had great skill, burst forth with astonishing splendour in his effects, and Rembrandt seconded him with a vigour till then unknown even by Correggio, but not, as has already been said, with his grace and sweetness. Many of Rembrandt's works are of extreme difficulty and beauty in their effects, and have a brilliancy of light almost rivaling that of nature. Many of his followers distinguished themselves by treading in his steps, and succeeded happily in their arrangements; and most of the painters of that country, notwithstanding the vulgarity of the subjects they chose, fascinate, by the skilfulness of their general effects, no less than by their laborious imitation of the subject-matter of their pictures.

In England the art of painting was rescued, and in this part more particularly by sir Joshua Reynolds, from the low state in which it was grovelling: the skill and taste of this great man enabled him to produce effects inferior to none in beauty, grace, and elegance. His pictures seldom or never fail to attract and gratify, at a casual view, however slight and unfinished they may appear on a closer inspection; and in some of his most highly studied works he is equal to the best, having made the happiest imitations of the beauties of others, and superadded a grace peculiarly his own.

EFFECTS, in *Commerce*, &c. the goods possessed by any person, whether moveable or immovable; particularly those which merchants and dealers acquire by trade. See CHATELLETS.

The effects of merchants are usually distinguished into three classes, good, bad, and doubtful. By an ordinance of the French court in 1673, every merchant is obliged to take an inventory or review every year of all his effects of every kind.

EFFECTS, *Vacant*. See VACANT.

EFFECTIONS, in *Geometry*, the geometrical constructions of propositions.

The term is also used in reference to problems and practices; which, when they are deducible from, or founded upon, some general propositions, are called the *geometrical effections* thereof.

EFFECTIVE, in a *Military Sense*, applies to such individuals in a company, regiment, or body of troops, as may be capable of acting efficiently in their several stations: thus, we say, four thousand five hundred and forty-five *effective*; meaning such as are fit for service, and totally excluding all who from wounds, sickness, or other causes, are not qualified to appear in the ranks. In the returns of battalions, a distinction

distinction is made between such as are included in the numerical strength of the corps, and such as are enrolled beyond the ordinary number of rank and file. Thus, when an adjutant or a quarter-master is attached to any particular company, wherein he occupies the place of lieutenant, or ensign, he is said to be *effective staff*; that is to say, he is on the numerical-effective strength of that company, and not enrolled abstractedly from any company in the regiment. Consequently, he stands in the way of promotion, and causes that in which he is enrolled to have one efficient officer less than any other company. On the other hand, when such a staff officer appears only on the list of staff in a regiment, without being enrolled in any company, he is said to be *non-effective*, because he forms no part of the complement of any company, all being completed with efficient officers, to the total exemption of such staff-officers. When there are officers, or men, beyond the regulated number, such are called *supernumeraries*. Whether an officer be *effective*, *non-effective*, or *supernumerary*, his promotion proceeds alike; such matters having no relation whatever to his army, or to his regimental rank. Hence, *supernumerary* officers are a great detriment to the promotion of the *effective*; and this was at one time so feverishly felt, that, in order to do away the uneasiness felt by the latter, the several regiments had an additional number of field officers appointed, partly takers from the *supernumerary* list, and filled up from the *effective* officers. These were called *en second*, a term taken from the French service, in which those officers who distinguished themselves were promoted over the heads of seniors of their respective ranks in the same regiments, but had no additional pay. In some instances, those who had been thus superseded regained their priority of rank, on being promoted to the same class with their supercessors. Of late this has been discontinued, owing to its being considered a grievance, and such meritorious individuals as pre-eminently distinguish themselves, are removed to the legion of honour; thus rewarding the brave, and opening a channel for the promotion of the *effective* officers of the corps. When a battalion is weak in officers, it is common to appoint the adjutant and the quarter-master, if they are old officers, to the charge of companies; but this by no means alters their designation of *non-effective*; in fact, temporary derangements in the economy, or in the strength of a regiment, cause no change in the establishments of the staff.

EFFELDER, anciently called *Affalters*, in *Geography*, a small town of Germany, in the duchy of Saxe Cobourg, with an old castle belonging to the duke of Saxe Gotha. It reckons about 300 inhabitants, and has a considerable manufacture of tiles.

EFFEMINATE, **EFFEMINATI**, according to the Vulgate, are mentioned in several places of scripture. The word is there used to signify such as were consecrated to some profane god, and prostituted themselves in honour of him.

The Hebrew word, *ladesh*, translated *effeminatus*, properly signifies consecrated, and hence was attributed to those of either sex, who publicly prostituted themselves in honour of Baal and Astarte.

Moses expressly forbids these irregularities among the Israelites; but the history of the Jews shews, that they were notwithstanding frequently practised. Levit. xxiii. 18.

EFFENDI, in the *Turkish Language*, signifies *master*; and accordingly it is a title very extensively applied; as to the musti and emira; to the priests of molques, to men of learning, and of the law. The grand chancellor of the empire is called *rei-effendi*. See **KODJA**.

EFFERDING, or **EFERTING**, in *Geography*, a small

town of Austria, not far from the Danube, in that part of Upper Austria which is called the Haufruch quarter, in the district which goes by the name of Donauthal, or valley of the Danube; nine miles W. of Linz. It has an ancient castle.

EFFIAT, a small town of France, in the department of the Cantal; six miles S.E. of Montpenfer.

EFFERVESCENCE, is popularly used for a light ebullition, or a brisk intestine motion produced in a liquor by the first action of heat, without any notable separation of its parts. See **BOLLING**.

Effervescence is a sudden and rapid disengagement of gas, taking place within a liquid and separating from it with a hissing noise. The gas of effervescence is produced by simple or compound elective affinity, and is always a sign of chemical action. In the former case, it is, for the most part, carbonic acid, and in the latter it is either nitrous gas or hydrogen. It is manifest that the gas must have little or no affinity with the fluid in which it is immersed, in order to produce effervescence: hence it is, that though carbonic and muriatic acids are each of them, when dry, in the form of gas, and are both extricated from their alkaline combinations by sulphuric acid, yet a solution of carbonate of potash in water shall produce with sulphuric acid a vehement effervescence, while muriat of potash, in the same circumstances, shall produce none at all, the carbonic acid having little or no affinity for water acidulated by sulphuric acid, while the muriatic acid will combine with the same very readily.

EFFICACIOUS, **EFFECTUAL**, in *Theology*. Within these two centuries there have been great disputes on the subject of efficacious grace. Grace is usually divided into sufficient and efficacious; though the Jansemits hold that there is no grace sufficient but what is efficacious, *i. e.* but what effectually determines the will to act.

Efficacious grace is that which enlightens the mind, and touches the heart, in such a manner, as always to produce its effect, however it be opposed or resisted by the will. See **GRACE**.

Some divines maintain that efficacious grace is efficacious of itself. Efficacious grace of itself, if there be any such thing, is that which produces its effect merely of itself, and not in virtue of any consent of the will. Calvin is the first that used the term, *gratia efficax per se*, "grace efficacious of itself."

A late divine holds the efficacy of grace in itself to consist in this: that efficacious grace is always joined with a moral necessity of doing the thing it inclines to; and sufficient grace, joined with a moral impotence of doing it. The Arminian and Popish way of conceiving the necessity of efficacious grace, is, that this grace is never wanting, at least to the righteous, except through their own default; that they always stand in need of other inner graces truly and properly sufficient, in order to draw down this efficacious grace; and that these do infallibly draw it down, when they are not rejected, though they often remain without effect, because men resist, instead of yielding their consent to it.

F. Malebranche maintains, that the mutual commerce between soul and body, *i. e.* life, has no other vinculum or principle but the efficacy of God's decrees; and that second causes have no proper efficacy, &c.

EFFICIENT, in *Philosophy*. An efficient cause is that which produces an effect. See **CAUSE**.

Philosophers usually distinguish four kinds of causes in nature; the *efficient*, *final*, *formal*, and *material*. See each under its proper article.

The school philosophers are exceedingly divided as to the nature

nature and essence of an efficient cause. Aristotle defines it, *id unde*, "that from which;" or the first principle of change and rest, *i. e.* of production and conservation.

The efficient is called *id unde*, "that from which;" as the end or final cause is that *propter quod*, "for which;" the exemplar, *ad quod*, "that to which;" the matter *ex quo*, "that out of which;" and the form, *per quod*, "that by which." Others of the schoolmen define efficient to be "principium per se influens in aliud sine mutatione sui." The Ramists, after Plato and Cicero, define an efficient to be that, *a qua res est*, "from which a thing is;" to which a great author objecting, that a thing may be also from its end, adds that an efficient is that, "a qua res vera causalitate proficiscitur." Others define efficient to be, *qua per actionem causat*, "that which causes by acting;" for to effect, every body knows is to act. Lastly, others define an efficient to be a cause, *a qua aliud producitur*, "from which something is produced;" consequently what arises from such a cause is called an effect; and thus God is the efficient cause of the world, and the world the effect of God; to which definition of an efficient, all the former definitions are reducible.

An efficient cause, which most properly deserves the name of a cause, because it produces the effect by some sort of active power or natural agency, is either physical, as the fire is the efficient cause of heat; or moral, as an adviser is the cause of a murder; or universal, which in various circumstances produces various effects, as God and the sun; or particular, as a horse which produces a horse; or univocal, which produces an effect like itself, as a horse begets a horse; or equivocal, according to the old doctrine, as the sun producing a frog; or natural, which acts not only without precept in opposition to artificial, but also from within, and according to its own inclination, in opposition to violent, as fire acts when it warms; or spontaneous, as a dog eating; or voluntary and free.

Others consider efficient causes, either as principal, or as instrumental: others, either as next or remote, or as mediate or immediate; others, in fine, divide efficient causes among all the kinds of beings, natural and supernatural, spiritual and corporeal, substantial and accidental, vital and not vital, &c.

But the most celebrated division of efficient is that into *first* and *second*.

A first efficient cause is that between which and the effect there is some necessary connection: of which kind there is none but God alone.

A second efficient cause is that from which an effect follows in consequence of the will or constitution of the Creator, and which the Cartesians call an *occasional cause*.

But these precarious or occasional causes are, in reality, no causes at all, but only antecedent effects. This is easily shewn; for, 1. All action, at least all corporeal action, is contained in motion; but motion can only result from the first cause, it being an allowed principle, that body of itself is inert and inactive. The true cause of motion, therefore, is a spiritual not a corporeal nature. 2. But neither can a finite spiritual nature be the chief cause of motion; for there is no necessary connection between the will, *e. gr.* of an angel, and the motion of a body, nor between that of any other being except God. Thus, when an angel wills, a stone moves, because God has constituted such a law between the will of the angel and the motion of the stone; and thus we move our hands when we please; not that the soul is the principal cause of motion, but only the occasional cause. See CAUSE.

EFFICIENTS, in *Arithmetic*, the numbers given for an operation of multiplication, called also the *factores*. See FACTOR and COEFFICIENT.

The efficient is the multiplicand and multiplier.

EFFIGY, EFFIGIES, a portrait or representation of a person to the life. See PORTRAIT.

EFFIGY, is also used for the print or impression of a coin, representing the prince's head who struck it.

EFFIGY, *to execute or degrade in*, denotes the execution or degradation of a condemned, contumacious criminal, who cannot be apprehended or seized.

In France, they hang a picture on a gallows or gibbet, wherein is represented the criminal, with the quality or manner of the punishment: at the bottom is written the sentence of condemnation. Such persons as are sentenced to death are executed in effigy.

EFFINGHAM, in *Geography*, formerly *Leavisflowen*, a township of America, in Strafford county, New Hampshire, S. E. of Offsee pond, in Olissee river, incorporated in 1766, and containing 451 inhabitants.

EFFINGHAM, a county of America, in the lower district of Georgia, bounded by Savannah river on the N. E., which separates it from S. Carolina, by Ogechee river on the S. W. which divides it from Liberty county. It contains 2072 inhabitants, including 762 slaves. Its chief towns are Ebenezer and Elberton.

EFFLORESCENCE, of *ex, out, and flos, flower*, in *Botany*, denotes the blooming of a flower.

EFFLORESCENCE, is the formation of a powdery crust, or of minute spicular crystals on the surface of any substance. It is applied in *Chemistry* to two distinct, and, in some degree, opposite phenomena, which it is of consequence to be aware of. Those salts, which, during crystallization, combine with a large proportion of water, are very apt, on exposure to a dry air, to lose a part of their moisture, in consequence of which they are at first superficially, and afterwards entirely reduced to powder. This effect, at least in its commencement, is called efflorescence. But there is another kind of efflorescence wholly distinct from this, as when we speak of the efflorescence of iron pyrites or of new mortar: in these cases it implies the appearance of a superficial covering of minute hair-like crystals, and is occasioned by the chemical changes that take place on the surface of the substance where these crystals appear. Thus sulphuretted iron is changed by efflorescence into sulphat of iron, or green vitriol: whereas sulphat of soda, when subjected to the kind of efflorescence first mentioned, although changed in form, remains the same in composition, except that it has lost part of its water. The one destroys crystals, the other produces them.

EFFLORESCENCE, in *Medicine*, a redness, or eruption on the skin, from *flos, a flower*. It is synonymous with *Exanthema*, which is from the Greek *ἄνθος*, also signifying a flower. See EXANTHEMA.

EFFLUI, in *Geography*, a town of Norway; 32 miles N. of Christianfand.

EFFLUVIA, fluxes, or exhalations of minute particles from any body: or emanations of subtle corpuscles from a mixed sensible body, by a kind of motion of transpiration.

Oderiferous bodies, every one knows, are continually emitting substantial effluvia, by means of which they excite in us the sense of smelling. These minute effluvia are sometimes perceived by the eye, in form of fumes and vapours.

Some bodies are found to emit effluvia for a great number of years, without any considerable loss, either as to bulk or weight; as different odorous bodies, the tenuity of whose emanant corpuscles is incredible; not but that the loss they sustain by the continual emission of effluvia may be made up

to them by the reception of other similar effluvia of the same kind of bodies diffused through the air.

It is added, that these effluvia are emitted in manner of *radii*, *rays*, *in orbem*; and the circumference or bound of the activity of the radiation exhibits the same figure as is that of the radiant. This the astronomers sufficiently prove, from the ratio of the refraction of the atmosphere. For the law of the emission of these effluvia, see *QUALITY*.

The effluvia may considerably operate upon and have great effects on bodies within the sphere of their activity, is proved by Mr. Boyle in an express Treatise on the Subtlety of Effluvia; where he shews, 1. That the number of corpuscles, emitted by way of effluvia, is immensely great. 2. That they are of a very penetrating nature. 3. That they move with vast celerity, and in all manner of directions. 4. That there is frequently a very wonderful congruity, or incongruity, in the bulk and shape of these effluvia, compared with the pores of the bodies they penetrate into and act upon. 5. That in animal and organical bodies particularly, these effluvia may excite great motions of one part of the frame upon another, and thereby produce very considerable changes in the economy. Lastly, that they have sometimes a power of procuring assistance in their operations from the more catholic agents of the universe, such as gravity, light, magnetism, the pressure of the atmosphere, &c.

That effluvia are emitted to very great distances, we have a notable proof in odoriferous effluvia being in many cases perceived at the distance of many leagues. Again, that the generality of effluvia retain the proper colour, smell, taste, and other properties and the effects of the bodies whence they proceeded, and this even after they have passed through the pores of other solid bodies, we have abundant proof. And the same we see confirmed in sympathetic inks and powders, and in the sagacity of bloodhounds, &c.

The wonderful extension of effluvia, and the small diminution of the body they issue from, is one of the strangest problems in physics.

The determinate natures of effluvia, according to the principal instances we have of them, are reducible to these three heads: 1. That these effluvia being by condensation, or otherwise reunited, they appear to be of the same nature with the body that emitted them. 2. Their determinate nature may be sometimes discovered by the difference that may be observed in their sensible qualities; so far as those effluvia which are endowed with them proceed from the same sort of bodies, and yet those afforded by one kind of bodies being in many cases manifestly different from those which fly off from another; this evident disparity in their exhalation argues, that they retain distinct natures, according to the nature of each body from which they proceed. 3. We may discover this different nature of effluvia from their effects upon other bodies than the organs of our senses; considering that the effects which certain bodies produce on others by their effluvia, being constant and determinate, and always different from those which other agents produce by their emissions on the same or other subjects, the distinct nature of the corpuscles, emitted on this occasion, may be sufficiently judged of, were it only from this. Boyle "On Effluvia."

EFFLUVIA, in *Medicine*, are those animal and vegetable exhalations which give rise to various diseases of the febrile kind.

These effluvia arise, as we have just stated, from two different sources, and produce different diseases, according to their origin from the animal body, when they are termed *contagious effluvia*; or from the remains of vegetable matter,

especially in combination with moisture, as in fens and marshes, when they are usually termed *marsh miasmata*. The effluvia from the animal body, or contagious effluvia, produce *continued fevers*; as the typhus, the ship, gaol, hospital, and other malignant fevers; or the various eruptive fevers, as small pox, measles, scarlet-fever, chicken-pox, &c. The effluvia of vegetable origin, as the marsh miasmata, give rise to fevers of the *intermittent and remitting* class; as the tertian, quartan, and quotidian ague; and the remittent fevers occurring in camps, and in hot and moist climates.

With respect to the animal, or contagious effluvia, it has already been observed, that they are produced in three ways. 1. The natural and healthy effluvia, or insensible perspiration of the human body, when accumulated and confined in a close and ill-ventilated place, become vitiated, and acquire a contagious property. 2. Where people, labouring under any diseases, especially of the febrile kind, are crowded together in great numbers, or in close apartments, the effluvia arising from their bodies are more readily rendered contagious, than in the former case; and the effluvia from the bodies of those already affected with malignant, or eruptive fevers, are always contagious. And, 3. Contagious effluvia are said to have been occasionally sent forth from putrefying animal matter. Of all these modes, in which contagious effluvia originate, examples were formerly adduced. See *CONTAGION*.

Of the vegetable effluvia, or marsh miasms, we shall have occasion to speak in detail, under the head of *Intermittent Fever*. See also *MIASMATA*.

It may be observed, that, after the discovery of the composition of the atmosphere, and of the chemical means of investigating the properties of every species of gas, or air, great hopes were entertained by some speculative physicians, that the power of detecting the presence of these contagious effluvia, which contaminated the air with contagion, would be by those means attained; and Dr. Mitchell, an American, imagined that he had detected this principle of contagion in the nitrogen, or azotic gas, which he thence denominated *septon*, considering it also as the principle of putrefescency. But these hopes and speculations were premature and visionary. It has been found, that, so long as the atmosphere retains the due proportion of its component parts, of oxygen and azote, it may, nevertheless, be greatly impregnated with contagious effluvia, which escape the detection of chemical tests, and are not cognizable by the endiometer: it has been found, too, that even chemistry does not enable us to discover any very material difference between the air abroad, and that in a heated and crowded room, nor any whatever between the air of the country and of the town. In short, the salubrity, or insalubrity of the air we breathe does not depend so much, in general, upon that arrangement of its component parts, which chemistry alone enables us to detect, (we except the occurrence of damps in mines, &c.) as upon the intermixture of those effluvia, which do not change its chemical properties.

EFFLUXION, a flowing out, from *ex*, out of, and *fluere*, to flow.

EFFOYES, in *Geography*, a town of France, in the department of the Aube; 3 leagues E. of Bar-sur-Seine.

EFFRACTURA, (from *effringo*, to break down,) a kind of fracture, in which the bone is much depressed by the blow.

EFFRONTES, in *Church History*, a sect of heretics, in 1534, who scraped their forehead with a knife till it bled, and then poured oil into the wound. This ceremony served them instead of baptism. See *BAPTISM*.

They

They are likewise said to have denied the divinity of the Holy Spirit.

EFFUSION, the pouring out of any liquid thing with some degree of force.

In the ancient heathen sacrifices there were divers effusions of wine, and other liquors, called *libations*.

EFFUSION, or *Fusion*, in *Astronomy*, denotes that part of the sign Aquarius, represented on celestial globes and planispheres, by the water issuing out of the urn of the water-bearer. See **AQUARIUS**.

EFFUSION, in *Medicine*, relates to various fluids which are poured out into the different cavities of the body, and upon the surfaces of different parts. Effusions of coagulable lymph are usually the result of inflammation, especially of membranous parts, and the appearance of layers of this portion of the blood after death is generally deemed a sufficient criterion of the previous existence of inflammation. This effusion is discovered on the membranes of the brain, in phrenitis; on the pleura and lungs, after pleurisy; in the wind-pipe, after croup; and so on: and it is through the medium of this effusion, that adhesions between inflamed membranes, and other parts, are effected. Thus, when the peritonæum is inflamed, it sometimes becomes glued to the intestines; the lungs to the ribs, in pneumonia, or catarrh; and sometimes suffocation is produced, in peripneumony, from the quantity of this effusion into the substance of the lungs. In a word, it is by this effusion of lymph that nature unites recent wounds, suppresses hæmorrhages, obliterates vessels bound by ligature, and effects other important changes in the animal economy.

Effusions of serum, or the watery part of the blood, into the different cavities of the body, or the interstices of the cellular membrane, constitute the various modifications of **DROPSY**; which see. Sometimes blood itself is effused into different parts of the body: when under the skin, if in the form of spots, it constitutes *petechiæ*; if in broader patches, *ecchymoses*, or *ecchymomata*; if in stripes, like the strokes of a whip, *vitæces*. These occur in malignant fevers, and in purpura and scurvy they are the leading and most obvious symptoms.

EFFUSION. This word, in *Surgery*, signifies the escape of any fluid out of the vessels, or viscera, naturally containing it, and its lodgment, either in another cavity in the cellular substance, or the substance of parts. Thus, when the chest is wounded, blood is sometimes effused from the vessels into the cavity of the pleura; in cases of false aneurism, the blood gets out of the artery into the interstices of the cellular substance; in cases of fistula in perinæo, the urine gets from the bladder and urethra into the cellular membrane of the perinæum and serotum; and when great violence is applied to the skull, blood is often effused even in the very substance of the brain.

Effusion also sometimes implies an oozing, or separation of some fluid, from vessels, which have not been ruptured. Thus, in cases of inflammation, surgeons frequently speak of coagulating being effused on different surfaces, and in the internal texture of the parts affected.

EFFUSION of Blood, *effusio sanguinis*, in our *Old Writers*, is used for the milt, sine, or penalty, imposed for the shedding of blood. This the king used frequently to grant to lords of manors. Among others it was granted to the abbot of Glastonbury.

EFLANI, in *Geography*, a town of Asiatic Turkey, in the province of Nætoia; 32 miles E.S.E. of Amasieh.

EFLANLU, a lake of Asiatic Turkey, in Nætoia; 36 miles W. of Boli.

EFRIM, a town of Egypt; 27 miles E.S.E. of Alexandria.

EFT, or **EFF**, in *Zoology*, the name of a creature very common in all parts of England, and called also *newt*, and the *swift*, and by others the *common lizard*, *lacerta vulgaris*. See **LACERTA**.

The beak, or snout, of this creature is oval and obtuse; its back of a rusty-iron colour; its feet have each five toes, and are armed with very sharp though small claws. That toe which is in the place of the fore finger with us is the longest of all; and that which answers to our thumb is placed lower. Ray's Syn. Quad. p. 264.

We have several species of this animal with us. 1. The common land eft, with the black spotted belly. 2. The snake-like eft, which is frequent in our heaths. 3. The small brown land eft. This is very scarce. 4. The yellow scaly land eft, described by Plott in his History of Staffordshire. And, 5. The brown and black spotted water eft. Ploet's Staff. p. 252.

The land eft, or, as the naturalists often call it, the land *salamander*, has something very remarkable in its outer coat. Its skin often appears dry, like that of the lizard kind, but often also it appears wetted, and as if covered with a fine shining varnish; the change from one to the other of these states is usually performed in an instant, and it frequently becomes immediately wet all over on touching it. It also contains, under the skin, a sort of milky liquor, which spurts out to a distance on pressing the body of the animal.

The passages for this milk are, a vast number of pores, or holes, many of which are plainly visible to the naked eye; and very probably the first-mentioned liquor, which covers the skin in manner of a varnish, may be the same with this, its white colour not being distinguishable when it is spread for thin over the surface of the animal. This milk resembles very much the milky juice which the tithymals, and many other of the succulent plants, afford on being cut, or broken. It is of an insupportably acrid and styptic taste; and though the tongue receives no injury from touching it, yet the sensation is so violent, that one is apt to imagine there must be a wound made in it. This animal, when bruised, yields also a very disagreeable smell.

It has generally been supposed, that this animal is of a poisonous nature; and the famous salamander of the old writers seems to be of the same genus, if not the same animal. Mr. Maupertuis, determined to inform the world of the truth in regard to these remarkable particulars, caused a larger number of these animals to be brought to him, which the country people, who had caught them about the bottom of old walls, brought to him with as much caution as if they had been vipers.

From his trials, it appeared very evident, that the stories of this creature's being poisonous, are as idle and groundless as those of its living in the fire.

One thing remarkable this gentleman observed in his dissections of the animal, which was, that he found in several of the females, at once, clusters of eggs, and living young ones. The eggs formed clusters resembling those of the ovaries of birds, and the young ones were contained in two tubes, or long pipes, the coats of which were perfectly transparent; and the young ones were easily distinguished through them; and there were counted in one female fifty-four of these, all living and vigorous. Med. Acad. Par. 1727.

The water eft affords an excellent opportunity of seeing the circulation of the blood by means of the microscope, particularly of the solar one. By this apparatus, the vessel are seen beautifully delineated on the skin; and the rube of blood, in the large ones, is equal to that of the stream of

water which is shewn in hydrostatical experiments thrown out of a vessel by condensed air. In either of these cases, you can see no appearance of separate drops, or globules, but the whole forms one continued body. In the lesser vessels the globules are seen passing along very swiftly, yet evidently separate from one another.

It is remarkable, that in the tail of this animal there seem a greater number of vessels than are immediately necessary to the circulation of the blood: for, when thus examined, there will be often seen two parallel vessels, in one of which only the circulation is performed, and this successively in one and the other of the vessels, the tide often leaving the one wholly empty, which had just before been full, and circulating in the other. Phil. Trans. N^o 460. p. 728.

EFF-Stones, in the *Materia Medica* of the American Indians, a name given to certain stones, said to be found in the stomach of a certain species of water newt, or eft, in the manner of the bezars in other animals. The waters of Brazil, Cuba, and Mexico, abound with this species of eft; but it does not seem well attested, that this sort of stone was ever found in any of them by those who have dissected numbers of them, on purpose to search for it. We have in Europe swallow-stones, and other such things, whose names, and their fabulous histories, would impart their being produced in animals. As many swallows have been destroyed in England in looking for these stones, as newts in Mexico in looking for those; and by the appearance of the American as well as the European stones, they both seem to be dug out of the earth, and to have been once the teeth, or other parts of fishes. Redi, Experim.

The virtues of the eft-stone of Mexico are celebrated by Ximenes, and all others who have been upon the spot. It is said to be a certain remedy for the gravel, and all other nephritic complaints, and even to break and dissolve the stone when already concentered in the bladder. But this account of its virtues seems as improbable as that of its origin. Redi tried these and many other stones of famous character among writers, and found no effect in any of them. These eft-stones never produced any visible effect in his trials, in nephritic complaints, nor the eagle-stone in women's labour, nor the stones swallowed by Caymans in quartans, though Menardes looks on these last as infallible in this case.

EGA, in *Geography*, a river of Spain, which runs into the Ebro, about a league below Calahorra.—Also, a town of Portugal, in the province of Beira; 7 miles S.S.W. of Coimbra.

EGABRA, in *Ancient Geography*, a town of Spain, in Boetia; now *Cabra* in Andalusia.

EGAKTO, in *Geography*, one of the smaller Kurile islands, in the North Pacific ocean. N. lat. 49° 5'. E. long. 152° 41'.

EGBEL, a town of Hungary; 8 miles W. of Tolpaltzen.

EGBERT, in *Biography*, the first king of England, was descended from the Saxon princes who established themselves in this country, and a branch of the royal family of the kingdom of Wexsex. He had, towards the end of the eighth century, withdrawn into France, seeking an asylum in the court of Charlemagne. Here he was received with hospitality, and served in the armies of that monarch, where he acquired those talents which rendered him superior to all his Saxon countrymen. In the year 800 he accepted the invitation of the nobles of Wexsex, and became their king. His first employment was against the Britons in Cornwall, whom he defeated in many battles. He went on conquering till he finally united the whole hep-

tarchy under his sovereign authority. This event, which gave political consequence to England, took place in 827. His government was quiet with regard to his own subjects, but the Danes made many incursions against England, which were long a source of great calamity to the country. In 832 they plundered the isle of Sheppey; they next landed on the coast of Dorset, where they were met by the king, and driven to their ships with much loss. In the midst of his warlike cares Egbert closed his life in the year 838, and left the government to his son Ethelwolf, who was perfectly unequal to the duties devolved upon him. Hume's Hist. vol. i.

EGEDE, HANS or JOHN, superintendent of the Danish mission in Greenland, was born in the year 1686, and at the age of 21 he became preacher at Bogen, in Nordland. Soon after he formed the project of converting the Greenlanders to the Christian religion, for which purpose he went to Greeland, established the Danish mission, and employed himself in the work with much zeal during fifteen years. He died in 1758, leaving behind him a good description of the natural history of Greenland, which has passed through several editions, and has been translated into the Dutch and French languages. The edition of 1763, printed at Geneva, was illustrated with a map and 10 plates. His son Paul, from the age of 12 years, was one of his most active assistants: Denmark was indebted to him for the success of its colony at Greenland; and the inhabitants of that desolate country are under great obligations to him for the anxiety which he felt, and the pains which he took to promote their welfare and comfort. He kept a journal from his twelfth year till his eightieth, which is said to contain a multitude of curious facts respecting the Greenlanders, their manners and customs, and the superstitious notions which they entertain. He died in June, 1789. Gen. Biog.

EGEK, in *Geography*, a town of Hungary; 8 miles E. S. E. of Levens.

EGELESTA, in *Ancient Geography*, a town of Spain, S.W. of Lobetum.

EGELN, in *Geography*, a town of Germany, in Lower Saxony, and duchy of Magdeburg; 16 miles S.W. of Magdeburg.

EGENBURG, a town of Germany, in the archduchy of Austria; 12 miles S.W. of Znaycn, and 36 N.W. of Vienna.

EGER. See **DRAMMEN**.

EGER, *Egra*, or *Cheb*, a handsome town of the empire of Austria, in the kingdom of Bohemia, in the territory of the same name, situated on the river Eger, on the boundaries of Franconia; 120 miles W. of Prague, and 250 N.W. of Vienna. E. long. 12° 30'. N. lat. 50° 2'. It is considered as next to Prague in point of importance, and remarkable for its mineral waters.

EGER-HORN, one of the *peaks* of the Wetterhorn group of mountains in Switzerland; which borders on the valley of Grindelwald, and slopes gradually from barren rock and snow to fertility and cultivation. There are two high pyramids, which tower near the Jungfrau, called from their position the exterior and interior Egers. The substance of these mountains is granite, covered with calcareous stone lying on reddish slate, which in many places forms a species of breccia, composed of an argillaceous base, covered with calcareous fragments. The height of the Eger is 13,086 English feet.

EGERI, a district of the canton of Zug, in Switzerland. See **ZUG**—Also, a lake, 8 miles S.E. of Zug.

EGERMIMATE, of *ex, aus*, and *germen, bud*, in *Botany*, signifies to bud or spring out.

EGERO,

EGERO, in *Geography*, a small island near the coast of Norway, in the North Sea; 24 miles S. of Stavanger.

EGERTON, THOMAS, in *Biography*, viscount Brackley, was born in Cheshire about the year 1540, and admitted commoner of Brazen-nose college in Oxford, in 1556. Here he laid the foundation of learning, and removed to Lincoln's-inn, where he applied with much diligence to the study of the law, and became a noted counsellor. In 1581 he was appointed solicitor general to queen Elizabeth, and in the following year he was elected Lent reader of Lincoln's-inn, and one of the governors of that society. In June 1592 he was made attorney-general, and soon after received the honour of knighthood. The mastery of the Rolls was conferred on him in 1593, and in 1596, by the queen's special favour, he received the seals, with the title of lord-keeper. He was, at the same time, sworn of the privy-council. Few persons have enjoyed their advancement with more general approbation than this eminent lawyer. He was consulted and employed on all weighty affairs of state. He acted as a true friend to the earl of Essex, endeavoured to mitigate the impetuosity of his temper, and to render him submissive to the higher powers. When the earl proceeded to open insurrection, the lord-keeper Egerton was sent, with others, to Essex house, to know the meaning of the tumultuous assembly held there. He commanded them to lay down their weapons and depart, which they not only refused, but held the delegates as prisoners, while Essex, with his associates, made their last attempt to raise the city. (See DEVEREUX.) Upon the death of Elizabeth, her successor James I. signified his pleasure that sir Thomas Egerton should continue to exercise the office of lord-keeper. Soon after he created him baron Ellesmere, for his faithful services to the late queen and himself; and immediately afterwards constituted him lord high chancellor of England, an office which he held above 12 years with dignity and reputation. In 1610 he was elected chancellor of the university of Oxford, the duties of which he performed with much honour to himself and with advantage to the church of England. His health began to decline about the year 1615, when he was attacked by sir Edward Coke in an affair relative to an interference of the court of chancery in a matter of common law. The case was argued before the king, assisted by several eminent lawyers, who decided in favour of the chancellor. He was soon after appointed high steward at the trial of the earl and countess of Somerset, for the death of sir Thomas Overbury, and after the earl's conviction, he steadily refused to affix the great seal to the pardon extended to him by the king. His age and growing infirmities induced him to solicit his dismissal from the office of chancellor, with which the king complied, though with much regret; at the same time raising him to the style and title of viscount Brackley. He died at York-house in the Strand, March 15, 1617, in the 77th year of his age; and the earldom of Bridgewater was conferred on his son as a reward of his father's virtues. This worthy man, and excellent lawyer, was in his disposition open and sincere; in his administration honest and upright. He was a zealous and faithful servant of the crown, and did not scruple to give his sovereign James the most wholesome advice on many very important topics. His private character was virtuous and honourable. In his life-time was printed a speech which he delivered in the Exchequer chamber, in Robert Calvine's cause; and after his death appeared his "Privileges and Prerogatives of the high court of Chancery"; and his "Observations concerning the Office of lord chancellor." He left his chaplain, Mr. (afterwards bishop) Williams, four MS. collections, relating to the pre-

rogative royal;—the privileges of parliament;—the proceedings in chancery;—and the power of the star-chamber: which are supposed to have been the chief source of that prelate's legal and political knowledge. He was thrice married, and left behind him John, afterwards earl of Bridgewater, and Mary, married to sir Francis Leigh. *Biog. Brit.*

EGESTION, from *egero*, I cast out, in *Medicine*, the fame with dejection.

EGG, in *Comparative Anatomy*. Under this term might be described, without impropriety, the parts immediately subservient to the development and growth of the embryo in all animals, even in those which are called viviparous; but as the English word egg is only in common use for the ovum of birds, we shall at present confine ourselves to a description of it in that class of animals, and refer our readers for a more general account of the subject to the article OVUM, in *Comparative Anatomy*.

The parts entering into the composition of the egg of birds are, the shell, the membranes, and the humours, or rather semi fluid substances.

The form of the egg in most birds is not an exact oval, although that figure appears to have derived its name from its close resemblance to the shape of the ovum in birds. Eggs, having one of the ends smaller, or more pointed than the other, allow a larger number of them to be placed in the nest, than if each were a perfect ellipsis, the variety in the shape of the ends being applicable to the different sized angles left by the irregular apposition of a number of round surfaces to each other. The usual form of eggs would seem to be designed to render this arrangement in the nest more compact during incubation, as, where the bird lays but few eggs, they commonly possess more strictly the oval figure; and the eggs of the ostrich, which, from the temperature of the climate, do not require the constant incubation of the parent, are of a shape between a sphere and an ellipsis.

The most prevalent colour of birds' eggs is a milk white; but to this there are numerous exceptions, especially amongst the *passerine* tribes. Eggs are often bespeckled with red, brown, &c. on grounds of different colours, and sometimes are of one strong plain tint, as green, &c. but a description of the varieties in the colour and form of eggs belongs to the department of natural history.

The shell, or calcareous investment, (cortex or putamen of the older anatomists,) is secreted from the internal surface of that part of the oviduct which is called the uterus, as already mentioned in the *Anatomy of Birds*. It adheres strictly to the external membrane of the egg, with which it appears to be in a degree intermixed, by being incruited in the interstices of its external surface.

The shell varies very much in thickness according to the size of the bird. In the eggs of very small birds the shell is thinner than the finest paper, while in the ostrich it is one-eighth of an inch thick; but in every instance the shell is porous in its texture, and always light and fragile in proportion to its thickness.

Aristotle, Pliny, and some other older writers on the subject, supposed that the shell acquired its hardness after being laid, from evaporation, and the influence of external air. Fabricius spoke doubtfully on this point, and the opinion was not re-uted until Harvey wrote. This error seems to have arisen from the circumstance of hens frequently laying their eggs before the shell is fully formed; in which case, the covering of the egg becomes much more firm after it is completely dry: but from the quantity of calcareous matter which the perfectly formed shell contains, it seems impossible that it should possess any pliancy, or accommodate its shape to that of the passage through which it is ejected, as the older writers supposed:

supposed: the common mode of ascertaining whether a hen be about to lay or not, by introducing the finger into the cloaca and touching the hard shell of the egg, sufficiently proves that no material change is produced on the shell by exposure to the air. The impressions, which frequently appear upon shells, and which some people imagine are occasioned by the construction of the anus, are formed in the oviduct at the time the calcareous matter is deposited. It sometimes happens, that a very small egg is found included in another of a common size. Harvey mentions his having met with an instance of this kind, in which he found both the external egg, and the one it contained, invested with a hard shell.

The earthy matter of the shell is composed of carbonate and phosphate of lime, which are said to be held in connection by a small quantity of gelatine. The analysis given by Wauquelin is as follows:

89.6	carbonat of lime.
5.7	phosphat of lime.
4.7	animal matter.
<hr/>	
100.0	parts of egg shell.

In one experiment we made, of dissolving the shell of the egg in vinegar, the animal substance which remained appeared only as a fine membrane, or cuticular covering, on the external surface of the shell; we conceive therefore that the calcareous matter of the shell is not deposited in the same manner as the earth of bones, but as a crust on the external membrane of the egg, and that the animal substance is confined to the superficies of the shell, from which arise its greater density and polished appearance.

The external membrane, or membrane of the shell, (*membrana aluminis* of Blumenbach) possesses exactly the form of the shell to which it serves as a lining; it is by far the strongest membrane in the egg; it is smooth and glossy on the inner surface, and a little flocculent on that next the shell, to which, as has been before observed, it intimately adheres. This membrane is devoid of fibres, it has a degree of elasticity which is equal in all directions. It has been long known to be composed of two layers; but we have been enabled to separate it into a greater number of laminae by boiling it, or by partially drying it.

The *folliculus aëris*, or *air cell*, is a circular space left between two layers of the external membrane at the great end of the egg. This separation of the membrane exists before the egg leaves the oviduct; it is, however, originally very inconsiderable; in a recently laid hen's egg it is about a quarter of an inch in diameter, but in stale eggs it is frequently found to measure an inch across, and in the later stages of incubation the external membrane is separated almost throughout into two layers by means of the air of the folliculus. The increase of the air before incubation depends upon the evaporation of the most fluid parts of the egg, which proceeds more rapidly than is commonly supposed; we have ascertained by experiment that an egg by evaporation alone loses several grains of its weight every day. The diminution of the fluids of the egg is more considerable during incubation, both from the exposure to a high temperature, and the consumption of these substances in the formation of the chick, and hence the necessity of the admission of so large a portion of air into the egg during the period of incubation. This air is commonly supposed to be designed for the respiration of the foetal chick: the arguments for such an opinion, with those against it, will appear more properly in the article *INCUBATION of the Egg*, which see. It

is sufficient at present to account for the existence of air in the egg, without discussing its uses.

The chemical properties of the air contained in unincubated eggs have not heretofore been exactly ascertained. It has been supposed by some to be hydrogen. Coxe and others have thought it to be oxygen. Others again, as Hales, Blumenbach, &c. have considered it as atmospheric air; which last opinion we are led to adopt both from reasoning and direct experiments made on the subject. It is universally allowed that the shell and external membrane of the egg are porous; if they were not so, evaporation of the humours could not take place to the extent we have stated; the same structure which gives passage to the fluids may admit likewise air; it is to be supposed, therefore, that except the small globule which exists before the shell is formed, the folliculus derives its air from the atmosphere. It is further to be observed, that the organization of the external membrane does not permit its performing any office like secretion. It is itself an excretion from the oviduct, and even during incubation, when the other membranes are vascular, it does not acquire blood-vessels, but remains unchanged in its structure.

With the view of proving whether the air in the folliculus was received from without, or produced within the egg, we have covered the shell with varnish, and, in several instances, in which this experiment was made, no sensible addition to the quantity of air originally contained in the air-cell took place: we have likewise essayed to analyse the air of a number of unincubated eggs, by collecting it in a graduated glass tube, over mercury and over water, and exposing it to the action of lime-water, phosphorus, and nitrous gas; by which experiments similar results were obtained, as, when atmospheric air was made the subject of inquiry. In some instances the air of eggs appeared to contain more carbonic acid gas, and less oxygen; but the deviation from common air, with respect to the quantity of these gases, was so inconsiderable, that it could not always be detected. Some effect, with regard to the purity of the air of eggs, might be expected in consequence of its remaining for a certain time in contact with the external membrane; if we may credit the assertions of Spallanzani, the air in the egg must be deprived of a considerable part of the oxygen. He states that he found the shells of eggs and of testaceous mollusca absorb oxygen freely. In order to satisfy himself if this gas was attracted by the calcareous matter, or the animal substance combined with it, he made corresponding experiments with snail shells which had been long deprived of their inhabitants, and had lost by decay and exposure almost all their animal substance, and with other shells which were in a more recent state, and he found that the absorption of oxygen was in proportion to the quantity of animal matter remaining in the shell. (*Journal de Physique*, Fructidor, an. 11.)

It is customary to judge of the freshness of eggs by the degree of warmth which is felt upon the application of the tongue to the large end of them: the sensation of heat in this way is never absolute, but comparative; that is to say, the temperature of the egg is not actually so high as that of the tongue; but the presence of the air-cell behind the shell at the great end, prevents that part abstracting the heat of the tongue so readily as the other portions of the egg.

The *whites* of the egg were described as a single humour by the elder anatomists; they were called by Aristotle *ovii albedo*; *ovii albus liquor* by Pliny; *ovii candidum* by Celsus; *ovii album et albumentum* by Apicius, and *albumen* by Fabricius ab Aquapendente: all of which appellations have arisen from the appearance of this humour when boiled. Harvey was the first who made the distinction of two whites. Leveillé, a late French writer, divides the albumen into

three portions; an external (*albumen cortical*), a middle (*albumen moyen*), and a central white (*albumen central*); the last, however, is merely a different name for those parts commonly described under the title of *Chalazas*.

The *external white* is the most superficial; lying immediately under the membrane which lines the shell; all the other parts of the egg are therefore included by it. This white is always most abundant in recently laid eggs; in those that have been long kept it is scarcely to be observed; it is at all times, however, much less in quantity than the middle white. It is a true albuminous fluid, but almost as liquid and transparent as water; two modes are employed for shewing the distinct existence of the superficial white; one is to open the shell and external membrane of a very fresh egg, when this humour will run off, leaving the principal white behind; the other mode is to boil a fresh egg, if gently, the external white will appear like milk, but if the boiling be long continued, the white will become hard, and the external one may be detached by a little pains from the other; it will then be obtained as a lamina diminished in thickness between the two ends of the egg.

Harvey said that the external white was covered with a proper membrane, but we have failed to discover it.

The *middle* or *principal white*, makes the chief part of that viscid, tenacious, transparent, semi-fluid mass which is commonly known under the name of the white of the egg; it is enveloped by the external white, and contains the yolk and the two chalazas; it is said to be inclosed by a membrane; this circumstance does not admit, however, of being clearly demonstrated before incubation, in the later periods of which the tunic of the white becomes exceedingly evident. If the contents of an egg be thrown unbroken into water, they become opaque and slightly coagulated upon the superficies, which presents a smooth membranous-looking surface, but if the white be broken, every part of it that may be in contact with the water assumes the same membranous appearance, so that no conclusion can be drawn with respect to the existence of a membrane from this experiment, unless it be admitted that the white be composed throughout of an arrangement of albuminous fibres or membrane. This is the opinion of Maitre Jean, who was perhaps the most accurate writer on this subject: he says, that the white is a composition of glairy fibres, intermixed with aqueous parts; if, he observes, one beats for a long time the white of an egg, it becomes as fluid as water, which can only happen in consequence of these fibres being broken or attenuated by the motion, so that not possessing any longer their arrangement, the consistence of the whole mass is changed. If other mucilaginous or glutinous liquors be beaten in the same manner, they do not become more fluid, because they do not possess that peculiar arrangement of their parts which can be destroyed by motion: he further observes, that the white of the egg has a structure, and composition altogether peculiar, although from its transparency we cannot perceive it. In order to be convinced of this, it is only necessary to make the following experiment; let an egg be opened, and suffer a small quantity of the white to run out in order to introduce some distilled vinegar in its place, in a little time some parts of the white will be seen penetrated by the vinegar and coagulated, and others still preserve their transparency, by which there will be an opportunity of observing some large fibres differently situated, and many others forming a species of membrane. Observations for la Formation du Poulet, par Maitre Jean, p. 20. 21.

The white of the egg does not float about promiscuously through the egg; it adheres to the membrane, lining the small end of the egg, and always preserves its proper relative

position to the yolk; this may be considered as an additional argument for the existence of solid albuminous fibres in the white.

The albumen, in its natural state, has little taste or smell. When spread thin and slowly over any body, it forms a varnish similar to what is made by gum arabic; which it also resembles in taste. It may also be again dissolved in water, and brought back to its original state. Uncoagulated albumen soon putrefies, unless it be dried; after which it may be preserved for any length of time.

It is infoluble in alcohol and ether: acids do not dissolve it unless it be coagulated and heat applied.

When alkalis are mixed with the solution of albumen in water, no apparent change takes place; but if a concentrated solution of pure potash be triturated with albumen for some time, and then allowed to remain at rest, the albumen gradually coagulates, or rather gelatinizes; for the coagulum has a striking resemblance to jelly. It gradually hardens; and at a particular period of its drying, it resembles very exactly the crystalline lens of the eye. When quite dry, it is brittle and transparent. Thomson's Chemistry, p. 400.

None of the earths form infoluble compounds with albumen, in this respect resembling the alkalis.

In a number of experiments mentioned by Dr. Thomson, in which he tried the effects of a great variety of metallic salts upon a solution of albumen, obtained by mixing the white of one egg with a pint of water, every metal, except cobalt, occasioned a precipitate: but no precipitate ever appeared, when the oxyd was held in solution, by an alkali or an earth. The effect of the metallic salts on albumen form a striking contrast with their effect on gelatine.

A solution of tan forms, with an aqueous solution of albumen, a very copious yellow precipitate, of the consistence of pitch, and infoluble in water, which is a combination of tan and albumen. When dry it is brittle, like over tanned leather, and is not susceptible of putrefaction. Nicholson's Journal, i. 272.

According to the chemical analysis which has been made of the white of the egg, 100 parts of it contain 80 parts of water, 4.5 of uncoagulable matter, and 15.5 of pure albumen. By distillation it affords water, carbonat of ammonia and empyreumatic oil, a coal remaining in the retort which yields soda and phosphate of lime.

The white of the egg is well known to be coagulable by heat, acids, alcohol, and even by water in a slight degree.

It has been supposed by Fourcroy and other chemists, that the coagulation of the albumen was produced by a combination with oxygen. To determine if this supposition were well founded, M. Carradori exposed the fresh albumen of an egg to the heat of boiling water, having previously covered its surface with olive oil: he asserts that coagulation was effected as readily in this way as in open air; and that there was no escape of elastic fluid through the oil, which would have happened had the water undergone any decomposition during the experiment. M. Carradori likewise observed, that when he coagulated albumen in contact with oxygen gas, no absorption of this fluid took place; he therefore concludes that the coagulation of the albumen is not effected by the oxygen, but by the action of the caloric alone. Annali di Chimica di Brugnatelli.

Scheele attributed the coagulation of the albumen to its combination with the matter of heat, which opinion he supported by some ingenious experiments. Mr. Thomson, on the other hand, observes that, as we know when a fluid is converted into a solid, caloric is usually disengaged, it is extremely probable that the same disengagement

takes place here. But the opinion has not been confirmed by experiment. Fourcroy, indeed, relates that he saw the thermometer rise several degrees; but as others have not been able to perceive any variation of temperature during the coagulation of albumen, it cannot be doubted that this philosopher has been misled by some circumstance or other to which he did not attend. Thomson's Journal, iii. 271.

It is remarkable, that if albumen be diluted with a sufficient quantity of water, it can no longer be coagulated. Scheele mixed the white of an egg with ten times its weight of water, and then, though he boiled the liquid, no coagulum appeared. Acids, indeed, and alcohol, even then coagulated it; but they lose their power if the albumen be diluted with a much greater quantity of water, as has been ascertained by many experiments.

When albumen is coagulated either by heat, alcohol, or acids, it is an opaque substance of a pearl white colour, tough, and of a sweetish mucilaginous taste; it is no longer soluble in water, and is less susceptible of decomposition than uncoagulated albumen. Mr. Hatchet kept it for a month under water without its becoming putrid. By drying it in the temperature of 212°, he converted it into a brittle hard, yellow, substance, semi-transparent like horn.

When this substance was digested for some hours in water, it softened and became white and opaque, like newly coagulated albumen.

When coagulated albumen is steeped in diluted nitric acid for some weeks, it communicates a yellow tinge to the acid, and becomes itself opaque, but does not dissolve: when the albumen, thus treated, is immersed in ammonia, the liquid assumes a deep orange colour, inclining to blood red, the albumen is slowly dissolved, and the solution has a deep yellowish brown colour. If the albumen, after being steeped in nitric acid, be washed, and then boiled in water, it is dissolved, and forms a pale yellow liquid which gelatinizes, when properly concentrated. If the gelatinous mass be again dissolved in boiling water, the solution is precipitated by tan and by nitro-muriat of tin. Hence we see that that nitric acid has the property of converting coagulated albumen into gelatine. For this important fact we are indebted to Mr. Hatchet.

Coagulated albumen is readily dissolved by a boiling lixivium of potash, ammonia is disengaged, and an animal soap is formed. Hatchet, Phil. Trans. 1800. Thomson's Chemistry, p. 494. &c.

The *albuminous cords*, which connect the yolk with the white were called, from a fancied resemblance to hail, by the older writers, *Chalazæ*, *Grainelles*, &c. From the use which Vic D'Azir ascribed to them, he named them *Ligaments suspenseurs du jaune*. Leveillé has described them as a third white, *albumen central*; and in this country they are popularly known, in consequence of a vulgar error, by the name of the *tread* or *treadle*.

These parts are two substances of a much more firm texture than any other portion of the white: they appear to be composed of an opaque albuminous membrane coiled upon itself, so as to form a cord; this cord is again convoluted or doubled upon itself, to which some thick greenish semi-transparent albumen adheres, so as to give the whole a knotted or granulated figure; from which it was formerly compared, though not very aptly, to hail. These cords are each attached by one of their extremities to the membrane of the yolk, at which place the cord is dense and compact; the other extremity is lost in the white, and is loosely formed, and ends in membranous folds; the attachment of the cords to the yolk membrane is at the two poles of the yolk, cor-

responding to the two ends of the egg. The chalazæ are not generally of the same magnitude; one is larger and more knotted than the other, and extends towards the great end of the egg: the smaller one lies next the small end, and makes a turn to one side of the egg. Sometimes one of these cords is wanting, and this happens more frequently in the eggs of the *guinea fowl*, than in those of the common *hen*.

The above description of the chalazæ corresponds with that generally given by authors, and with what we have observed in nature, but differs very materially from the account of these parts which Leveillé has published.

He considers the chalazæ not as separate bodies; he says, they are conjoined by means of a light train of albuminous substance, and thence look upon them as a distinct white. He asserts, that their relation to the yolk is not the same that has been described even by the most modern authors; they are not, he says, situated at the two opposite poles of this globe; but divide its circumference in two segments, of which the difference in extent is very remarkable, and is in the proportion of 24 to 100.

In speaking of the cords themselves, he says, they never have been described by him; although, in his own language, he had before him the description of Maitre Jean, who says, "Ils semblent naitre l'un & l'autre de la membrane, qui reconvre le jaune, par un pedicule qui semble composé de deux petits cordons, ou boyaux entortillés comme une corde." (Observations sur la Formation du Poulet, p. 15.)

Leveillé proceeds to say of these two cords, one is purely membranous, twisted upon itself, and joined to the membrane of the yolk, from which it is easily detached by dissection or the blentils of the egg; this cord is often wanting. The other is truly vascular, twisted on itself, and formed like an umbilical cord; it is continuous and incorporated with the membrane of the yolk, one cannot separate it without breaking this particular tunic, and opening the cavity which contains the yolk. It is always to be observed in fresh eggs; but in those long kept, it is, as it were, macerated and detached. It is to this detachment and disorganization produced by time, that we attribute the want of success in incubation; it is this conduit which explains the point of communication between the yolk and the white. Its vascular structure is not equivocal, if after having divided it in a transverse direction it be observed with the naked eye, as we have done in the presence of Cuvier, or examined with a magnifying lens of small powers. Sometimes we have seen it injected with a yellow fluid, and upon this point we claim the testimony of Déyieux. The free extremity of this cord is pencillous and divided into an infinite number of very small filaments, which may be considered as the ramifications of the principal trunk, intended to form for many suckers calculated to absorb the most fluid part of the albuminous substance. (Dissertation Physiologique sur la Nutrition des Fœtus considérés dans les Mammifères & dans les Oiseaux, par J. B. F. Leveillé, &c. &c. Journal de Physique, tome v. Floreal, an. 7.) M. Leveillé assumes this explanation of the use of the albuminous cords, as an original discovery; although Maitre Jean had long since declared a similar opinion in these words: "Quoique j'appelle ligamens ces deux appendices qui sont aux deux côtés du jaune, je n'estime pas que leur seul usage soit d'attacher le blanc au jaune, mais qu'ils servent encore à préparer le blanc ou à le filtrer & le conduire dans le jaune."

With respect to the points of attachment of the two albuminous cords to the membrane of the yolk, we have no hesitation in saying, that Leveillé has mis-stated the fact, and that they are placed at the poles of the yolk, and as

near as may be, in the words of Maitre Jean, diametrically opposite (diametralement opposés.)

We have repeatedly examined the albuminous cords with the view of discovering the vacuolity of one of them, as stated by Leveillé, but have never been able to perceive it; although the observations were conducted with much care and attention, and made under a variety of circumstances, and with glasses of different magnifying powers; we have also made several attempts to inject the cords with coloured fluids, in both directions, but without success. We are, therefore, led to conclude, that there is no vessel in either of the chalazas; for we entertain but little inclination to credit the evidence of Leveillé respecting this circumstance, from finding his representations so erroneous in general, so much so indeed, that we should not have thought it necessary to have noticed his opinions at all, had he not associated with them the respectable names of Cuvier and Déyex.

Leveillé has said likewise, that the chalazas are covered with a membrane; this, however, is not visible even during incubation, although at that time the membranes become so much stronger; and its existence does not seem probable, as the dense albumen of which the chalazas are composed is gradually lost in the common substance of the principal white.

The yolk, or *vitellus*, is that well known spherical yellow mass which occupies the centre of the egg; it is inclosed in an extremely thin but dense membrane, which is apparently without fibres, and is inelastic; this membrane is at all times really double, but it is extremely difficult to demonstrate the internal layer previous to incubation.

The globe of the yolk, as before stated, is enveloped by the white; it is not, however, situated exactly in the centre of the albumen, but somewhat nearer the great than the small end of the egg; and it is always found near the superior surface of the albumen in whatever way the egg may be placed.

The yolk varies a good deal in size, it is occasionally found double. It is always a smaller mass in the egg of birds than the white, which was observed by Aristotle, although some late writers have expressed doubts with respect to this circumstance. Its absolute weight is considerably less than that of the white. An entire egg weighs usually about two ounces. In one instance, where we weighed the parts separately, the white was found to be one ounce one drachm and five grains, and the yolk only five drachms and fifty-seven grains; the white, therefore, was three drachms and eight grains heavier than the yolk. When a given portion of the white and the yolk are compared, the latter is found to possess less weight than the former. It is in consequence of the greater specific gravity of the white that the yolk is always seen near its upper surface. If a yolk of an egg be thrown into a vessel containing a quantity of albumen, it will be found to descend a little farther than it is observed to do in the white while in the egg; the circumstance of its rising so near the surface of the white in the egg, depends, therefore, probably in part, upon the manner in which these two substances are there connected with each other. If the covering of the yolk be ruptured, and the contents poured upon some albumen, it floats entirely on the surface, which seems to prove that it is the concentrated and globular form which preserves the yolk under the surface of the white while in the egg.

The yolk is usually of a bright yellow colour; but in some birds it is pale, in others it is a saffron colour, and a red-yellow in some others; it is always a much more fluid humour than the white.

The yolk has not the same structure or composition

throughout; the external part is of a deeper colour; it is less tenacious, and contains more oil. The centre is a clear yellow, is viscid, and resembles cream. When the yolk is boiled, the external part appears pale-coloured, porous, dry, and of a farinaceous texture, while the centre forms even a more firm conglobum than the albumen.

The substances into which the yolk is resolvable, are water, oil, albumen, and gelatine; if after being boiled the yolk be heated in a pan, it foams, and when squeezed between the finger, drops of oil exude; if put into linen in this state, and pressed, an oil may be forced out. This oil is of a yellow colour, and insipid, unless too much heat has been employed in preparing it. Its properties are those of fixed oil, or rather of semi-fluid fat. Chandelier obtained this oil without the assistance of heat.

The residue, after the separation of the oil, possesses the properties of albumen, though it is still a little coloured by the remains of the oil; hence, when washed with water, a kind of emulsion is obtained. It is owing to the presence of albumen that the yolk hardens when heated.

When this albumen is boiled in water, the liquid is said to separate a little gelatine. (Thomson's Chemistry.)

Mr. Hatchet found, that when he boiled potash with yolk he obtained a pale olive-coloured concrete animal soap, which being dissolved in water, and saturated with muriatic acid, was thrown down in the state of fat; when burnt, the yolk left a small residuum of phosphat of lime and phosphat of soda. (Phil. Trans. 1800.)

Maitre Jean has observed, that if we harden in boiling water the eggs of young hens, in which the yolk is usually a pale yellow; those of a guinea hen, which have the yolk of a saffron colour; and some duck eggs, in which the yolk is a deep red-yellow; and if we afterwards take equal weights of each of these yolks, and extract the oil from them in the usual manner, we shall obtain more oil from the yolks of the guinea hen than from those of the pullet, and most of all from the yolks of the duck: from which experiment it may be concluded, that the yolk owes its colour, in a great measure, to the oil it contains.

Leveillé relates an experiment on the yolk, which he considers very curious and inexplicable. He states, that he repeated it several times before Déyex, Fourcroy, and Cuvier. He took the yolk of an egg, divested of its membrane, and agitated it in some water, which became, in consequence, turbid and milky. Being suffered to stand for a few instants, the liquid became a very delicate red; this rose-coloured tinge disappeared as soon as all the yolk was dissolved, and seemed to depend entirely upon the solution of the yolk in the water. (Journal de Physique, p. 395.)

It is well known, that the yolk of an egg acquires a reddish hue by being broken and exposed to the air: may not, therefore, this change of colour, in both cases, depend upon the absorption of oxygen?

There is always to be seen upon the centre of the superior surface of the yolk a *white spot*, which, when minutely examined, is observed to be formed of several concentric parts.

Maitre Jean describes this appearance on the yolk under the name of *la tache blanche*; but it is most commonly called the *striaicula*. The latter appellation was given to it by Fabricius ab Aquapendente, under the supposition, that the appearance was occasioned by the separation of the yolks from the peduncles which sustain the capsules of the eggs in the ovary, in the same manner as we see a mark left upon a fruit at the place where the stalk was attached to it. The explanation of Fabricius was, however, perfectly erroneous, for the pedicles of the capsules have no such connection with the ova; this was pointed out by Harvey, but

the name of cicatrícula has been ever since generally employed by writers on the subject notwithstanding; Haller calls the central part of the white spot the *follicle of the yolk* (*follicule du jaune*.)

Maitre Jean gives the following description of the cicatrícula. Upon the superficies, and usually on the side of the large end of the egg, there is always to be observed a whitish spot, sometimes round and sometimes oblong and irregular; in the middle of which one may perceive another small spot of an ash-colour, which usually corresponds in figure with the other; and in the centre of this last, and a little towards the side, there is a small body of a little lighter colour than the other parts of the whitish spot, it is oblong, and a little folded, and seems to float in a liquor. Around the whitish spot there is a narrow grey circle, then another broader one of a yellowish colour, which is surrounded by another of a greyish hue, and lastly, by a fourth circle, which is at first of a deep yellow, and becomes insensibly lighter, until it is lost in the general colour of the yolk. The number of these circles is not always the same; it is sometimes less, at others more, but whatever the number may be, the one distinguished by the deep yellow colour always surrounds the others. (Observation du Poulet, p. 13.)

The obscure ash-coloured spot is the part which is particularly called cicatrícula; because, when the membrane is carefully removed, it is found to be a real depression or cell in the substance of the yolk: this hollow, Maitre Jean describes as being filled with a limpid fluid. Many authors have considered it as the amnios, and believed that it contained the rudiments of the chick. Haller was at great pains to prove that this follicle had no connection whatever with the amnios; and he asserts, that it does not even contain any fluid: we shall defer the discussion of these opinions until we treat of incubation; the changes which the cicatrícula undergoes during that process being highly illustrative of both the structure and uses of this part of the egg.

The *vital properties* of the egg must be necessarily obscure before incubation has excited ostensible actions in the membranes and fluids; they must be confined to the maintenance of the proper organization of the several parts in opposition to the influence of temperature and some other external agents.

The power of generating heat was fully proved to exist in eggs, by some experiments of the late Mr. Hunter, which, as being highly interesting, we shall quote at length.

"I had long suspected," he says, "that the principle of life was not wholly confined to animals, or animal substance endowed with visible organization and spontaneous motion; but I conceived, that the same principle existed in animal substances, devoid of apparent organization and motion, when the power of preservation was simply required.

"I was led to this notion twenty years ago, when I was making drawings of the growth of the chick in the process of incubation. I then observed, that whenever an egg was hatched, the yolk (which is not diminished in the time of incubation) was always perfectly sweet to the very last; and that part of the albumen which is not expended on the growth of the animal, some days before hatching, was also perfectly sweet, although both were kept in a heat of 103°; in the hen's egg for three weeks, and in the duck's for four: but I observed, that if an egg was not hatched, that egg became putrid in nearly the same time with any other dead animal matter."

To determine how far eggs would stand other tests of a living principle, I made the following experiments.

"Having put an egg into a cold about 0, which froze it, I then allowed it to thaw; from this process I imagined, that

the preserving powers of the egg must be destroyed. I next put this egg into the cold mixture, and with it one newly laid; and the difference in freezing was seven minutes and a half; the fresh one taking far much longer time in freezing.

"A new laid egg was put into a cold atmosphere fluctuating between 17° and 15°, it took above half an hour to freeze, but when thawed, and put into an atmosphere at 25°, it froze in half the time. This experiment was repeated several times with nearly the same result."

To determine the comparative heat between a living and a dead egg, and also to determine whether a living egg be subject to the same laws with the more imperfect animals, I made the following experiments.

"A fresh egg, and one which had been frozen and thawed, were put into the cold mixture at 15°, the thawed one soon came to 32°, and began to swell and congeal. The fresh one sunk to 29½°, and in 25 minutes after the dead one it rose to 32°, and began to swell and freeze.

"From these experiments it appears, that a fresh egg has the power of resisting heat, cold, and putrefaction, in a degree equal to many of the more imperfect animals; and it is more than probable, this power arises from the same principle in both." (Hunter's Animal Economy, p. 106.)

The above experiments are very important in different points of view. They prove that vital temperature is not necessarily dependent upon the function of respiration, or any one analogous to it; for eggs, so far from requiring exposure to air, are best kept entirely excluded from it: hence, when varnished or covered with tallow, their vitality may be maintained for an indefinite period. These experiments likewise shew, that the humours of the egg are endowed with life as well as the membranes; for it is not to be supposed that any power of regulating temperature residing in the membranes alone could account for the phenomena related by Mr. Hunter. Had Blumenbach reflected upon these experiments, he would not have referred all the vital properties of the egg to the membranes. (Blumenbach's Lectures, M.S.)

Mr. Hunter's experiments further prove, that the evolution of animal heat does not require vascular action, for even supposing that invisible vessels existed in the membranes at all times, their influence could not be extended beyond these membranes.

It should be added, that during the first hours of incubation, the fluid parts of the egg undergo certain changes in organic structure, and that the membranes exhibit actions, and alter their form previous to the existence of the vessels. Every part, therefore, of the egg, except the external membrane and the shell, must be admitted to possess vital properties. See the articles OVUM, and INCUBATION of the Egg.

EGGS, *Analysis of, in Chemistry and Pharmacy.* The egg-shell is carbonate of lime in a state of very considerable purity, being mixed only with a little animal matter and a minute portion of phosphat of lime. When egg-shells are digested with very dilute nitric acid, the whole dissolves except a few flocculi of animal matter. If the clear solution be supersaturated with pure ammonia, the small trace of phosphat of lime which was taken up by the acid is precipitated singly, after which, the carbonate of lime may be thrown down by any carbonated alkali.

The white of the egg has been generally considered as very pure albumen, the properties of which have been described under that article. It is, however, not perfectly pure albumen, as a more accurate chemical analysis has detected several other substances. The latest and most exact is that of Dr. Boftock.

The white of egg, even when quite fresh, turns syrup of violets to green, whence it is inferred to contain a small portion of naked alkali, which (as in the bile, in serum, and some other animal fluids) is probably soda, and the quantity appears to be no more than about $\frac{1}{100}$ of the whole. The oxalic acid flows a small proportion of lime in white of egg, which is probably contained in the form of phospha. When white of egg is heated it coagulates, and the properties of this coagulum, which may be considered as nearly pure *albumen*, have been described under this article.

It does not all coagulate however, for a portion, which is estimated by Dr. Boileau at about a fourth of the whole, escapes this change. This part is entangled with the coagulum, but may be separated by cutting the latter in slices, and digesting it in boiling water, by which the uncoagulated portion is extracted. On adding to this watery solution some Goulard's extract, (or litharge dissolved in vinegar,) a copious precipitate is formed, but no effect is produced either by infusion of galls or corrosive mercurial nitrat. If the watery solution be slowly evaporated, it does not gelatinize on cooling when concentrated, as the watery solution of jelly does, but gradually inspissates as the water escapes, and at last a hard brittle transparent matter is left behind, which more corresponds with the properties of animal mucilage than any other single animal principle.

A faint smell of sulphuretted hydrogen escapes from the watery solution of the white of egg when boiling, and the vapour blackens silver; whence sulphur is inferred to be contained in the egg, though in an extremely minute quantity.

When the coagulated white of egg is kept for some days by a fire side, or in a temperature rather higher than that of a summer atmosphere, it shrinks, hardens, becomes transparent, and of an amber yellow colour, and the consistence of tough horn. In this state it may be kept unchanged for an indefinite length of time. White of egg loses by this drying process no less than four-fifths of its weight on an average, which loss is merely water.

Owing to this desiccation of white of egg into a clear yellow hard substance, it is often used for varnishing, and with very good effect.

The *yolk* of the egg is a still more compounded fluid than the white. Its colour is yellow, and the taste is bland and rich. It contains a large portion of albumen, whence it coagulates firmly, by the same heat which is sufficient to harden the white, but it also contains a considerable portion of a clear insipid oil, that may be extracted from the hardened yolk by pressure. This oil (*oleum ovorum*) has been in some use in pharmacy, but is now obsolete. It is thus prepared. Take the yolks of any number of hard-boiled eggs, put them in a glazed earthen pan over a moderate fire, crush them to a paste, and beat them with constant stirring, avoiding that degree of heat which would turn them red, till an oily matter sweats out from their surface, and they swell prodigiously; then put them while still hot into a hair bag under a press, the plates of which are heated by boiling water, and the clear oil will flow out, which is of a golden colour, a pleasant smell, and a sweet agreeable taste. From fifty yolks of eggs, about five ounces of oil may be obtained.

The yolk of egg, when rubbed with any watery fluid, mixes with it uniformly into a smooth emulsion, and in this way also it serves as an intermedie in pharmacy, to unite oily and resinous substances with water for more convenient exhibition. See the preceding article.

Eggs, in *Diet*, serve for an agreeable and nourishing aliment; but it is necessary, that they should be fresh and moderately coagulated by heat. If, upon holding them to a candle, they appear of a turbid colour, they are usually

reckoned stale; or if, upon presenting them to the fire, they exhale a moisture, they are fresh. As the substance of eggs affords a matter peculiarly suited to the formation of the young animal, it must be considered as containing a large proportion of nutritious matter; and, consequently, any quantity of it taken into an animal body must be supposed to introduce a large proportion of such matter. But as the white of egg is generally taken into the stomach in its coagulated state, or even if it be taken in its liquid state, the first change that happens to it there is its being coagulated, it must in all cases be again dissolved by the peculiar power of the gastric juice, probably for the purpose of its being mixed with other matters necessary to constitute the proper animal fluid. Dr. Cullen observes, (*Mat. Med.* vol. i.) that although it is surprising what a quantity of egg may be digested by some persons, yet this power is in most cases so limited, that a smaller bulk of this than of any other food, will satisfy and occupy the digestive powers of most men. He observes, at the same time, that egg seems to be a less alkaliescent food than almost any other animal substance, and during its digestion to be less stimulant. With respect to the particular qualities of the eggs of different birds, he is disposed to think, that they are not very different; and he is certain, that in many instances, the peculiar odour and taste of the flesh of the bird, are in no degree communicated to their eggs. He adds, however, that in certain different birds the colour of the yolks and the density of the coagulated whites are somewhat different from one another. The yolk is used in many medicinal preparations, as emulsions, &c.

Eggs, *Albumina*, or *whites of*, are of some use in medicine, though rather externally, in the preparation of collyriums for the eyes, and anacollemeta, on account of their cooling, agglutinating, and astringent quality, than internally.

Albumina are used for burns, and in some mixtures with bole armenic, &c. for consolidating fresh wounds, and under bandages, and compresses to prevent the luxation of bones after reduction. A late writer recommends them as a secret in the jaundice. *Junc. Conf. Therap.* tab. xiii. p. 379. *Quinc. Dispens. part. ii.* § 12. p. 204. *Ephem. Germ. dec. 3.* an. 2. obf. 35. p. 43.

Besides medical, the whites of eggs have also their chemical uses, *e. gr.* for the clarifying of liquors; to which purpose being mixed, and incorporated with the liquors to be clarified, and the whole afterwards boiled, the whites of eggs are by this means brought together, and hardened, and thus carry off the gross parts of the liquor along with them. They likewise form a very white and shining varnish, which is applied to several kinds of work, and particularly to pictures.

Egg shell white, in *Painting*, is sometimes used in water-colours, and preferred to flake or the Troy-white: it is prepared by peeling off the inner skins, and levigating the shell to a proper fineness, and washing over the powder.

Egg, what is termed *centenium ovum*, among *Naturalists*, denotes a sort of hen's egg, much smaller than ordinary, vulgarly called a "cock's egg," from which it has been fabulously held, that the cockatrice or basilisk was produced. *Brown, Vulg. Err. lib. iii. cap. 7.*

The name is taken from an opinion, that these are the last eggs which hens lay, having laid a hundred before; whence *centenium*, *q. d.* the hundredth egg.

These eggs have no yolks, but in other respects are like common eggs, having the albumen, chalazas, membranes, &c. in the place with others.

In the common of the yolk is found a body resembling a little serpent,

ferpent, coiled up, which doubtless gave rise to the tradition of the basilisk's origin from hence.

Their formation is probably ascribed by Harvey to this, that the yolks in the vitellary of the hen are exhausted before the albumina. Harvey De Generat. Animal. Exerc. 12.

M. La Peyronie has carried the history of the ovacentina to a greater length, as well as certainty; a hen was brought to him, which, for a considerable time, laid no other eggs. The same hen was also observed to crow like a cock, and to render by the cloaca a thin yellow matter, much like the yolk of an egg diluted in water. Upon opening her, she was found hydropical; a bladder as big as the fist, full of water, was found contiguous to the oviduct, which it pressed and crowded in such manner, as not to leave the cavity thereof above five lines in diameter; so that a common egg, such as it is when it falls from the ovary into the tube, could not pass without bursting, by which the yolk was let out, and discharged another way. Mem. Acad. Scienc. an. 1710. P. 730.

Eggs, preservation of. M. de Reaumur, of the Paris academy, thinking nothing that could be a public benefit beneath the cognizance of a philosopher, bestowed considerable pains on finding a method of preserving eggs for a long time, and succeeded at length so far in it, as to be able to produce eggs of months, nay years old, which tasted as fresh and well as if they had been laid but the day before. The egg always is quite full, when it is first laid by the hen, but from that time it gradually becomes less and less to its decay; and however compact and close its shell may appear, it is nevertheless perforated with a multitude of small holes, though too minute for the discernment of our eyes. The effect of these, however, is evident, by the daily decrease of matter within the egg, from the time of its being laid, a fluid matter is continually perspiring through these perforations of the shell, which occasions the decay; and this is carried on in a much quicker manner in hot weather than in cold. To preserve the egg fresh, there needs no more to be done than to preserve it full, and stop its transpiration; and the plain and rational method of doing this, is by stopping up these pores through which the matter transpires, with a matter which is not soluble in watery fluids, and therefore cannot be washed away by the matter perspired by the egg; and on this principle, all kinds of varnish, prepared with spirit of wine, will preserve eggs fresh for a long time, if they are carefully rubbed all over the shell. This might seem to most people a very common and cheap substance for this purpose; but the misfortune is, that in country places, where it should be put in practice, no such thing is to be had: and the poorer sort of country people are not easily brought into the use of any thing to which they are not accustomed.

To obviate the difficulty arising from this, Mr. Reaumur thought of substituting in the place of varnish some other substance more common; and soon found, that another substance, which is very cheap, and every where to be had, would very well supply the office of varnish; for experiments proved, that any hard fat would have the same effect. The best of all fat for this purpose, is found to be a mixture of that of mutton and of beef; these should be melted together over the fire, and strained through a linen cloth into an earthen pan; and when thoroughly melted, an egg is to be dipped into it, and immediately taken out again; and it is then in a state to keep perfectly fresh more than a twelvemonth. Memoirs Acad. Scienc. Par. 1735.

The only difficulty attending this method is, that the eggs cannot be so easily plunged into the fat, as that all their surfaces shall be covered by it; for if they are held in a pair of

pincers, the parts of the egg where the pincers touch will be bare; but the eggs may be suspended by a loop at the end of a thread, and by that means plunged in; and the thread being then coated over with the fat, as well as the surface of the egg, will preserve that part which it covers as well as the coat of fat will the rest. The great care is to use this means while the eggs are perfectly fresh; it ought indeed to be done on the very day when they are laid; for if the evaporation is begun, and the empty space once made, there is room for a fermentation, which never terminates but in the destruction of the egg.

There is one advantage in this use of fat rather than varnish, which is, that the eggs rubbed over with it boil as quick as if nothing had been done to them. The fat melting off as soon as they touch the hot water; whereas the varnish not being soluble even in hot water, only becomes softened by it, and still hanging about the egg, prevents the transpiration of juices, necessary to bring the egg to that state in which it is to be eat. When the egg, which has been preserved by fat, is taken out of the water, there remains very little fatness upon it, and what there does is easily wiped off with a napkin, the egg is as nicely fresh as if laid but the day before, and no palate can distinguish the least difference.

The method of preserving them by means of fat, is greatly preferable also to that by varnish, when they are intended for putting under a hen to be hatched; as the fat easily melts away by the heat, while the varnish remains and impedes the hatching. By this means the eggs of foreign fowls might be sent over and hatched here, whereby many beautiful and valuable birds may be naturalized among us.

At Tonquin they are laid to keep eggs entire for three years, by covering them up in a paste made of ashes and brine.

Eggs, Ant. See ANT.

Eggs of Flies. After the congress with the male, the female fly is seldom so much as twenty-four hours before she begins to deposit her eggs on some substance proper to give nourishment to the worms that are to be produced from them.

The eggs are but a little time in hatching; and the growth, and all the changes of the animal, take up but a little time. The creature is found to make its way out of the upper part of the egg; and it is not more than three weeks from the laying of the egg that is taken up, before the creature is seen in the form of a perfect fly, if a female, and ready to deposit hers.

Among the butterfly class the female has but one congress with the male by which the eggs are fecundated, and immediately after it begins to deposit her eggs, and continues so doing, without interruption, till she has finished; but it is much otherwise with the two-winged flies; for they, after having laid one set of eggs, have repeated congresses with the male for several days; and after every one of these, lay a new set.

The female of the butterfly class does not deposit her eggs on any plant at random, on which she happened to be placed when the male coupled with her, but searches out such a species of plant for leaving them on, as is what she loved when in the caterpillar state, and what the young caterpillars to be hatched from them will be able to feed on, that they may find food ready for them at the moment of their birth. She does not scatter them about irregularly, and without order, but she disposes them with perfect symmetry, and fastens them one to another, not by their own glutinous nature, but by a viscid liquor, which she separates for that purpose. In many species also, where the hinder part of the body of the female is covered with long hairs, she by

degrees

degrees throws off all those hairs, and with them makes a nest for the eggs she is laying, where they are kept very soft and safely till the time of their hatching. This, indeed, is the whole business of her life; and when the eggs are all laid, she dies. *Memoirs Acad. Scienc. Par. 1736.*

The eggs of butterflies are of very different sizes, according to the species; they are also of many different figures, some are spheric, others segments of spheres, others conic, in different forms and degrees: nor is this all, their surfaces are very different also in the different kinds. Some are elegantly wrought, as it were; some dented, and others more deeply notched at the sides; and others channelled or furrowed all over. In short, the most ingenious artist could scarcely contrive for many various ornaments as there are on these eggs, all which also are invisible to the naked eye, being discoverable no way but by the microscope.

The eggs of the different species of the two-winged flies are also of very different figures.

There are some species which fasten their eggs to the sides of vessels of water: these all lay oblong eggs: some of them, however, are perfectly smooth in all parts; and those of other species smooth only in their inner surface, and ridged longitudinally on the other. What is also the more remarkable in these, is, that they all have a fine thin flake running down all along the two sides, diametrically opposite; and these two bands surrounding the whole egg in this manner, have much the appearance of a case, and give the egg the appearance of being enclosed in a paper frame. It is probable that the use of this frame is to hold the body of the egg the better fastened against the vessel; and probably those eggs which have it not, are deposited from the body of the female fly with a viscid matter about them, in sufficient quantity to fasten them on without this assistance.

There are some eggs of the fly kingdom which must necessarily be held fast to some other body, in order for the worm to be able to make his efforts towards the opening of them, without carrying them away; and some of the species require much more strong attachments of this kind than others.

On the stalks of the common meadow grasses there are also frequently found the eggs of flies deposited in great numbers. On other stalks of grass, one may often see also yellow spots and blotches, which may naturally enough pass with an incurious observer for maladies of the plants; but when examined with the microscope, they appear to be, in reality, clusters of eggs, and amassed in different numbers: sometimes also they are formed perfect and whole, and at others, with their ends eaten. These last are such eggs from which the worms have made their way. These worms are white, and have a variable head, armed with two hooks, but their changes are not known. *Reaumur, Hist. Insect. vol. iv. p. 276—383.*

Eggs of Gnat. There are few creatures in the winged kingdom more prolific than the gnat. Its whole series of changes, from the egg to the perfect animal, is usually accomplished in three weeks or a month; and there are commonly seven generations of them in a year, in each of which every female is the parent of two or three hundred young ones; if all the eggs come to proper maturity. These eggs are arranged by the animals in the form of a small boat, and each separate egg is of the shape of a ninepin. The thicker ends of these are placed downwards; they are all firmly joined to one another by their middles; and their narrower, or pointed parts, stand upwards, and make the upper surface of the boat of eggs, as it were, rough or prickly.

When these eggs are examined singly by the microscope, they appear not exactly of the ninepin shape: the larger

end is rounded, and terminated by a short neck, the end of which is bordered with a ridge, which makes a kind of mouth. The neck of each of these is sunk within the water on which the boat swims; for it is necessary that it should keep on the surface, since, if wholly submerged, the worms could never be hatched.

It is only in the morning hours that the gnats are to be found laying their eggs; and then they will frequently be found about the surfaces of such waters as are in a proper condition to give support to their young. The female gnat here places herself on a small stick, the fragment of a leaf, or any other such matter, usually near the water's edge, and places her body in such a manner, that the last ring but one touches the surface of the water; the last ring of all, where there is the passage for the eggs, is turned upward, and every egg is thrust out vertically: and the creature, when it is almost disengaged, applies it against the sides of the already formed clusters, to which it readily adheres, by means of mucilaginous sticking matter with which it is naturally covered, like the eggs of many other insects. The greatest difficulty to the creature is, the placing of the first laid eggs in a proper position to receive the rest, and sustain themselves and them in a proper direction; these she with great precaution places exactly by means of her hinder leg; and when a sufficient number of them are thus arranged together, the rest is easy, because they serve as a support to all the following. *Reaumur, vol. iv. p. 615, &c.*

Eggs, Hatching of. See HATCHING.

Egg, Wind. See WIND Egg.

Egg, Sea, Echinus Marinus. See ECHINODERMA.

Egg, Cow's, is a name which some authors give to a kind of bezoard, found in the stomach of the cow kind.

Egg, in Architecture, an ornament of an oval form, cut in the echinus, or quarter round of the Ionic and Composite capitals. The profile, or contour of the echinus, is enriched with eggs and anchors, alternately plated.

Egg, in Geography, a town of Norway; 48 miles E.N.E. of Drontheim.

Egg, one of the western islands of Scotland, about 10 miles in circumference; 4 miles S. of Sky. This island and Canna are the only popish islands.

Egg Harbour, a town of America, in Gloucester county, New Jersey, on Great Egg harbour, famous for the exportation of pine and cedar.

Egg Harbour river, Great, a river of America, which rises between Gloucester and Cumberland counties, in New Jersey; and which, after running E. S. E. a few miles, becomes the line of separation between cape May and Gloucester counties, and falls into a bay of its own name. The inlet from the Atlantic ocean lies in 39° 22'. This river is navigable 20 miles for vessels of 40 tons, and abounds with various kinds of fish, adapted to the market at Philadelphia.

Egg Harbour inlet, Little, lies about 17 miles N. E. of Great Egg harbour inlet. It receives Mulicus river, which rises in Gloucester and Burlington counties, and forms part of the separating line, a few miles from the bay. It is navigable 20 miles for vessels of 60 tons. The township of "Little Egg harbour," in Burlington county, consists of about 23,000 acres of barren and unimproved land. The compact part of the township is called "Clam Town." It has a small trade to the West Indies.

Egg Island, an island on the N. E. side of Delaware-bay, in Cumberland county.

Egg Bird, in Ornithology, the *STERNA fuliginosa*; which see.

Egg-Plant, in Botany. See SOLANUM.

EGGE, in *Geography*, a river of Germany, which runs into the Danube, between Dettingen and Hockstet.

EGGENBERG, a town of Germany, in the duchy of Stiria; three miles W. N. W. of Graz.

EGGERON, a town of Egypt; seven miles S. of Atfeh.

EGGYNA, in *Ancient Geography*, a town of Sicily, mentioned by Cicero.

EGHAM, in *Geography*, a parish in the hundred of Godley and Chertsey, Surrey, England, is situated on the south bank of the river Thames, at the distance of 18 miles from London. In 1801, the parish contained 363 houses, and 2190 inhabitants. The place is a great thoroughfare between the metropolis and the south-western counties of England. In the vicinity of Egham is Runnymede, a place memorable in the English annals, for the ratification of Magna Charta by King John. The same field or meadow is now occasionally used as a race-course. Near the western extremity of this parish is Camomile-hill, a place so named from the quantity of camomile which has been cultivated here, and now grows wild.

EGILSHA, one of the Orkney islands, about six miles in circumference, E. of Rousa.

EGINA, in *Ancient Geography*. See ÆGINA.

EGINHART, in *Biography*, the most ancient German historian, who flourished in the ninth century, was educated with the sons of Charlemagne. To this great sovereign he afterwards became secretary and son-in-law. He appointed him superintendent of his buildings, and sent him to Rome in 806, as his agent with pope Leo III. Upon the death of Charlemagne he was taken into the confidence of Lewis le Debonnaire, who entrusted him with the education of his sons, and settled upon him ample estates. Eginhart, being now well provided for, devoted himself to religious concerns, was placed at the head of the monasteries, and became abbot of Seligstadt. Notwithstanding the partiality which he had for retirement, he was frequently called to the court of his sovereign, to give advice and direction in affairs of moment. At length, he was permitted to renounce all secular affairs, and shut himself up in his monastery, maintaining no other correspondence but with a few men of letters in foreign countries. He died in the year 839, leaving behind him a life of Charlemagne, written in the Latin language, and with a purity of style which was uncommon in that age. Its impartiality and veracity have been called in question, but the editor, it is said, took unwarrantable liberties with it in altering the language. Suetonius was the model which our historian chiefly looked to in the composition of his work. Eginhart compiled the annals of France from the year 741 to 829; these, and his memoir of Charlemagne, were inserted by Bouquet in his collection of French historians. He left behind him likewise 62 epistles, which relate to the history of the times in which he flourished, and which were published at Frankfort in the year 1714. Moreri. Bayle.

EGLANTIERIA, EGLENTERIA, *Eglanderia*, or *Eglanderium*, in *Botany*, the name of a species of Rose, corrupted, as it appears, from the French *Eglentier*, or *Eglantier*, of whose derivation we are ignorant. In English *Eglantine* or *Eglentine*. Turner's herbal. 103. These names unquestionably belong to the common English Sweet Briar, or *Rosa sylvestris foliis odoratis*, Bauh. Pin. 483; *R. foliis odoratis*, *Egletina dicta*, Bauh. Hist. v. 2. 41. *R. rubiginosa*, Linn. Mant. 2. 564. Sm. Fl. Brit. 540. Engl. Bot. t. 991. This therefore is what most authors have taken for *R. Eglanderia* of Linnæus, all whose synonyms in the first edition of Sp. Pl., and consequently the specific character taken from

Haller, belong to it. We learn also from Dr. Afzelius's Dissertation on Swedish Roses, in Sims and Konig's Annals of Botany, v. 2. 213, that this is the true Swedish plant, *R. Eglanderia*, Linn. Fl. Suec. ed. 2. 171. except that the description following the place of growth, is accidentally made from another species, not found in Sweden, the Yellow Briar, or *R. lutea simplex* of Bauhin's Pinax. Now it unfortunately happened that Linnæus originally confounded this Yellow Briar with our Sweet Briar, both having highly fragrant leaves, and he being really, at that time, very slightly acquainted with Roses at all. Accordingly the original marked and numbered specimens of *R. Eglanderia* in his herbarium, are this Yellow Briar, of which an excellent figure may be seen in Curtis's Magazine, t. 363. Long afterwards he received from Myrdin specimens of our Sweet Briar, which he described at the end of his second Mantissa, by the very apt name of *R. rubiginosa*, derived from its specific character and Haller's synonym. He takes care to distinguish it from his *Eglanderia*, though by a strange fatality he quotes Bauhin's *R. lutea* as a synonym, confounding; moreover, the single and double yellow roses that author together, though none can be more distinct.

Of all this we have long ago been sufficiently aware, though entirely obliged to our learned friend for ascertaining the Swedish plant, nor was it without due consideration that we determined to abide by the decision of the able authors and editors of the Hortus Kewensis, to which we still beg leave to adhere. We therefore retain the name of *Rosa rubiginosa* for our Sweet Briar, as being indisputably certain, peculiarly expressive, and now sanctioned by Jacquin, Roth, Willdenow, indeed by general use. Lightfoot named it *R. savaisfolia*, which is at least equally applicable to the Yellow Briar, and has been followed in the Flora Danica only. But on the other hand, we do not follow even Linnæus in his errors, nor apply the word *Eglanderia* to a wrong plant. The Yellow Briar is best named *Rosa lutea* after all the old authors, an appellation first adopted by Miller, nor is there any occasion to call it *foetida* with Allion, though we agree with those who think the smell of its flower unpleasant; especially as the foliage is so very sweet. Neither can any ambiguity arise between it and the Double Yellow Rose, so well named *sulphurea* in the Hortus Kewensis, where it was first properly discriminated. Ehrhart indeed called this last *glaucophylla* and our Yellow Briar *chlorophylla*, expressive names, but altogether superfluous. Even the confusion of English names, which Mr. Curtis dreaded, see his Magazine, t. 363, is avoided by terming one a Briar the other a-Rose, which is perfectly correct. On turning to Lamarck's Flore Francoise in hopes of learning something of the derivation or meaning of the word *églantier*, but in vain, we perceive he has taken the orange-coloured variety of *R. lutea*, or Austrian Rose, Curt. Mag. t. 1077, for Linnæus's *rubiginosa*, an error as remarkable as his making the Apple Rose, or *R. villosa*, a variety of the Sweet Briar. For the use of those who may hereafter write in this work the difficult article ROSA, we must protest against a mistake of our excellent friend Afzelius, in making our *R. tomentosa* the real *villosa* of Linnæus. The latter species depends altogether on his synonyms, and is the large Apple Rose so common in gardens, and wild in the north of England, from which we first, in N. Brit., distinguished this *tomentosa*. We know our friend's candour will excuse us, and we look with anxiety for the sequel of his remarks, to confirm the suggestions, or dispel the doubts, in his admirable essay.

Ambiguity respecting the Eglantine is not confined to systematic botanists. Our great poet in his Allegro has

confounded it with the Woodbine or Honeysuckle, as Mr. Curtis has well remarked in his *Flora Londinensis*, fasc. 1. t. 15.

“Through the sweet-briar, or the vine,
Or the twisted eglantine.”

We have not been able to find any thing in the old heralds to account for this mistake in a writer usually so supremely accurate, nor do the Italians, with whom he was so conversant, throw any light upon this matter. They seem not even to have adopted the word eglantine in any shape, but have appropriate names for the Sweet Briar and Woodbine. Shakspeare, in his *Midsummer Night's Dream*, and Cymbeline, evidently uses the word in question according to its common acceptation. S.

EGLANTINE. See EGLANTERIA.

EGLÉTONS, in *Geography*, a small town of France, in the department of the Corréze, chief place of a canton in the district of Tulle; 18 miles N. E. of Tulle, 12 miles W. of Neuvic, with a population of 886 individuals. The canton contains seven communes, and 5331 inhabitants, on a territorial extent of 145 kilometres.

EGLISAU, a small town of Switzerland, in the canton of Zurich, on the north side of the Rhine, in the district of the same name, remarkable for being more subject to earthquakes than any other part of Switzerland. It is a great thoroughfare from Switzerland to Germany.

EGLISE NEUVE SUR BILLON, a small town of France, in the department of the Puy-de-Dôme; 18 miles S. E. of Clermont.

EGLON, in *Ancient Geography*, a royal town of Palestine, in the tribe of Judah, which, in the time of Eusebius, was merely a village. E. of Eleutheropolis.

EGMONT, JUSTUS VAN, in *Biography*, a painter of history, born at Leyden, but mostly employed in France by Lewis XIII. and XIV. in the establishment of the royal academy of painting and sculpture at Paris. He assisted Vouet in many of his historical works, and painted many of his own composition in large and small, for which he was highly esteemed and liberally rewarded by the French monarch. He died in 1674, aged 72.

EGMONT, LANORAL, *Count of*, a nobleman of great distinction in Flanders, was born in 1522, and at an early age devoted himself to the profession of arms. He accompanied Charles V. into Africa in 1541, and was made captain-general of the lances. In 1546 he went to the emperor's assistance against the protestant princes of Germany, and attended him to the diet of Augsburg. He next came to England, as ambassador, to conclude the marriage between Queen Mary and Philip II. By this sovereign he was appointed governor of Flanders and Artois, and general of the cavalry. From his conduct in war, and in negotiation, he was very highly esteemed at the commencement of the troubles in the Low Countries; and from his services to the crown, and his attachment to the Roman catholic religion, might have been supposed to possess the favour of the court. But his devotedness to the sovereign did not make him less the advocate of the rights of the people, which excited against him cruel enmities. Egmont united with the prince of Orange in opposition to the Spanish councils, by which the Low Countries were now to be governed; they, with count Horn, wrote letters to the king, charging cardinal Granvelle with a mal-administration of affairs, who by their representations was removed, but still the same plans were adopted by the council. Egmont then went to the court of Spain, to lay before the king full information of the state of affairs, and was received with every mark of confidence and outward

esteem; but his destruction was at the same time secretly determined on. He had vindicated the people's rights, a crime not to be forgotten, and when the duke of Alva was sent over for the express purpose of quashing by force all opposition, the prince of Orange in vain endeavoured to persuade count Egmont to withdraw from the storm. One of the first measures of the duke was to seize the counts Egmont and Horn, and to send them out of the province, contrary to the privileges of the maner's subjects, where they were kept in custody, till a special commission was made out to bring them to trial at Brussels. Trial and condemnation, in their case, were terms of the same import, and they were both publicly beheaded in June 1568, to the grief of the whole Flemish people. Egmont was only in his forty-sixth year. The French ambassador wrote on the occasion to his court, “I have seen that head fall which twice made France to tremble.” *Nouv. Dict. Hist.*

EGMONT, in *Geography*, a town of Holland, on the sea-coast; three miles S.W. of Alcaer.

EGMONT Bay, a bay on the S.W. of the island of St. John, in the gulf of St. Lawrence. N. lat. 46° 30'. W. long. 64°.

EGMONT Island, an island in the South Pacific ocean, discovered by Capt. Byron in 1767, and so called by him. S. lat. 19° 20'. W. long. 158° 30'.

EGMONT, Mount, a lofty peak on the coast of New Zealand, situated in S. lat. 39° 16'. W. long. 185° 15'; and so called by Cook in 1770. It appeared to tower above the islands, and was covered with snow. Its base seemed large, and it rose with a gradual ascent. Being near the sea, surrounded by a flat country, and clothed with verdure and wood, it was the more conspicuous. To the shore under it, which forms a large cape, he gave the name of “Cape Egmont.”

EGMONT, Port, is situated in Falkland island, and was so called by commodore Byron in 1765, who represents it as one of the finest harbours in the world. The mouth of it is S. E. distant seven leagues from a low rocky island, which is a good mark to know it by. Within inland, and about two miles from the shore, there is between 17 and 18 fathom water; and about three leagues to the westward of the harbour there is a remarkable white sandy beach, off which a ship may anchor till there is an opportunity for running in. The whole navy of England, says the Commodore, might ride here in perfect security from all winds. In every part of port Egmont there is fresh water in the greatest plenty. Geese, ducks, snipes, and other birds, are very numerous; wild eckery and wood-forrel may be obtained in great abundance; nor is there any want of muscels, clams, cockles, and limpets. Seals and penguins are innumerable, and the coast swarms with sea-lions, many of which are of an enormous size.

EGNATIA, in *Ancient Geography*, a town of Italy, in the part called Pucetia, situated on the sea-coast E. of Bœium, now called Agnazzo.—Also, an episcopal town of Africa, in the Byzantine territory.

EGNAZIO, BATTISTA, in *Biography*, a learned Italian, was born at Venice of poor parents about the year 1478. Having received a good education, he opened a private school, at which the belles lettres were to be taught, when he was only eighteen years of age. The success and reputation which attended the labours of Egnazio excited the jealousy of Sabellico, a public professor of the same city; they became violent enemies, but on the death-bed of Sabellico a full reconciliation took place. Finding himself near his end, he sent for Egnazio, besought his forgiveness, and entrusted to his care his ten MS. books of “*Examples*.” These he published,

lified, and pronounced the funeral oration over the ashes of Sabellico. Egnazio had now conferred upon him the right of citizenship, and was afterwards presented with ecclesiastical preferment. In 1515 he was sent with others to Milan, to compliment king Francis I. to whose honour Egnazio composed a panegyric, for which he was rewarded with a gold medal. In 1520 he was elected public professor of eloquence at Venice, in opposition to many rival competitors. So high was his reputation in this department of literature, that he had frequently five hundred auditors to hear him daily. He was consulted upon important affairs by the senators, who had a great opinion of his wisdom. Towards the decline of life he was desirous of resigning his employment, but was persuaded by the senators to continue, and his salary was augmented. He at length obtained his dismissal, but enjoyed the emoluments of his office without any deduction. He died in 1553, at the age of 75. He was the author of many works, viz. "Orations," "Epistles," a treatise "De Romanis principibus vel Cæsaribus," containing the lives of the Roman emperors from Julius Cæsar to Paleologus, and from Charlemagne to Maximilian I.; a treatise "On the Origin of the Turks," and a work in nine books, "De exemplis Virorum illustrium." He was, as he grew old, very irritable; against Robertello, the person who had censured his writings, he drew his sword, giving him a wound which had nearly proved fatal. Moren.

EGOISTS, in the history of *Philosophy*, a set of philosophers in France, who sprung up after Des Cartes, and who maintained that we have no evidence of the existence of any thing but ourselves. These philosophers are mentioned by many authors, and particularly by Buffier, in his "Treatise of First Principles;" and they have followed the method of Des Cartes, in resting upon the truth of their own thoughts as a first principle, agreeably to his maxim, "Cogito, ergo sum," but requiring arguments for the proof of every other truth of a contingent nature; but none of them, excepting Mr. Locke, has expressly treated of first principles, or given any opinion of their utility or inutilty. Their general opinion may be collected from their following Des Cartes in requiring proof, or pretending to offer proof of the existence of a material world, which surely, says Dr. Reid, (Essays on the Intellectual Powers of Man, p. 642,) ought to be received as a first principle, if any thing be, beyond what we are conscious of.

EGOTOS, a term used by Van Helmont to express the light of understanding, by which we reflect and reason within ourselves.

EGONA, in *Ancient Geography*, a river of Gaul.

EGORBEUSK, in *Geography*, a town of Russia, in the government of Riazan; 28 miles N. of Riazan.

EGOREVSKOI, a town of Russia; 40 miles N.E. of Kologn.

EGOSA, in *Ancient Geography*, a town of Spain, in the Tarragonens territory.

EGRA, a town of Arabia, near the gulf of Ail.

EGRA *Water and Salt*, the celebrated mineral spring near Egra, in Bohemia, appears to be a clear sparkling water, chalybeate when fresh taken from the springs, and which besides contains a considerable quantity of a vitriolic salt, which is doubtless Glauber, and not Epson salt, as it does not become turbid by an alkali. Besides the great consumption of the water at the spring head, much of it is evaporated on the spot, and the residuary salt, which is probably almost entirely sulphat of soda, is sold in Germany and Bohemia under the title of Egra salt. Both the water and salt are much extolled by Hoffmann, and they probably effect all that can be expected from a powerful saline chalybeate.

EGRA, in *Geography*. See EGER.

EGREMONT, a township of America, in Berkshire county, Massachusetts, and incorporated in 1760, and containing 835 inhabitants; 145 miles W. of Boston.

EGREMONT, a market town, and formerly a borough, in the ward of Allerdale, and county of Cumberland, England, is seated on a small river which falls into the Irish sea, near the promontory of St. Bee's. It is five miles from Whitehaven, and 389 from London, has a small weekly market on Saturday, and one annual fair. In 1801 the town consisted of 319 houses, which were occupied by 1515 inhabitants. Many of the houses appear ancient, and some of them have piazzas in front. On a considerable eminence are the remains of an old castle; a part of which has been fitted up as a court, for the steward of the earl of Egremont, who is lord of the manor, and receives his title from the place. Hutchinson's History, &c. of Cumberland, 2 vols. 4to.

EGRET, in *Ornithology*, a species of ARDEA. See HERON.

EGREVILLE, in *Geography*, a town of France, in the department of the Seine and Maine, and district of Nemours; three leagues S.E. of Nemours.

EGRISSELLES, a town of France, in the department of the Yonne, and district of Sens; seven miles S. of Sens.

EGUILLETTE, in the *Manege*. See YERKING.

EGUILLES, in *Geography*, a town of France, in the department of the mouth of the Rhone, and district of Aix; two leagues N.W. of Aix.

EGUMUHA, or ELGIMUHA, a town of Africa, in the empire of Morocco, at the foot of mount Atlas, near which is an iron mine.

EGUISCE. See AIGUISCE.

EGUISEM, in *Geography*, a small town of France, in the department of the Upper Rhine; three miles south of Colmar, and six miles N. of Rouffach.

EGUIZENSIS, in *Ancient Geography*, an episcopal see of Africa, in the pro-consular province.

EGURENDE, in *Geography*, a town of France, in the department of the Correze, and district of Ussil; four leagues N.E. of Ussil.

EGUZON, a small town of France, in the department of the Indre, chief place of a canton in the district of La Châtre, with a population of 1056 individuals. The canton has a territorial extent of 152½ kilometers, 10 communes, and 6199 inhabitants.

EGYPT, a country of Africa, called by its ancient inhabitants Chemia, and by the Copts Chemi, from Ham, the son of Noah, as some have supposed, and in scripture denominated the land of Mizraim, whence the Arabians, and other oriental nations, still call it Mesr. The Greek name Egypt has been derived by some from one of its kings, denominated Egyptus; by others from *ait*, signifying in Greek a country, and *Ægyptos*, softened into Egyptus, and thus denoting "the land of the Copts;" and by others again from the blackness of its soil and the dark colour both of its river and inhabitants, such a blackish colour being called by the Greeks *egyptios*, from *gypt* and *gypte*, a vulture, which is a bird of that hue. Egypt is bounded on the north by the Mediterranean sea, on the south by a chain of mountains, which separates it from Nubia, on the east by the Red sea and the isthmus of Suez, and on the west by the deserts of Libya, in the midst of which stood the temple of Jupiter Ammon. Its greatest length, according to Savary's statement, is from Sienna or Syene, situated almost under the tropic of Cancer, to cape Burlos, which, forming the most advanced point of the Delta, almost terminates the 32d degree of latitude. This distance is about 225 leagues. Its

greatest breadth is 68 leagues, drawing a right line from the ruins of Pelusia to the tower of the Arabs, formerly called Tapofiris. This measure agrees with that of the ancients, which made the breadth of the Delta 54 leagues from Pelusium to Canopus, and 14 from Canopus to Tapofiris. Accordingly Diodorus Siculus and Strabo allow the base of the Delta, extending from Pelusium to Canopus, now called Aboukir, 1360 furlongs, which may be estimated at 54 leagues, to which if we add 14 leagues from Canopus to the tower of the Arabs, we shall have 68 leagues. Herodotus reckons 60 furlongs or 80 leagues from mount Calius to the gulf of Plintine, where Tapofiris was situated; but mount Calius being 12 leagues to the eastward of Pelusium, by subtracting this number from the former, we obtain 68 leagues from Pelusium to Tapofiris. Ancient and modern geographers have not been agreed as to the precise limits of this country. Accordingly some have assigned to its length from north to south 500 miles, and to its breadth, including the greater and lesser Oasiss, about half that measure. Egypt, however, is in reality a narrow vale on both sides of the river Nile, bounded by parallel ridges of mountains or hills. Some of the ancient geographers have even hesitated to what portion of the globe they should ascribe Egypt. Ptolemy and Strabo, with the modern geographers, fix the isthmus of Suez as the boundary of Asia and Africa. Di nysius, Mela, Pliny, Salust, Hirtius, and Solinus, have preferred for that purpose the western branch of the Nile, or even the great Catabathmus, or descent, which last would assign to Asia, not only Egypt, but part of Libya.

Ancient Egypt is divided by some into two parts, the Upper and the Lower Egypt, and by others into three parts, viz. the Upper Egypt, properly called, or Thebais, now called Said; the Middle Egypt, or Heptanomis, now Vostani; and the Lower Egypt, the best part of which was the Delta, now called Bahira or Raf. (See THEBais, HEPTANOMIS, and DELTA.) Besides this larger division, Egypt was also distributed into several governments or prefectures, called by the Egyptians "Tabir," and by the Greeks "Nomes;" the number of which is uncertain, as they depended upon the pleasure of the reigning prince. In general they were about 36, and were named from the chief city of each nome. This division is attributed to Sesostris.

Upper Egypt, according to the modern and commonly received division of the country into Upper and Lower Egypt, is a long valley, commencing at Sienna or Syene, (Asovan,) and terminating at Grand Cairo. Two chains of mountains, taking their rise from the east cataraet, form the limits of that country. Their direction is from south to north, until they reach the latitude of Cairo, where they separate to the right and to the left; one of them taking the direction of mount Colzoum, and the other ending in banks of sand near Alexandria. The former is composed of high and steep rocks; the latter of sandy hillocks, over a bed of calcareous stone. Beyond these mountains are deserts, bounded by the Red sea on the east, and on the west by Africa, in the midst of which is that long plain, which is no more than seven or nine leagues broad, where it is the widest. Here the Nile flows, between two insurmountable barriers, with varied current, sometimes smooth and tranquil, and at other times impetuous and overflowing the country, which it covers with its waters and fertilizes for the space of 150 or 200 leagues (See NILE.) This valley, in which the sciences were first cultivated, and whence they were diffused through Greece and other parts of the world, is still as fertile as it was in ancient times; but it is less cultivated, and many of its former cities, overwhelmed by despotism and ignorance, are laid level with the dust, and their former ce-

lebrity is now chiefly known by their magnificent ruins (See THEBais.) The capital of Upper Egypt is Girge, which see.

Lower Egypt comprehends the whole country between Cairo, the Mediterranean, the isthmus of Suez, and Libya. This immense plain presents, on the borders of its parching sands, a strip of land cultivated along the canals of the river, and in the middle the triangular island, to which the Greeks gave the name of Delta. (See DELTA.) To describe Egypt in two words, says Volney, let the reader imagine, on one side, a narrow sea and rocks; on the other, immense plains of sand; and in the middle, a river flowing through a valley of 150 leagues in length, and from three to seven wide, which, at the distance of 30 leagues from the sea, separates into two arms, the branches of which wander over a country, where they meet no obstacles, and which is almost without declivity. We do not really enter Egypt, says this writer, until we arrive at Rafetta (Rafschid). There the sands peculiar to Africa end, and a black, fat, and loamy soil, the distinguishing characteristic of Egypt, begins; and there also, for the first time, we behold the waters of the celebrated Nile, which, rolling between two steep banks, considerably resembles the Seine, between Anteuil and Passy. The basis of Egypt, from Syene (Asovan) to the Mediterranean is a continued bed of calcareous stone, of a whitish hue, and somewhat soft, containing shells, analogous to those found in the two neighbouring seas, and principally consisting of echini, volutes, bivalves, and a species in the form of lentils. The same kind of stone is discoverable in the pyramids, and in the Libyan rock on which they stand. It is likewise found in the cisterns, in the catacombs of Alexandria, and in the projecting shelves upon the coast. It is also seen in the eastern mountain, in the latitude of Cairo, and in the materials with which that city is built. This calcareous stone forms the immense quarries that extend from Sawadi to Mansalout, for the space of more than 25 leagues, as we learn from father Sicard; who also informs us, that marble is found in the valley of Carte, at the foot of the mountains bordering on the Red sea, and in the mountains to the north-east of Asovan. Between that place and the Cataraet are the principal quarries of red granite, which are continued lower down; because, on the opposite shore of the Red sea, the mountains of Oreb, of Sinai, and their dependencies, at two days' journey towards the north, are loomed of this substance. Not far from Asovan, to the north-west, is a quarry of Serpentine stone, employed in its native state by the inhabitants for the manufacture of vessels, which will stand the fire. In the same parallel, on the Red sea, was formerly a mine of emeralds, the traces of which are now lost. Copper is the only metal of this country mentioned by the ancients. In the road to Suez is found the greatest quantity of what are called Egyptian flints, or pebbles, lying on calcareous stone, that is hard and sonorous; and here are likewise discovered those stones, which, from their form, have been taken for petrified wood. The two lakes of Natron are situated in the desert of Shayat, or St. Macarius, to the west of the Delta. (See NATRON.) In the midst of these minerals, of various qualities, and in the midst of that fine and reddish-coloured sand peculiar to Africa, the earth of the valley through which the Nile flows, manifests properties, which prove it to be of a distinct class. Its blackish colour, and its clayey cementing quality, evince its foreign origin, and indicate its descent with the river from the heart of Abyssinia. Without this fat and light mud, Egypt must have been altogether unproductive. This alone seems to contain the seeds of vegetation and fecundity, and these are owing to the river, by which they are deposited.

The

EGYPT.

The fertility of Egypt, and the excellence of its productions and fruits, are highly celebrated by ancient writers, and even by Moses, who was well acquainted with this country. It abounds in grain of all sorts, but particularly rice; inasmuch that it was formerly the granary of Rome and of Constantinople. The exports of rice are still very considerable, and also great quantities of wheat from Upper Egypt, in favourable years. No oats are seen in Egypt; and the barley is consumed by the horses. The most plentiful parts of Egypt are the *Delta*, (which see), and the province of Faioum, (see FAI OUM,) supposed to be the ancient Hæraclæotic nome; the capital of which, of the same name, is thought to have been Hæraclæopolis, Nilopolis, or Arinoce, and is said by the natives to have been built by Joseph, to whom they owe themselves obliged for the improvements of this territory. Being the lowest part of Egypt, they say that it was nothing but a standing pool, till that patriarch, by making drains, and particularly the great canal, which extends from the Nile to the lake Moeris, discharged the water, and clearing it of the rushes and marshy weeds, rendered it fit for tillage. It is now the most fertile and best cultivated land in the whole kingdom, containing, as it is said, above 350 villages, and yields linen, grapes, and other fruits in abundance; and it fails not bearing even in those years, when the Nile's not rising to its usual height occasions a scarcity in the other parts of Egypt. The flourishing state of agriculture amongst the ancient Egyptians sufficiently appears from the immense works which they constructed for the distribution of their canals, and for watering the lands. At present there are reckoned 30 canals, like rivers, all dug by manual labour, several of which are 20, 30, and 40 leagues in length. These receive the inundation, and circulate the waters through the country. The others, nearly choked up, are dry, upon the fall of the Nile. The large lakes of Moeris, Belhère, and Marcotis formed vast reservoirs for containing the superfluous waters, and for spreading them over the adjacent plains. They were raised upon the elevated grounds by means of vertical wheels, the invention of which is owing to the skill of the Egyptians. One ox was sufficient to turn them, and to water an extensive field. Besides these reservoirs, all the towns, at some distance from the Nile, were surrounded by spacious ponds, to supply the wants of the inhabitants, and for the advantage of cultivation. Some great dykes, the ruins of which are still to be seen, served to keep in the river; others were opposed to the torrents of sand, which have a continual tendency to cover the face of Egypt. The waters are conveyed by aqueducts to the very summits of the hills. There they were received in immense basons hewn out of the rocks, from which they flowed into the midst of deserts, and converted them into fruitful fields. However, in the period of 1200 years, during which this country has been subject to nations that have not directed their attention to cultivation, nor bestowed much labour upon it; the greatest part of the noble works of antiquity has decayed and gone to ruin; and the barbarism of the present government tends to accelerate and complete their destruction. The limits of cultivated Egypt are encroached upon annually, and barren sand is accumulating from all parts. In 1517, the era of the Turkish conquest, lake Marcotis was at no distance from the walls of Alexandria and the canal which conveyed the waters into the city was still navigable. At this day, the lake has disappeared, and the lands watered by it, which, according to historians, produced abundance of corn, wine, and various fruits, are changed into deserts, in which are found neither shrub, nor plant, nor verdure. The canal itself, the work of Alexander, necessary to the subsistence of the inhabitants of the city,

which he built, is nearly choked up, and preserves the waters only when the inundation is at its greatest height, and for a short time. About half a century ago, part of the mud deposited by the river was cleared out of it, and it retained the water three months longer. Schemes have lately been adopted for opening and perfecting this canal. The Pelusiæ branch, which discharges itself into the eastern part of the lake of Tanais, or Merzidè, is utterly destroyed. With it passed the beautiful province which it fertilized, and the famous canal begun by Necos, and finished by Ptolemy Philadelphus. The famous works, executed by kings, who sought their glory and happiness in the prosperity of the people, have not been able to resist the ravages of conquerors, and that disposition, which destroys every thing, till it buries itself under the wreck of the kingdoms, whose foundation it has sapped. The canal of Amrou, the last of the great works of Egypt, and which formed a communication between Foïfat and Colzoum, reaches at present no farther than about four leagues beyond Cairo, and loses itself in the lake of Pîgrims. Upon the whole, it may be confidently affirmed, that upwards of one-third of the lands formerly in cultivation is metamorphosed into dreary deserts. For the cause and the fertilizing effects of the annual inundation of the Nile, we refer to the article NILE. This river, in Upper Egypt, is confined by high banks, which prevent any inundation into the adjacent country; and the case is the same in Lower Egypt, except at the extremities of the Delta, where the Nile is never more than a few feet below the surface of the ground, and where, of course, inundation takes place. Egypt is indebted for its fertility to the assistance of human art. The lands near the river are watered by machines; and if they extend to any breadth, canals have been cut; and, by means of canals, the Nile becomes the source of fertilization. The soil in general is so rich as to require no manure. One of the principal articles of cultivation in Lower Egypt is rice; which is sown from the month of March to that of May. During the inundation of the Nile, the fields are covered by its waters, and for the purpose of retaining them, small dikes or raised embankments are thrown up, round each field, to prevent their running off. Trenches are also dug in order to convey thither a fresh supply, in order to give the plant a constant watering. Rice is nearly six months before it arrives at maturity, and it is generally cut down before the middle of November. As the use of the flail is unknown in Egypt, the rice plants are spread in thick layers on floors, formed of earth and pigeons' dung, which are well beaten and very clean; and then, in order to separate the grain from the straw, they make use of a sort of carts, constructed like our sledges, with two pieces of wood joined together by two cross bars. Between the longer sides of this sledge are fixed transversely three rows of small wheels, made of solid iron, and narrowed off towards their circumference. On the fore part is fixed a high seat, on which a man sits, for the purpose of driving two oxen that are harnessed to the machine, and thus moving it in a circular direction over every part of the heap of rice, till the grain is completely separated from the straw; the grain is then spread in the air to be dried. The dried rice is carried to the mill, where it is stripped of its chaff or husk. This mill consists of a wheel turned by oxen, which sets several levers in motion; and at their extremity is an iron cylinder, about a foot long, and hollow underneath. These cylinders beat in troughs which contain the grain; and at the side of each trough there stands a man, whose business it is to place the rice under the cylinders. The next operation is to sift the rice in the open

air, by filling a small sieve, which a man lifts over his head, and thus lets fall, with his face turned to the wind, which blows away the small chaff or duit. This cleaned rice is put a second time into the mill, in order to bleach it; it is afterwards mixed up in troughs with some fat, which contributes very much to its whiteness, and also to its preservation; and in this state it is sold. Rice is furnished in great quantities in the Delta; and that which is grown in the environs of Rosetta is more esteemed, on account of its preparation, than that which is produced in the vicinity of Damietta. The produce of the one and the other is equally wonderful. In a good season, that is, when the rise of the Nile occasions a great expansion of its waters, the profit of the proprietors of rice fields is estimated at 50 per cent. clear of all expences. Savary says, that it produces eighty bushels for one. As soon as the ground is cleared of the rice, the Egyptians sow a fine variety of trefoil, (Trif. Alexandrinum or Forkal,) which they call "barfim". Its seed is scattered without ploughing, or even turning up the ground, and it sinks to a sufficient depth in the moist soil. This trefoil produces three crops before the time for again sowing the rice; and in its dry or green state it is the most common and the most succulent food for cattle; both at pasture and in stalls. Of the various plants which have rendered Egypt celebrated for its superior abundance, wheat claims the pre-eminence. We have already said, that it was formerly the granary of Rome and Constantinople, and by their means, of neighbouring nations. At this day, Arabia derives from it the means of subsistence. The numerous caravans which set sail from Upper Egypt for Celsair, a port on the Red sea, carry nothing but corn. It is thence conveyed to Djedda, and distributed over part of Arabia. Wheat is sown as soon as the waters of the Nile have retired from the lands appropriated to it; the seed-time varies with the latitude, and also the harvest, which are earlier in Upper than in Lower Egypt. Near to Syene they sow the barley and the corn in October, and reap it in January. Towards Girgé they cut it in February, and in the month of March in the vicinity of Cairo. This is the usual progress of the harvest in the Said. There is also a number of partial harvests, as the lands are nearer or at a greater distance from the river, lower or more elevated. In the Lower Egypt they are sowing and reaping all the year. Wherever the waters of the river can be procured, the earth is never idle, and furnishes three crops annually. In descending from the cataracts in January, the corn is seen almost ripe; lower down it is in ear, and advancing further, the plains are covered with verdure. The cultivator, in general, merely casts the seed upon the moistened earth; the corn soon springs up from the mud, its vegetation is rapid, and four months after it is sown it is fit to be reaped. In performing this operation, the sickle not being used, the stalks are pulled up by the roots, and carried to large floors, like those which are used for treading out rice; and by a similar operation the corn is separated from the ear. Unripe ears of corn are dried and slackly baked in an oven, and being afterwards bruised and boiled with meat, form a common dish in Lower Egypt, called "férik." As they have neither water-mills nor wind-mills in Egypt, the useful arts of the miller, and also of the baker, are here in the rudest state of infancy. Their bread is made in small thin cakes, and is unleavened; and is very slightly baked, so that it is heavy and difficult of digestion. In the towns they have a kind of loaves or cakes, some of which are covered with fennel-seed, procured from Upper Egypt, which give them an aromatic flavour, and others are lost, pierced with holes, and sprinkled with sesamum, or oily grain, which

gives them an agreeable taste. The culture of barley occupies a considerable portion of land throughout all Egypt: it is ripe a month earlier than the wheat, and its harvest is equally abundant. This is the common food of horses in Egypt, as it is in all parts of the East, where oats and rye are unknown. From the most remote periods flax has been in general use in Egypt; and it is a considerable article of cultivation and commerce. Its thread has been employed in the fabrication of the garments of a numerous people. A considerable quantity of cloth is manufactured from it at this day; and the plant, from which indigo is extracted for dyeing it, grows also in this country, where it is called "Nile." Of the hemp, which is abundantly cultivated in this country, the inhabitants prepare intoxicating liquors, and also by pounding the fruits into thin membranous capsules, they form a paste, which answers a similar purpose; and they also mix the capsules with tobacco for smoking. The sugar-cane is also one of the valuable productions of Egypt. The common people do not wait for the extraction of the sugar, but eat the canes green, which are sold in bundles in all the towns. They begin to ripen in October, but are not, in general, fit to be cut till November or December. The sugar refineries are in a very imperfect state. Fruit trees of various species abound in this country. Among these we may reckon the olive-tree, fig-trees which yield figs of an exquisite flavour, and the date-tree, which is to be found every where in the Thebais and in the Delta, in the sands as well as in the cultivated districts, requiring little or no culture, and yielding a very considerable profit, on account of the immense consumption of its fruit. The species of palm tree that furnishes dates produces also a bark; which, together with its leaves and the rind of its fruit, afford filaments, from which are manufactured ropes and sails for boats. The leaves are also used for making baskets and other articles. The very long rib of the branches is employed, on account of its lightness and solidity, by the Mameluks, in their military exercises, as javelins, which they throw at each other from their horses when at full speed. A species of Cyperus, which produces a fruit resembling the earth-nut, but of a much more agreeable flavour, is cultivated in the environs of Rosetta; and the small tubercles are sent to Constantinople and other towns of the Levant, where they are much valued. The Egyptians press from them a milky juice, which they deem pectoral and emollient; and give them to nurses, in order to increase the quantity of their milk. The banana-trees, though not natives of the soil of Egypt, are nevertheless cultivated in the northern parts of that country. The papaw, or cultard apple-tree, is also transplanted into the gardens of Egypt, and yields a fruit equally gratifying to the taste and smell. In the shade of the orchards are cultivated various plants, the roots of which are refreshed by the water that is conveyed to them by little trenches; each inclosure having its well or reservoir, from which the water is distributed by a wheel turned by oxen. The mallow (*malva rotundifolia*) grows here in abundance; it is dressed with meat, and is one of those herbs that are most generally consumed in the kitchens of Lower Egypt. Two other plants, used as food, are the garden Jew's mallow, and the sculent hibiscus. Another tree, which appears to be indigenous in this country, is the "Atlé," a species of large tamarisk (*tamarix orientalis*, Forsk.) The wood of this tree serves for various purposes; and among others, for charcoal. It is the only wood that is common in Egypt, either for fuel or for manufactures. Fenu-greek is a plant cultivated for fodder, though for this use a plant already mentioned, and called barfim, is preferred. This plant, called "helbé," is cried about for sale in November,

in the streets of the towns; and it is purchased and eaten with incredible avidity, without any kind of seasoning. It is pretended, that it is an excellent stomachic, a specific against worms and the dysentery, and, in short, a preservation against a great number of disorders. Lentils form a considerable article of food to the inhabitants of Upper Egypt, who rarely enjoy the luxury of rice. The Egyptian onions are remarkably mild, more so than the Spanish, but not so large. They are of the purest white, and the lamina are of a softer texture and looser contexture than that of any other species. They deteriorate by transplantation; so that much must depend on the soil and climate. They remain a favourite article of food with all classes; and it is usual to put a layer or two of them, and of meat, on a spit or skewer, and thus roast them over a charcoal fire. We need not wonder at the desire of the Israelites for the onions of Egypt. Leeks are also cultivated and eaten in this country, and almost all the species of European vegetables abound in the gardens of Rosetta. Millet and Turkey corn, the vine, the henné or Egyptian privet, the water-melon, &c. &c. are cultivated in Egypt; and the country furnishes a variety of medicinal plants, as carthamus, fenna, colequintida, &c.

Of the animals of Egypt the most useful is the ox; and though the number of oxen now subsisting in Egypt is inconsiderable, these animals were anciently held in high estimation. The worship of them was universal, and sacred oxen were kept in several cities. The celebrity of Apis is well known. (See APIS.) Common oxen, when they chanced to die, were interred with funeral rites, and it was forbidden to put to death those that had already worked. At present, though the race is tolerably handsome, it is much degenerated through long neglect: their horns are generally small, and they are of a fawn colour, more or less deep. The oxen of Egypt are employed in tillage and in giving motion to a variety of hydraulic machines; and as they are harnessed so as to draw from the pitch of the shoulders, their withers are higher than those of our countries; and, indeed, they have naturally some resemblance to the bison (*bos ferus*) or bunched ox. It has been said that the cows of Egypt bring forth two calves at a time; this is an instance of fecundity which sometimes happens, but is not reckoned very common. Their calves are reared to maturity, as usual, which is forbidden by the law of the Mahometans, and the Copts also abstain from the use of it, is not eaten in Egypt. The buffalo is an acquisition of the modern Egyptians, with which their ancestors were unacquainted, and it was brought from Persia into their country. The species is more numerous than that of the ox, and is equally domestic. It is easily distinguishable by the constantly uniform colour of the hair, and still more by a remnant of ferocity and intractability of disposition, and a wild lowering aspect, the characteristics of all half-tamed animals. The females are reared for the sake of the milk, and the males to be slaughtered and eaten. The flesh is somewhat red, hard, and dry; and has also a musky smell, which is rather unpleasant. This country has also horses, asses, mules, and camels. The horses of Egypt, next in rank to those of the Arabians, are remarkable for their beauty and valuable qualities; and this commendation has been justified by the testimonies of both ancients and moderns. According to the Jewish history, it was chiefly in Egypt that Solomon purchased, at a very high price, the prodigious multitude of horses which he kept in his numerous stables (2 Chron. ix. 25. 1 Kings, iv. 26; x. 28, 29.) See also Shaw's Travels, p. 239. In Egypt, and also in Arabia, and almost every other part of the East, it is a general custom to abstain from castrating horses; and the cavalry of Egypt is formed of stone-horses: The asses of this country

have no less a claim to distinction than the horses; and these, as well as those of Arabia, are esteemed for their vigour and beauty the finest in the world. They are sometimes sold for a higher price than even the horses. They are more hardy than horses, less difficult as to the quality and quantity of their food, and are, therefore, preferred in traversing the deserts. The handiomest asses seen at Cairo are brought from Upper Egypt, and Nubia. On ascending the Nile, the influence of climate is perceptible in these animals, which are most beautiful in the Said, but are in every respect inferior towards the Delta. With the most distinguished race of horses and asses, Egypt possesses also the finest mules; some of which at Cairo exceed in value the price of the most beautiful horses. In desert places they have tygers, antelopes, foxes, jackals, hares, sheep, goats, and deer. Egypt has also a species of ape, stronger and more savage than others, called by the Greeks cunoccephalus, from the resemblance which its head bears to that of a dog. There are few towns in the world that contain so many dogs as those of Egypt; and the worship of the dog was formerly spread over the whole of this country. The dogs of Egypt are a race of large grey hounds; and it is a singular circumstance respecting them, that they never quit the quarter where they are born, but form distinct tribes, which have limits that they never exceed; and if one dog should go into another quarter, he would soon be attacked by the whole of the strange tribe. The Bedouens are so much attached to their dogs, that a person who killed them would expose his own life to danger. In Ancient Egypt cats were held in great veneration, so that the killing of a cat, even involuntarily, incurred capital punishment; and cats that happened to die were carried to the sacred temples, and after having been embalmed were buried at Bubastis, a city in Lower Egypt. There are still cats in all the houses in Egypt, and they are treated with much tenderness and attention. The ichneumon was one of the sacred animals of Ancient Egypt. Particular care was taken of it whilst it lived, and honours were paid to it after its death. Lands were appropriated to the support of this animal; and it was fed like cats with bread soaked in milk, or with the fish of the Nile cut in pieces; and it was every where forbidden to be killed. At present the ichneumon is not domesticated in Egypt, nor do the inhabitants rear them in their houses; for though they hunt rats and mice, they destroy poultry. By destroying the eggs of crocodiles, it prevents their increase. However, in more than half of the northern part of Egypt, that is, in that part comprehended between the Mediterranean sea and the town of Siout, they are very common, although this part has no crocodiles; but they are more scarce in Upper Egypt, where crocodiles are more numerous: and, therefore, many fables have been recorded concerning the antipathy of the ichneumon to the crocodile, that are destitute of foundation. Upper Egypt, below the cataracts, is much infested with crocodiles; and though the ichneumon had received the honour of carrying on a perpetual war against these animals, a species of tortoise of the Nile, called *Thirfe*, is more successfully employed in their destruction. As soon as the young crocodiles are hatched and reach the river, this tortoise attacks and devours them. Rats and mice are very numerous in Egypt, and would render the country uninhabitable, if they were not destroyed by other animals, and also by the inundation of the Nile. Many canards are found in the neighbourhood of Cairo; and lizards and vipers of various sorts abound in different parts of the country. Swarms of winged insects supply food for swallows and wagtails; but the most numerous, as well as most troublesome insects, are flies. Gnats also fly in swarms

After the rice-harvest, from the inundated fields in which the preceding generation had deposited its eggs; and their sting is no less sharp and painful than that of the mosquitoes of South America. The habitations of Egypt are also filled with an enormous quantity of bugs, the bite of which occasions very considerable and painful swellings. Bees form a principal article of culture and commerce in Egypt. As Upper Egypt only retains its verdure for four or five months, and the flowers and harvests are earlier there, the inhabitants of Lower Egypt profit by this difference. They collect the bees of different villages in large boats. Each proprietor trusts to them his hives, which have a particular mark. When the bark is loaded, the men, who have the management of them, gradually ascend the river, and stop at every place where they find flowers and verdure. The bees, at the break of day, quit their cells by thousands, and wander in search of the treasures with which they compose their nestar. They go and come several times laden with their booty. In the evening they return to their habitations. After travelling three months in this manner on the Nile, the bees, having culled the perfumes of the orange-flowers of the Said, the essence of roses of the Faicum, the treasures of the Arabian jessamine, and a variety of flowers, are brought back to the places from which they had been carried. This industry procures for the Egyptians delicious honey, and abundance of bees'-wax. The proprietors, in return, pay the boatmen a recompence proportioned to the number of hives which have been thus carried about from one extremity of Egypt to the other. Wasps are also very common in Upper Egypt; and the hideous insects called scorpions grow to a very large size, and are said to occasion by their bite intense pain, swoonings, convulsions, and sometimes death. It would far exceed our limits to enumerate the various species of birds that are itatedly or occasionally found in Egypt; or to recite the different sorts of fish with which the Nile and its other waters abound.

The climate of Egypt is, as we might naturally infer from its latitude, commencing at the Torrid and extending 9° into the Temperate zone, extremely hot. In July and August Fahrenheit's thermometer stands, in the most temperate apartments, at 85° and 88° above the freezing point. In the Said it rises much higher. Of this extreme heat, the height of the sun, which, in summer nearly approaches the zenith, is a primary cause; but when we consider that in other countries, under the same latitude, the heat is less, we may be allowed to seek another secondary cause, no less powerful than the former; and this is, probably, the inconsiderable elevation of the country above. On this account some have distinguished only two seasons in Egypt; the spring and summer, that is, the cool season and the hot. The latter continues from March to November; and from the end of February, the heat, even at nine o'clock in the morning, is hardly supportable by an European. During the whole of this season the air is inflamed, the sky sparkling, and the heat oppressive to all that are unaccustomed to it. The body sweats profusely, and the slightest suppression of it is a serious malady. The departure of the sun tempers, in some degree, these heats. The vapours from the earth soaked by the Nile, and those brought by the west and north-west winds, absorbing the fire dispersed through the atmosphere, produce an agreeable freshness, and even piercing cold, if we may credit the natives and some European merchants; but the Egyptians, almost naked and accustomed to perspire, shiver with the least degree of cold. The thermometer, which, at the lowest, in the month of February, stands at 50° or 52° of Fahrenheit above the freezing point, indicates, that snow and hail are phenomena, which no

Egyptian has seen in fifty years. Some writers reckon two summers in Egypt; the first occurring in March, April, and May, during which the excessive heats and parching winds cause various disorders; but in the second summer, in June, July, and August, and in the autumn and winter, the air is much cooler, the weather more constant, and Egypt becomes one of the most delightful countries in the world. The season, however, being uncertain, those who can afford it, and particularly the European merchants, wear furs; and it must be allowed, that the northerly and westerly currents of air, which almost continually prevail, cause a very considerable degree of coolness out of the sun. These northerly winds serve the purpose of wafting a prodigious quantity of clouds into Abyssinia. From the month of April to July these are seen incessantly ascending towards the south; and it might be expected, that rain would ensue; but this parched country is destined to receive its supply of moisture in another form. In the Delta it never rains in summer, and but rarely, and in small quantities, during the whole course of the year. It rains still less as you ascend towards the Said. Accordingly, rain is more frequent at Alexandria and at Rosetta than at Cairo, and at Cairo than at Minich, and it is almost a prodigy at Djéda. To us it seems to be astonishing that a country should subsist at all without rain; but in Egypt, besides the quantity of water which the earth imbibes at the time of the inundation, the dews which fall in the summer might suffice for vegetation. These dews, as well as the rains, are more copious towards the sea, and decrease in proportion to their distance from it, but they differ from the latter by being more abundant in summer than in winter. At Alexandria, after sun-set, in the month of April, the clothes, exposed to the air, and the terraces, are soaked by them, as if it had rained. Like the rains, these dews are more or less plentiful, according to the prevailing wind. The southerly and the south-easterly produce none; the north wind a great quantity, and the westerly still more. These varieties are accounted for by observing, that the two former proceed from the deserts of Africa and Arabia, which afford not a drop of water: while the northerly and westerly winds, on the contrary, convey over Egypt the vapours from the Mediterranean, which the first cross, and the other traverses lengthways. Another phenomenon, no less remarkable, is the periodical return of each wind, and its appropriation to certain seasons of the year. In Egypt, when the sun approaches the tropic of Cancer, the winds, which before blow from the east, change to the north, and become constant in that point. In June they always blow from the north and north-west; the winds continue northerly in July, but very sometimes towards the west, and sometimes towards the east. About the end of July, and during the whole month of August and half of September, they remain constantly in the north, and are moderate; brisker in the day, however, and weaker at night. At this period an universal calm reigns on the Mediterranean. Towards the end of September, when the sun re-passes the line, the winds return to the east, and then more regularly from that point than from any other, except the north. As the sun approaches the other tropic, the winds become more variable and tempestuous; they most usually blow from the north, the north-west, and west, in which points they continue during the months of December, January, and February, which is the winter season in Egypt. The vapours of the Mediterranean, condensed by the coldness of the atmosphere, descend in mist and rains. About the end of February and in March, when the sun returns towards the equator, the winds are more frequently southerly than at any other season. During this last month, and that

EGYPT.

of April, the south-easterly, south, and south-westerly winds prevail and at times the west, north, and east; the latter of which becomes the most prevalent about the end of April; and during May, it divides with the north the empire of the sea. The southerly winds, which we have mentioned, are known in Egypt by the general name of *Kamsin*, or "winds of 50 days," so called because they prevail more frequently in the 50 days preceding and following the equinox. For an account of them, see *KAMSIN*. These southerly winds, which are distinguished by their heat and aridity, are in December and January as cold in Egypt as those from the north, because the sun, having reached the southern tropic, no longer burns up the northern parts of Africa, and because Abyssinia, which is extremely mountainous, is covered with snow. It might naturally be imagined that Egypt, on account of the heat to which it is subject, and from its wet and marshy condition for three months, must be an unhealthy country; but the case is otherwise. This circumstance, so different from the effect which might be expected, is ascribed by Volney to the natural dryness of the air, to the proximity of Africa and Arabia, which incessantly draw off the humidity, and to the perpetual currents of wind, which meet with no obstacle. This aridity is such, that flesh meat expost, even in summer, to the north wind, does not putrefy, but dries up, and becomes hard as wood. Besides possessing this drying quality, the air appears to be strongly impregnated with salts, the proofs of which are every where apparent. This property of the air and the earth, added to the heat, gives vegetation an activity almost incredible in our cold climates. Notwithstanding the heat in Egypt, the climate is not, upon the whole, insalubrious. The inhabitants are a robust and healthy race of people. Many of them live to old age. Attentive to their regimen during the hot season, their health is thus preserved. At this time they subsist chiefly on vegetables, pulse, and milk. They make frequent use of the bath, eat little, rarely drink fermented liquors, and mix a great deal of lemon juice in their aliment. By this course of sobriety their vigour is maintained to a very advanced age. The water of the Nile is also said to have a great influence on the health of the inhabitants, and to the use of this water, either as a bath or as a beverage, some have ascribed the fecundity of the Egyptian women. The Nile, however, has been the subject both of panegyric and of censure. Sonnini and other travellers concur with the ancients in commendation of its salubrity; and so far from considering it as a source of disorder, those who for a number of years have drank only this water, ascribe to the use of it the good health which they have enjoyed. Such is the generally received opinion in Egypt, where this water is reckoned not only very wholesome, but is also supposed to possess qualities truly miraculous. The method employed in this country for purifying the water of the Nile, when it is loaded with slime, has been described by Prosper Alpinus, and by more modern travellers. Savary says, that it consists in beating about in the water, contained in great jars, some sweet almonds slightly bruised, and in rubbing with this the edges of the vase. At the expiration of a few hours, the impure particles settle at the bottom of the jar, and the water remains clear and limpid. The water thus purified is poured out for use into small vessels, made of dried but unbaked clay, which the Turks call "bardacks," and the Arabs "kollat." These are not varnished, so that on being exposed to the open air the water gradually oozes through their pores; and it is perfectly cooled by the continual evaporation. Notwithstanding the commendations given of the salubrity of Egypt by Herodotus, Strabo, and Diodorus Siculus, and also by many modern travellers, others, and particularly M. Pauw, have asserted that it is

the cradle of the plague. Savary, however, and Volney, whose testimony is confirmed by Sonnini and others, have undeceived the public with regard to this circumstance. It is now ascertained, that this dreadful disorder, which is endemial in other countries of the East, is not so in Egypt, and never originates in that country. Whenever it makes its appearance, it has been brought thither, either from Constantinople, from some other part of Turkey, or from the interior of Africa. This latter kind, which is called the "Said plague," because it comes from Upper Egypt, is much dreaded, and is in fact more destructive than any other. It is further affirmed, that no epidemical diseases prevail in this country; and that experience amply attests the purity and salubrity of its atmosphere. In Egypt, however, though its diseases are neither frequent nor epidemical, putrid and inflammatory disorders attack those, whose constitution is bilious. Herniae are not common; and they originate from the relaxation occasioned by the use of warm baths, from incautious riding, and from the extraordinary width of a part of the Egyptian dress. Cutaneous diseases are common, and would be more prevalent if they were not counteracted by the use of the bath. The leprosy and the elephantiasis sometimes make their appearance, but they seldom occur, and do not seem to be very contagious. The elephantiasis is peculiar to the northern part of Egypt, and seldom appears at any distance above Cairo. There is, perhaps, no country in the world, where diseases, that corrupt the sources of generation, are more widely spread than Egypt. The ravages of the Syphilis, although checked by the heat of the climate, abundant perspiration, and warm baths, are not the less dreadful; and no remedy being applied to stop its progress, it sometimes produces the most frightful effects. But a malady, truly endemial, is the ophthalmia, or inflammation of the eyes. Eyes, perfectly sound, and which are wholly free from deficiencies, are rarely to be seen. This disorder has been ascribed to a variety of causes. Some have attributed it to the reverberation of a burning sun, to the effect of the southerly winds, to the subtle dust, with which the air is filled, or to the vapours which exhale from the stagnant waters. Savary seeks its origin from the custom which the Egyptians have of sleeping in the open air in summer, either on the terraces of their houses, or near their huts. The nitre, he says, generally diffused through the air, and the heavy dews of the night, attack the delicate organ of sight, and deprives them either of one or both eyes. Eight thousand of these unhappy people are kept in the great mosque of Cairo, and there provided with a decent subsistence. The principal cause of this disorder, says Sonnini, are the excessive heat, the air impregnated with nitrous particles, and the acid and burning dust which the wind carries into the atmosphere. These, he says, are the principal causes; besides which, there are other secondary causes that render these disorders more frequent than they were in the time of the ancient Egyptians, such as the bad quality of the food on which the present inhabitants subsist, and which communicates to the humours an acrimony that affects the sight; to which may be added the excessive propensity of the Egyptians to pleasures, which are seldom those of love. To this purpose, Avicenna observes, (iii. c. 5.) "Multiplacatio coitus est acerbior res oculo." The air, says Volney, to which the inhabitants of Cairo, the Delta, and also the coast of Syria, are exposed during sleep, acquires some noxious quality from the vicinity of the sea; and this quality, in his opinion, is moisture combined with heat, which becomes a first principle of these disorders. The saline quality of the air, so remarkable in the Delta, contributes still farther to the effect, by the irritation and itching it oc-

easons in the eyes. The usual diet of the Egyptians appears likewise to be a powerful cause. The cheese, four milk, honey, confection of grapes, green fruits, and raw vegetables, which are the ordinary food of the people, produce in the stomach a disorder, which physicians have observed to affect the sight; and also the raw onions, which they devour in great quantities, have a peculiar heating quality. A disposition to this disorder, transmitted by generation, becomes a fresh cause of malady; and hence the natives are more exposed to it than strangers. He adds, it will appear more probable, that the excessive perspiration of the head is a principal cause, when we consider that the ancient Egyptians, who went bare-headed, are not mentioned by physicians as being so much afflicted with ophthalmies; and that the Arabs of the desert, who cover it very little, especially when young, are equally exempt from them. History informs us, however, that several of the Pharaohs died blind. Blindness in Egypt is, in many instances, occasioned by the small-pox, which, for want of proper treatment, is very fatal in this country. Inoculation is either unknown, or little practised. The spring, which, in Egypt, is the summer of our climates, brings with it malignant fevers, which soon arrive at a crisis. The Egyptians, in general, are of a bilious habit, as appears from their eyes and black eye-brows, their brown complexion, and meagre make. Their habitual malady is the colic; and most of them frequently complain of a sourness in the throat, and an acid nausea; emetics and cream of tartar are, therefore, generally efficacious. The malignant fevers sometimes become epidemic, and are then mistaken for the plague.

The population of Egypt is not easily estimated; because the usual mode of determining the number of inhabitants from the number of houses cannot be applied to this country: a large proportion of the people having no visible dwelling. Ancient Egypt furnished subsistence for about eight millions of inhabitants; but at this day we do not reckon, says Savary, half the number. Mr. Browne, another intelligent traveller, who estimates the population of Cairo at 300,000 persons, suggests, that Egypt may contain, in all, two millions and a half. Volney, stating the number of towns and villages as not exceeding 250, which was the number in 1783, and the number of inhabitants in each of them, one with another, including Cairo, which contains about 250,000, as not more than a thousand, estimates the whole number of inhabitants in Egypt at two millions three hundred thousand. The cultivable lands, according to d'Anville, contain 2100 square leagues; whence results, for each square league, 1142 inhabitants. This great decrease is principally owing to the nature of its government, which is despotic and oppressive. Egypt, deprived 23 centuries ago of her natural proprietors, has seen her fertile fields successively a prey to the Persians, the Macedonians, the Romans, the Greeks, the Arabs, the Georgians, and, at length, the race of Tartars, distinguished by the name of Ottoman Turks. Several of these various nations have left vestiges of their transient possession; but they have been so blended, that it is not easy to discriminate their respective characters. Volney, however, distinguishes them into four principal races of different origin.

The *first*, and most generally dispersed, is that of the Arabs; who may be distributed into three classes; *viz.* 1. The posterity of those, who, on the conquest of Egypt by Amrou in the year 640, halted from Hedjaz, and every part of Arabia, to settle in a country justly celebrated for its fertility. Accordingly, the Delta was soon filled with foreigners, to the prejudice of the vanquished Greeks. This first race is preserved in the present class of fellahs, or hul-

bandmen, and artizans, who still retain the characteristic features of their ancestors, but are rather taller, and more strongly formed, from the natural effect of a more plentiful nourishment than that of the deserts. Their skin, tanned by the sun, is almost black, but their countenances are not disagreeable. 2. Another class of Arabs is that of the Africans, or Occidentals, in Arabic "Magarbe," the plural of "Magrebi," western, who have arrived at different periods, and under different chiefs, and united themselves to the former. Like them, they are descended from the Mussulmen conquerors, who expelled the Greeks from Mauritania; like them, they exercise agriculture and trades; but they are more especially numerous in the Said, where they have villages, and even distinct sovereignties of their own. (See MOGRABIANS.) 3. The third class is that of the Bedouins, or inhabitants of the deserts, known to the ancients by the name of "Scenites," that is, dwellers in tents. (See BEDOUINIENS.) It is calculated, says Volney, that the different tribes of those in Egypt might form a body of 30,000 horsemen; but these are so dispersed and dissipated, that they are only considered as robbers and vagabonds. A second race of inhabitants consists of the Copts. (See COPTI.) A third race is composed of Turks, who are the masters of the country, or, at least, possess that title. The name "Turk" was not originally peculiar to the nation to which it is now applied; it denoted, in general, all the hordes dispersed to the east, and even to the north of the Caspian sea, as far as beyond lake Aral, over those extensive countries which have taken from them the name of "Tourkistan." (See TURKS.) These people were known to the ancient Greeks by the names of Parthians, Massagetæ, and even of Scythians, for which we have substituted that of Tartars. They were a nation of shepherds, continually wandering, like the Bedouin Arabs, and, in every age, distinguishing themselves as brave and formidable warriors, whom neither Cyrus nor Alexander could subdue; though the Arabs, about eighty years after Mahomet, invaded their country, and compelled them to embrace their religion, and to pay tribute. Like the Bedouins they were divided into tribes, or camps, called, in Chinese language, "orden," of which we have made "horde;" and these tribes, allied or at variance, according to their several interests, were perpetually engaged in wars. In 1517, sultan Seim took possession of Syria and Egypt, and from that time the Turks established themselves in that country, but they were not settled much among the villages. Individuals of that nation are chiefly found at Cairo, where they exercise the arts, and occupy the religious and military establishments. Formerly they were advanced to posts under government; but, at a later period, they possess merely the title, without the reality of power; and they are not very numerous. This revolution has been effected by the *fourth*, and last race, that occupy Egypt. The individuals of this race, all born at the foot of mount Caucasus, are distinguished from the other inhabitants by the flaxen colour of their hair, which is entirely different from that of the natives of Egypt. These were found there by the Crusaders in the 13th century, and called by them "Mamelcs," or, more correctly, "Mamlouks." After remaining almost annihilated for 230 years, under the government of the Ottomans, they have found means to regain their consequence. For their history, character, &c. see MAMLOUKS. The Jews in Egypt are not very numerous. These, as well as the Christians of Syria and the Greeks, devote themselves to commerce, to the exchange, and the arts. The acuteness and subtlety which distinguish them have rendered them alternately directors of the custom-houses and intendents of

EGYPT.

the revenues of Egypt. Many of them are goldsmiths, and work in gold, silver, and precious stones; and their works in fillagree have been admired. Some of them have established manufactures of light stuffs, which they fabricate with Bengal cotton and Syrian silk. In order to understand the nature of the present government of Egypt, we should advert to the first introduction of the Mamlouks into the country in the year 1257. Before this period, from the middle of the 6th century, till about the year 1250, the Arabs were in possession of Egypt, and it formed a part of the vast empire of the Caliphs, who sent thither visitors, invested with unlimited powers, to govern in their name. These formed a body of soldiers of tried courage and extraordinary beauty, who were trained up to military exercises. By degrees, the soldiers, like the Pretorian hands of Rome, gave laws to their master; and ultimately appointed one of their own chiefs instead of the sultan whom they deposed and massacred, investing him with the title of sultan, and retaining for themselves that of Mamlouks, which signifies military slaves. About the year 1250, immediately after the defeat of St. Louis, the government of the Arabian princes terminated in Touran Shah, the last prince of the family of the Aioubites. Thus, were these nominal slaves converted into despots, who, for many centuries, have continued to give law to Egypt. Claiming the right of authority merely by conquest, the Mamlouks had no other rule of conduct and government besides the violence of a licentious and insolent soldiery. At length, in 1517, Selim, sultan of the Ottomans, having taken and hanged Toumam-Bey, their last chief, put a period to that dynasty. Selim, instead of exterminating the whole body of Mamlouks, according to the principles of Turkish policy, projected such a form of government, that the power, being distributed among the different members of the state, should preserve such an equilibrium, as should keep them all dependent upon himself. The remnant of the Mamlouks, who had escaped his first massacre, appeared fit for serving his purpose; and he therefore established a divan, or council of regency, composed of the pacha, or bashaw, and the chiefs of the seven military corps. (See BASHAW and BEY.) The sultan, likewise, established tributes, one part of which was destined to pay 20,000 infantry, and a corps of 12,000 cavalry, resident in the country; the other, to procure for Mecca and Medina the necessary supplies of corn, and the third to swell the treasury of Constantinople, and to support the luxury of the seraglio. In all affairs that concerned religion, they were to maintain strict obedience to the musli of Constantinople, and to insert the name of the Ottoman emperors in the prayers, and on the coin. This was a kind of mixed government, composed of monarchy, represented by the pacha, and aristocracy, composed of the Beys; but the people, who were to defray all charges, were considered as mere passive agents, and remain in subjection to all the rigours of a military despotism. This form of government has subsisted for more than two centuries; but within the greatest part of the last century, the Porte having relaxed in its vigilance, innovations have taken place; the Mamlouks have increased; become masters of all the riches and strength of the country, and gained such an ascendancy over the Turks, that the power of the latter is almost annihilated. (See ALI-BEY, BASHAW, BEY, and MAMLOUKS.) The Beys, dreading the displeasure of the Porte, dare not declare their independence; but their submission is more formal and verbal than real. The Mamlouks have taken care to degrade the military corps of the Azabs, or Janizaries, which, on the part of the Turks, were formerly the terror of the pacha; and the whole military force of Egypt really consists in the

Mamlouks, who are dispersed through the country to maintain the authority of their corps, collect the tributes, and improve every opportunity of extortion. These are the men, who at present govern and decide the fate of Egypt; men, who have still the manners of slaves, though advanced to the rank of monarchs. Sovereignty with them centres in the means of possessing more women, more toys, horses, and slaves, and satisfying all their caprices. It consists in managing the court of Constantinople, so as to elude the tribute, or the menaces of the sultan; and in purchasing a number of slaves, multiplying partisans, counter-mining plots, and destroying their secret enemies by the dagger, or by poison. See BEY.

What is the condition of the people in a country thus governed it is not difficult to determine. Wherever, says Volney, the cultivator enjoys not the fruit of his labour, he works only by constraint, and agricultural languishes; wherever there is no security in property, there can be no industry to procure it, and the arts must remain in their infancy; wherever knowledge has no object, men will do nothing to acquire it, and their minds will continue in a state of barbarism. Such is the condition of Egypt. The greater part of the lands in Egypt is to be considered as divided between the government, and the religious bodies who perform the service of the mosques, who have obtained possession of what they hold by the munificence of princes and rich men, or by the measures taken by individuals for the benefit of their posterity. Hence, a large proportion of the tenants and cultivators hold either of the government, or the procurators of the mosques. But there is one circumstance common to both, *viz.* that their lands, becoming unoccupied, are never let but upon terms ruinous to the tenants. Besides the property and influence of the Beys, the Mamlouks, and the professors of the law, are so extensive, and so absolute, as to engross into their own hands a very considerable part; the number of the other proprietors is extremely small, and their property liable to a thousand impositions. Every moment some contribution is to be paid, or some damage repaired; there is no right of succession, or inheritance for real property, except for that called "Wakf," which is the property of the mosques; every thing returns to government, from which every thing must be repurchased. The peasants are hired labourers, says Volney, to whom no more is left than what is barely sufficient to sustain life. (But Browne says, that these terms can be properly applied to very few of them. The occupier of the land, assisted by his family, is the cultivator; and in the operations of husbandry scarcely requires any other aid. And the tenant of land commonly holds no more than he and his family can cultivate, and gather the produce of. When, indeed, the Nile rises, those who are employed to water the fields are commonly hired labourers.) The rice and corn they gather are carried to their masters, and nothing is reserved for them but doura, or Indian millet, of which they make a coarse and tasteless bread, without leaven. This, with water and raw onions, is their only food throughout the year; and they think themselves happy, if they can sometimes procure a little honey, cheese, four milk, and dates. Their whole clothing consists in a shirt of coarse blue linen, and in a black cloak. Their head-dress is a sort of cloth bonnet, over which they roll a long handkerchief of red woollen. Their arms, legs, and breasts are naked, and some of them do not even wear drawers. Their habitations are mud-walled huts, in which they are suffocated with heat and smoke, and in which, besides the experience of other inconveniencies, they are perpetually distressed with the dread of the robberies of the Arabs, and the extortions of the

the Mamlouks, family feuds, and all the calamities of a perpetual civil war.

The more considerable sources of revenue in Egypt, as well as of the Porte at this day, and also of the Caliphate while the sovereignty remained with the Arabs, are nearly coeval in their institution with Mahometanism itself. The most ancient tribute due from the subject to the government was the "Zecchât," a tenth of all the permanent productions of the earth. This was imposed by Mahomet himself, and designed for the relief of the necessitous. This impost or tax is still continued, but it is diverted from its original purpose, and applied to necessary expences or needles prodigality. It is not, however, now applicable to land or houses, but to the merchandize imported into the country. The duties on these, when demanded of Mahometans, are taken under the name of "Zecchât." The second impost is the "charage," which signifies the product of lands; and it denotes, not only any tax on land, but also on the persons of "dhummies," that is, Christians and Jews; though in the latter case it receives the appellation of "Jizi," the capitation tax, or salvage for their persons, which otherwise, according to the letter of the Koran, the true believer is not bound to spare. In most of the revenue of the Porte, which is derived from various sources, is known under the name of "Miri;" the private one of the emperor is supplied in a different way, and termed "Chafné." The imposts in Egypt, one of the earliest territorial acquisitions of the successors of Mahomet, are not distinguished by any remarkable severity; and if that country has been since impoverished and depopulated, it appears not to result from the original institutions, so much as from the abuses, which happened at an early period of the Egyptian Caliphate. These abuses, which have been long gradually increasing, are now so far multiplied as to be incapable of further extension consistently with the being of the peasantry. The principal local tribute is a tax on land of two pataches each "foddan" all over the country, which was continued by Sultan S-Im. Taking the cultivable lands in Egypt at two million one hundred thousand acres, this should produce the sum of twelve thousand nine hundred purses, or at the present exchange of 630,000/ sterling; but at this time only two thirds of these lands are actually cultivated, which reduces the sum to 420,000/. On the other hand, however, the Beys insist on receiving, in many instances, five or six pataches per "foddan," which again raises this single branch of revenue to a million and a quarter, or even more. There are, indeed, some districts in the Upper Egypt, always several years in arrear. The patache may be rated at from 3s. to 3s. 4d. The "foddan" is a given measure, deriving its name from the quantity that a yoke of oxen can plough in a day, roughly taken, equivalent to an acre. The other articles are the customs of Alexandria, Damietta, Suez, and Cosser, and what is drawn from the commerce of Africa in its passage by Charjé, Assout, and Cairo. The amount of these is not easily ascertained; but it is very considerable. The "Jizic," already mentioned, is supplied, by Mr. Browne, not to amount to more than 1500 purses. The remaining revenue is made up of casualties: as forfeitures, small imposts, and tolls, passing on the Nile, and other parts of the interior; and above all, the incalculable profit arising from continued plunder of all ranks and denominations. Five, ten, twenty to thirty thousand pataches, are demanded, in one day, of the Christians engaged in commerce, at another of the Mahometans, and at another of the Franks. The wandering Arabs or Bedouins are exempt from any regular tribute, though they are often plundered. All the prostitutes, public baths, places where

brandy is sold, &c. &c. are under a particular jurisdiction, and pay something to government. The articles above enumerated form collectively the "Miri," or public revenue of 1200 purses of which should be annually forwarded to Constantinople, but it is retained by the Beys, under pretence of repairing mosques or other public works. The Pacha receives for his whole expences 1000 "mahbûbs," or 3000 piastras per day. (See BASHAW and BEY.) The collectors of the "Miri" are the Copt writers, who exercise their office under the direction of the secretary of the ruling Bey. These writers have registers of each village, and are employed in receiving the payments and accounting for them to the treasury. Rigorous and unjust in their exactions, they often sell the oxen, the buffaloes, and even the mat on which the oppressed wretches lie. It is calculated, that the whole produce of the "Miri," collected as well in money as in corn, barley, beans, rice, &c. may amount to about two millions sterling, when bread falls at somewhat more than a half-penny per pound of 14 ounces. The administration of the customs seems to be, in Egypt, one of the principal offices of government. The person who exercises it is at the same time the comptroller and farmer-general. On him depend all the duties on entry, exports, and the circulation of commodities. He names all the subalterns who collect them; and to this he adds the "pales," or exclusive privileges of the natron of Terane, the keli of Alexandria, the castles of the Thebas, the fenna of Nubia; and, in a word, he is the despot of commerce, which he regulates at his pleasure. His office is never held for a longer period than a year. The price of his contract, in 1783, was one thousand purses, which, at the rate of 500 piastras per purse, and 50 sols the piastre, makes 12 hundred and 50,000 livres, or above 52,000/. The custom-house were formerly managed, according to ancient custom, by the Jews; but when they were ruined in 1769 by Ali Bey, in consequence of an enormous extortion, they passed into the hands of the Christians of Syria, with whom they still remain. Those Christians who came from Damascus to Cairo almost a century ago, consisted at first of about two or three families, their profit attracted others, and their number has since multiplied to about 500. From the time of their taking possession of the custom-house, after the ruin of the Jews, they have acquired great opulence.

Egypt is excellently situated for commerce and navigation; the trade of the western parts of Asia, Europe, and the North, lying open to it, by the Mediterranean sea; and that of Arabia, Persia, and India, and the southern and western coasts of Africa, by the Red sea: the eastern merchandize being commodiously brought into Egypt on camels, by the isthmus of Suez. It is therefore to be presumed, that the inhabitants would supply themselves with those articles which their country wanted, such as metals, wood, pitch, resin, &c. by bartering their own rich productions and manufactures, such as corn, linen, paper, glass, and other valuable commodities. Sir John Marsham supposes, that the Egyptians did not apply themselves to merchandize till the time of the Ptolemies, but in this opinion he seems to be mistaken; though these princes did very much encourage trade, recovering that of the East to their subjects, by building Berenice, Myos Hormos, and other ports on the Arabian gulf, so that Alexandria became the greatest mart in the world; yet the Egyptians certainly traded very considerably with foreigners long before. The Egyptian Pharaohs were undoubtedly acquainted with the advantages of trade. The numerous canals which they formed served, not only to diffuse fertility by means of the water of the Nile, but to transport with facility the produce.

EGYPT.

produce of the country from one end of the empire to another. The fairs they established in the Delta and the Thebais united the inhabitants of the most distant provinces. The Egyptians must also be regarded as one of the most ancient nations of navigators. They made voyages on the Red sea, as it is said, long before the famous expedition of the Argonauts. Danaus, according to Herodotus, carried into Greece, then in a state of barbarism, the art of navigation and of commerce. His brother Sesostris, if we credit some historians (see SESOSTRIS), soon after reduced the interior kingdoms of Asia, and with a fleet of 400 sail took possession of the ports of the Arabic gulf, sailed through the straits of Babel-Mandel, and penetrated into the Indian ocean. From this era we must date the commerce of Egypt with Asia, which has never been discontinued since that remote period. Sesostris founded several colonies, one of which fortified itself on the coast of Phœnicia. If we admit the truth of what some writers have reported concerning Sesostris, his efforts produced no permanent effect, and they appear to have been so contrary to the genius and habits of the Egyptians, that on the death of Sesostris they resumed their ancient maxims, and many ages are said to have elapsed before the commercial connections of Egypt with India became of any great importance. Tyre soon prepared to dispute the glory of navigation with the mother-country, sending her ships as far as the pillars of Hercules, and spreading the arts every where with her commerce. The Egyptians on their side mounting the Bosphorus, entered the Black sea, exchanging with their brethren, settled in Colchis, the productions of their country with those of the northern nations; whilst the fleets of the Red sea went in search of the pearls, the diamonds, the perfumes, and the precious stuffs of the eastern world. Egypt, as a commercial state, soon attained a high degree of power; the colleges of her priests, applying to the study of the heavens, taught navigators that astronomy which served to guide them through unknown seas; and rich in her own productions, she with her trade propagated the light of the sciences. Greece, enlightened by the great men who acquired knowledge of various kinds in the schools of Memphis and Heliopolis, was divided into several republics, each of which wished to possess commerce and a navy. Psammeticus, to say nothing of Osiris, the Mercury of the Egyptians, to whom the invention of commerce is ascribed, gained great riches by trade, as we learn from Diodorus, before he became king of all Egypt; and we learn from scripture, the most ancient and authentic history extant, that the Midianites and Ishmaelites traded to Egypt so early as the time of Jacob; and, moreover, it is presumed, that they had anciently the sovereignty of the Red sea, by which they engrossed all the trade of India, and other ports; which were then carried on that way. (See EDOM.) Psammeticus, says Herodotus, being a friend to the Greeks, opened to them the ports of Egypt; and he began his reign in the year 660 B. C. His son Necho, the Pharaoh-Necho of scripture, who succeeded him 616 B. C., attempted to open a communication between the Nile and the Red sea; but failing in this attempt he directed his views to another enterprize. Having fitted out a fleet and engaged Phœnician mariners, he ordered them to make a tour of Africa. According to they sailed out of the Red sea through the straits of Babel-Mandel, steered down the eastern shores of Africa, and doubling the Cape of Good Hope, coasted up northward till they came to the pillars of Hercules, or straits of Gibraltar, by which they entered the Mediterranean, and thus returned to Egypt, having performed their voyage in three years. Apries, the Pharaoh-Hophra of scripture,

ascended the throne in the year 600 B. C. and defeated in a naval combat the combined fleets of the Tyrians and Cypriots, two of the most renowned people in the art of navigation. Amasis having, as some have said, dethroned Apries and usurped the kingdom, 569 B. C., made a conquest of Cyprus and became master of the Mediterranean; and in order to give activity to commerce, permitted the Greeks to build Naucratis at the entrance of the Canopic branch, and at the same time restricted their vessels from landing merchandize in any harbour but that of this town. The fairs established there, and the successive arrival of ships, rendered it very commercial. At this time the prosperity of the kingdom was at its height. The arts had arrived at a great degree of perfection. Astronomy predicted eclipses with accuracy. The sculptor engraved fine stones, and fashioned at his pleasure the hardest marbles. Mechanism elevated in the air masses of astonishing size. Chemistry stained glass, gave brilliancy to precious stones, and dyed stuffs with indeleible colours. Agriculture had enriched the country with the productions of India. From Egypt they passed to the Greeks; from thence to the Romans; and by the Romans they were transmitted to the Gauls. Commerce enriched the country, and called forth into exercise a variety of talents; so that whilst treasures were collected in great abundance from adjacent and distant nations, the arts and sciences were cultivated with singular ardour. The gold dust rolled down by the torrents of Ethiopia, the pearls of Ormuz, the perfumes of Arabia, the stuffs of Bengal arrived at Memphis, and it became the most commercial city upon earth. In this flourishing condition Egypt was attacked by Cambyzes with innumerable armies. Amasis had given cause of discontent to the militia of the kingdom, by giving preference to the Grecian troops, and 150,000 men abandoned their country. This desertion threw the kingdom into the hands of the Persian monarch, who ravaged it with fire and sword, 525 B. C. After sacrificing thousands of soldiers in the mad expedition which he undertook against the temple of Jupiter Ammon, and the Ethiopians, he left a detachment of his army in Egypt, and returned into Persia. Although commerce suffered at this time, it soon recovered its vigour, and followed its established course. Darius, the son of Hystaspes, was sensible of its utility, and favoured it through the whole extent of his empire. About the year 332 B. C. Alexander of Macedon turned his arms against Egypt. This nation having supported with impatience the Persian yoke, submitted willingly to the great conqueror, and the country was subdued without a battle. In order to secure Egypt, he founded in it a large city, encompassed by three harbours, fit to receive the fleets of Greece and the merchandize of all nations. On his premature death, his generals divided his spoils, and Ptolemy, son of Lagus, called Soter, having received Egypt for his share, 323 B. C. endeavoured to carry into execution the great projects of his master, and to promote the commercial prosperity of his new government. The improvement of Alexandria engaged his particular attention; and as her ports were situated to the west, the north, and south, he received the merchandize of the whole universe, and became, as Strabo calls her, the greatest market in the world. (See ALEXANDRIA.) Ptolemy Philadelphus, who succeeded his father 284 B. C. pursued the course which he had marked out, and rendered Egypt fruitful and happy. This prince, either better acquainted with the level of the sea, or more fortunate than Necho and Darius, who had unsuccessfully prosecuted the same object, continued the canal which was to join the Nile to the Red sea, and had the glory of completing it. He began at the Pelusian branch and extended it as far as Arsinoë, now called Aggerout.

Aggerout. He founded the city Berenice, &c. (See BERENICE and PTOLEMY.) For the protection of the Egyptian merchants, the Ptolemies kept up a formidable navy in the Red sea and the Mediterranean. Ptolemy Evergetes (246 B. C.) imitated the example of his predecessors, and founded his power on trade, which he encouraged to the utmost of his power; and during his reign the wealth of the Egyptians was at its height. The abundance of gold, and of every kind of goods, produced at Alexandria great luxury, and corrupted the court of the kings. But notwithstanding the immense treasures that were consumed by various indulgences and expences, the country long continued rich and flourishing. Ptolemy Phycon (169 B. C.) dispatched Eudoxus on an embassy to several of the potentates of India; and he brought back reports, which gave a new spur to the avidity of the merchants. They made fresh expeditions to the East, and penetrated by the Ganges even to Bengal. After the king's death, his widow, Cleopatra, ordered Eudoxus to visit the nations at the extremity of Africa, and having embarked on the Red sea, he touched on the coast of Soffala. Under Ptolemy Lathyrus (116 B. C.) Eudoxus sailed out of the straits of Babel-Mandel, doubled the point of Africa, and returned to the pillars of Hercules. This was the second time of performing this adventurous voyage. Under Ptolemy IX. the merchants of Alexandria continued to navigate the Black sea, the Persian gulf, and even to the extremities of India. When Egypt passed under the dominion of the Romans, the conquest was, with regard to Rome, what Peru has been for Spain, and Bengal for England. It diffused gold and silver there in such abundance, that lands, merchandize, and every article, doubled their prices. However, it hastened the downfall of that empire. Deprived of their monarchs, and subjected to the Romans, the Egyptians became their factors. In proportion as the Romans extended the limits of their empire, they adopted the vices as well as the ordinary usages of the conquered people. Egypt contributed much to influence their manners, because it was the most ample source of wealth. The beautiful linen and cotton manufactured at Alexandria, her magnificent tapetery, her crystals of various colours, were conveyed to Rome. The grain of the Thebais, and her abundant productions, fed the capital of Italy; so that, from this period, she no longer stood in need of manufactures, and she ceased to encourage the labours of the husbandman. After Constantine had transported the seat of the empire from Rome, Egypt long supported the tottering throne of the emperors of Byzantium. When Egypt became a province of the empire of the Caliphs, she gradually lost her commerce and the arts. The commerce of the Mediterranean was neglected, through dread of intercourse with Christian princes, and the Egyptians confined themselves to that of the Red sea, and the interior of the country. Agriculture, however, still flourished, and some of the Arab princes encouraged the sciences. At length the Venetians found means to open for themselves the ports of this country, and to keep consuls there; and they carried on the trade with India under the protection of the Egyptians. From this intercourse they derived great advantages, and became the first navigators of Europe, which they furnished with all the productions of Asia and Africa. The Genoese partook with them for some time of these advantages; but the marine of the Venetians, having rapidly increased, reigned triumphant in the Mediterranean. When the Ottomans took Egypt from the Arabs, they were excited and aided by the Venetians to equip a fleet on the Red sea, and to put a stop to the conquests of the Portuguese, who had formed settlements in India. Albu-

querque, who then governed them, fought the Ottoman fleet, penetrated into the Arabian gulf, and determined to destroy Egypt, by turning the waters of the Nile into the Red sea. But this destructive project of ambition, for the execution of which he had formed a treaty with the emperor of Abyssinia, was defeated by Albuquerque's death. While the maritime powers of the world are endeavouring to found the prosperity of their states on the basis of commerce, in aid of internal cultivation and manufactures, Egypt, without arts, without a marine, and groaning under the tyranny of 24 Beys, is unable to derive any advantage from her situation, or to enter into competition with the Europeans. Her ignorant mariners no longer navigate to India; scarcely do they dare to make the circuit of the Red sea. Their most distant expeditions are annual voyages to Mocha. Their sails, ill equipped, and incapable of defence, load there the coffee of Yemen, the perfumes of Arabia, the pearls of the Baharein isles, the muslins and the linens of Bengal, which are brought there by the Banians. Even this limited commerce is advantageous to them. The coffee alone is an annual object of eleven millions of livres. They export the principal part to Constantinople, to Greece, to Marseilles, and to the coast of Syria, and consume the remainder in the country. Egypt might again recover her splendour, as she contains within herself the source of genuine riches. Her abundance of grain, with which she feeds Arabia, Syria, and a part of the Archipelago; her rice which she sends throughout the Mediterranean; the flower of the carthamus, with which the inhabitants of Provence yearly load several vessels; her sal-ammoniac, which is conveyed throughout Europe; the kali produced there in abundance; her beautiful flax, so much valued in Italy, and her blue linen are important and profitable articles of trade. The Abyssinians bring her gold dust, elephants' teeth, and other precious substances, which they barter for her produce. The articles exported thither by France are by no means sufficient to pay the various commodities she receives in exchange. The copper vessels and the furs landed by the Turks in the port of Alexandria do not balance the corn, the rice, the lentils, the coffee, the perfumes they load there, which are chiefly paid for in specie. In a word, excepting at Mocha, and at Mecca, where the Egyptians leave every year a great quantity of sequins, all those who carry on a trade with them bring them gold and silver. These precious metals are still in such abundance in the country, that Ali Bey, on flying into Spain, carried with him about a million sterling, and Ismael Bey, who a few years after escaped in the same way, loaded 50 camels with sequins, patches, pearls, and precious stones. Egypt is still capable of great improvement, and of deriving great advantages from commerce, if the character of her government and consequent condition of her inhabitants were meliorated. What cloth might be manufactured with the beautiful wool of her sheep! What linen with her delicate flax! What muslins with the two sorts of cotton, one annual, one perennial, which grow there! What stuffs, with the silks, which might be easily introduced in a country, where the silk-worms must thrive! What an affluence of benefits might be procured by clearing the canals, repairing the dykes, and restoring to agriculture the third part of her lands now buried under the sands! With what success might not her mines of emeralds be explored, almost equalling in hardness that of the diamond! The granite, the porphyry, and the alabaster, which are found in several of her mountains, would form a valuable branch of commerce. The manufacturer might employ to great advantage her indigo, her carthamus, and other materials for dyeing, that are spread over her deserts. Egypt has poss-

E G Y P T.

essed these advantages for many ages. She has lost them by a despotic government. A wise administration would restore to her all the treasures which nature has lavished upon her, and which have rendered her in former ages eminently distinguished among the nations of the earth. The commerce with Egypt is, even now, when uninterrupted by contending nations, far from being inconsiderable. According to Niebuhr's account, about 800 bales of cloth from Languedoc and Provence, and the same quantity from England, Flanders, Germany, and Venice, arrive in Egypt every year. They also require in Egypt, every year, at least 80 barrels of cochineal, and in times of war between France and England, about 200 barrels pass through Egypt into India. From Europe are annually exported into Egypt 400 bales of pepper, each bale containing near 300 pounds. Europe furnishes Egypt with several kinds of drugs, both for medicinal and culinary use. The Europeans send thither annually 60 barrels of pewter, and as many of wine, and a certain quantity of chests containing needles, scissars, knives, small looking-glasses, &c. &c. From Europe, and particularly from Venice, according to the statement of Vansleb, are exported, among other things, a great quantity of small glass ware, as beads, &c., writing-paper, different species of cutlery and looking glasses; from Zante, wine; from Leghorn, cloth; from Genoa, China-ware, and pieces of eight in silver; from Messina, Syracuse wine, velvet, and other silk-luffs. Egypt has no direct commerce with Holland and England; but it is carried on by Venice and Leghorn. From Marseilles are conveyed money, nuts, almonds, chestnuts, &c., and also cloth and paper. Since the time of Vansleb, the commerce of Egypt has much increased; and it draws every species of merchandize from the different states of Europe. The English, besides cloths, send thither works of polished steel, and all sorts of iron-ware, fire-arms, and gunpowder. The articles of trade which arrive in Europe by the way of Alexandria and Damietta are, flax, spun cotton, printed cottons, muslins, India camlets, dimities, all linsens and cottons of different qualities. The exportation of all kinds of grain, roots, and seeds, with which the country abounds, is prohibited; notwithstanding which prohibition, great cargoes of rice and linseed are shipped for Europe. These two ports also afford coffee, *affæctida*, fenna, *castia fitularis*, sugar, sal ammoniac, the black vomica nut, tamarinds, gums, incense, myrrh, aloes, spikenard, cinnamon, *carthamus tinctorius*, dates, ostrich-feathers, balm of Mecca, *coloquintida*, buffaloes', bulls', and cows' hides, and precious stones.

How different has been the government of Egypt in modern times from that which laid the foundation of its celebrity at an earlier period of its existence! The Egyptians are said to have been the first who found out the rules of government, and the art of making life easy, and a people happy. Their laws and institutions were not only highly revered by those who lived under their immediate influence, but by other nations, and particularly the Greeks, whose first sages and legislators travelled into this country to acquire a knowledge of them, and who borrowed from them the best part of those which they afterwards established at home. Nevertheless, as much as the Egyptians seemed to excel other nations in the wisdom of their laws and constitution, they yet surpassed them more in superstition. Idolatry was so ancient among them, that the Grecians confessed they borrowed not only their religious ceremonies, but the names of almost all their gods, from Egypt. For the Egyptians are said to have been the first people who erected altars, images, and temples, and the first inventors of festivals, ceremonies, and transactions with the gods by the mediation of others; and also to have first

given names to the twelve gods. They had a great many deities of different ranks and orders. Those who were chiefly honoured in Egypt were Osiris and Isis, by which they most probably meant the sun and the moon, whose influences governed, and preserved the world. These two luminaries being reckoned by them the great causes of nutrition and generation, and, as it were, the sources from which the other parts of nature, which they also looked upon as gods, and to which they gave distinct names, were derived. These were Jupiter or spirit, Vulcan or fire, Ceres or the earth, Oceanus (meaning the Nile) or moisture, and Minerva, called Neith, or air. Besides these celestial or immortal gods, there were also terrestrial or mortal deities, who had merited the honours paid them by the benefits which they conferred on mankind. Several of them had been kings of Egypt; some of these bore the same names with the celestial gods, and others had proper names of their own. Such were the Sun, Cronus or Saturn, Rhea, Jupiter, called by the Egyptians Ammon, Juno, Vulcan, Vesta, Hermes or Mercury, Orus, Venus, Pan, Anubis, Nephthys, Harpocrates, and others. Serapis is said to have been introduced by one of the Ptolemies at Alexandria; but others suppose him to have been the same with Osiris, who was also called Bacchus. Osiris was supposed to be a god of a good and beneficent nature; but his brother Typhon was the reverse, and held in detestation for the evils brought by him on his family and nation. Although the bodies of these mortal deities remained in their sepulchres on earth, yet the Egyptians believed their souls shone in the stars of heaven, as that of Isis in the Dog-star, that of Orus in Orion, and that of Typhon in the Bear. Notwithstanding the polytheism of the Egyptians, they are said in reality to have acknowledged one supreme God, the maker and ruler of the world, whom they sometimes denoted by the name of Osiris or Serapis, sometimes by that of Isis, and at other times by Neith, who had a temple at Saïs. The inhabitants of Thebais are reported to have worshipped only the immortal and unbegotten god *Cneph*, (which see,) for which reason they were exempt from all contributions towards the maintenance of the sacred animals which were worshipped in Lower Egypt. From this god *Cneph*, they supposed a secondary god proceeded, representing the world, called *Phtha*, a word which is used by the Copts to signify the divine being. Idolatry of the grossest kind seems, in process of time, to have prevailed throughout Egypt; and they bestowed divine honours on several animals, and even on vegetables, as leeks and onions: and these honours were appropriate to particular places; inasmuch that the chief cities of Egypt were named by the Grecians after the gods or animals that were worshipped in them. This diversity of worship was attended with very ill consequences in some cases, especially if their deities happened to be enemies to one another, and thus the inhabitants of one place rendered worship to animals, which were held in abhorrence in other places. Hence proceeded discord and even war; such as happened in particular between the inhabitants of Heracleopolis, who worshipped the ichneumon, and those of Arsinoe, who worshipped the crocodile; and also between the cities of Oxyrynchus and Cynopolis, the former of which sacrificed and eat dogs, which were the deities of the latter. For a more particular account of the Egyptian deities, see OSIRIS, ISIS, SERAPIS, JUPITER, and AMMON. ANUBIS, HARPOCRATES, ORUS, CANOPUS, APIS, &c. &c. &c. The objects of the Egyptian worship were such animals as the cat, dog, ibis, the wolf, the crocodile, and several others of a similar kind; and they were treated with a respect of a singular nature whilst they lived, and if they were wilfully killed,

killed, the guilty person was punished with death; and when they died, they were lamented with the deepest concern and sorrow, and buried with funeral honours. Some have traced the origin of this strange and preposterous kind of worship to the use they made of the images of these animals on their standards; for the arrangement of their troops; others suppose that these images were used in the most early times to distinguish the first civil societies, which united for mutual defence against the violence of their fellow-creatures: others again ascribe the worship of these animals to the benefits that were derived from them; as the ox in tilling the land, the sheep in supplying milk and wool, the dog in protecting the house, the ibis and hawk in destroying serpents and noxious insects, the crocodile in defending the country against the incursions of the Arabian robbers, the ichneumon in preventing the multiplication of crocodiles, and the cat for its service against the asp and other venomous reptiles, &c. &c. Others pretend, that the worship paid by the Egyptians to animals did not terminate in the animals themselves, but in the gods, whose symbols they were, and to whom they had some peculiar relation. Such was the strict attachment of the populace to the grossest kinds of polytheism and superstition, that Herodotus represents them as the most religious of men. As the objects of their worship were not only gods, heroes, and eminent men, but various kinds of animals and plants; Juvenal has justly ridiculed their superstition in the following passage, (Sat. xv. v. 1, &c.);

“ Quis nescit, Voluæ Bithynicæ, quædam demens
Ægyptus portenta colat? Crocodilon adorat
Pars hæc; illa pavet saturam serpentibus Ibin,” &c.

Thus rendered,

“ Who knows not, that there's nothing vile or odd,
Which brain-sick Egypt turns not to a god?
Some of her fools the crocodile adore,
The ibis cramm'd with snakes, as many more.
A long-tailed ape, the supplants most admire
Where a half Memnon tunes his magic lyre:
Where Thebes, once for her hundred gates renown'd,
An awful heap of ruins strews the ground;
Whole towns in one place, river-fish reverse,
To sea-fish some as piously adhere:
In some a dog's high deity is seen;
But none 'mind Dian, tho' of dogs the queen:
Nay vegetables here take rank divine;
On leeks and onions 'tis profane to dine.
Oh holy nations! where the gardens bear
A crop of gods through all the live-long year!

The Egyptians were the first who assigned each month and day to a particular deity, and observed the time of each person's nativity, by which they judged of their future fortune. If they were not the first people who established oracles, and introduced the custom of consulting them, the most ancient and celebrated oracles among the heathens, particularly those of Jupiter in Libya, and at Dodona, owed their origin to Egypt. Amidst the numerous oracles which existed in Egypt, those which they chiefly revered were the oracle of Latona in the city of Butus, and in later times that of Serapis in Alexandria. The sacred animals, as well as the deities, Hercules, Apollo, Minerva, Diana, Mars or Jupiter, had their respective oracles, as the apes, the goat, the lion, and the crocodile. The ancient Egyptians also offered human sacrifices at the tomb of Osiris, at Heliopolis, and to Juno or Lucina, at a city in Upper Thebais. This barbarous custom, however, was abolished by Amasis, who ordered that so many images of wax should be offered instead

of them. Of their temples we shall give an account in the description of the cities in which they were constructed; and for their monuments of art, we refer to CATACOMBS, LABYRINTH, OBELISK, PYRAMIDS, &c.

The theology, and also the philosophy, of the Egyptians, were of two kinds; the one exoteric, addressed to the vulgar, the other esoteric, confined to a select number of priests, and to those who possessed, or were to possess, the regal power. The mysterious nature of their concealed doctrine was symbolically expressed by images of sphinxes placed at the entrance of their temples. The former sort of religion is universally known to have consisted in the grossest and most irrational superstition. Concerning the esoteric, or philosophical doctrine of the Egyptians, it seems evident, that they conceived matter to be the first principle of things, and that before the regular forms of nature arose, an eternal chaos had existed, which contained, in a state of darkness and confusion, all the materials of future beings. This chaos, which was also called night, was worshipped, in the most ancient times, as one of the superior divinities. This material principle, called Chaos or Night, was probably worshipped by the Egyptians under the name of “Athor,” which, in the Coptic language, signifies Night. This divinity the Grecian mythologists confounded with Venus. The symbol of this divinity, which in their usual manner the Egyptians placed in her temple, was a cow. Besides the material principle, it seems capable of satisfactory proof, that the Egyptians admitted an active principle, or intelligent power, eternally united with the chaotic mass, by whose energy the elements were separated, and bodies were formed, and who continually presides over the universe, and is the efficient cause of all effects. By the united testimony of many writers, who give accounts of the Egyptian gods, “Phtha,” or Vulcan, and “Cneph,” or Agathodæmon, it is rendered probable, that these were only different names expressing different attributes of the supreme divinity. The name “Phtha,” in the Coptic language, denotes one by whom events are ordained; and the appellation “Cneph” denotes a good genius; and he was represented under the symbol of a serpent. Upon a temple dedicated to Neitha, at Sais, the chief town in Lower Egypt, was this inscription, “I am whatever is, or has been, or will be, and no mortal has hitherto drawn aside my veil; my offspring is in the sun.” If it be granted, that Neitha and Phtha were only different names of the same divinity, this inscription will confirm the opinion, that the Egyptians acknowledged the existence of an active intelligence, the cause of all things, whose nature is incomprehensible. The doctrine of an ethereal intelligence pervading and animating the material world, appears, among the Egyptians, to have been from the earliest time accompanied with a belief in inferior divinities. Conceiving emanations from the divinity to be resident in various parts of nature, when they saw life, motion, and enjoyment communicated to the inhabitants of the earth from the sun, not, as they supposed, from other heavenly bodies, they ascribed these effects to the influence of certain divinities derived from the first deity, which they supposed to inhabit these bodies. From the same source it may be easily conceived, that among the Egyptians, as well as in other nations, would arise the worship of deified men. When they saw their illustrious heroes or legislators protecting their country by their prowess, or improving human life by useful inventions and institutions, they concluded that a large portion of that divinity, which animates all things resided in them, and that, after their death, good demons that animated them passed into the society of the divinities.

It is universally agreed that the Egyptians believed the human soul to be immortal. Herodotus asserts, though perhaps

haps without sufficient ground, that they were the first people who taught this doctrine, and Diodorus Siculus relates, that the Egyptians, instead of lamenting the death of good men, rejoiced in their felicity, conceiving that, in the invisible world, they would live for ever among the pious. But it has been a subject of dispute, into what place, according to the Egyptian doctrine, the souls of men passed after death. Plutarch speaks of the Amethes of the Egyptians, corresponding to the Hades of the Greeks, a subterraneous region, to which the souls of dead men were conveyed. With this agrees the account given by Diodorus Siculus of the funeral customs of the ancients. Herodotus, on the contrary, gives it as the opinion of the Egyptians, that when the body decays, the soul passes into some other animal, which is then born; and that after it has made the circuit of beasts, birds, and fishes, through a period of 3000 years, it again becomes an inhabitant of an human body. Diogenes Laertius also relates, after Hecataeus, that, according to the tenets of the Egyptians, the soul, after death, continues to live, and passes into other bodies. These different notions might be held by different colleges of priests, some of whom might maintain the doctrine of transmigration, while others held, that the souls of good men, after wandering for a time among the stars, were permitted to return to the society of the gods; or the seeming inconsistency of these opinions may be reconciled by adopting the doctrine, that God is the soul of the world, from which all things come, and to which they will return. But as different minds have contracted different degrees of impurity by their union with the body, it is necessary that they should pass through different degrees of purgation, to be accomplished by means of successive transmigrations. According to this system, bad men would undergo the metempsychosis for a longer, good men for a shorter period: and the Amethes or Hades may be conceived to have been the region, in which departed souls, immediately after death, received their respective designations. The Egyptians, whilst they held that the world was produced from chaos by the energy of an intelligent principle, conceived that there is in nature a continual tendency towards dissolution.

Of preceptive doctrine the Egyptians had two kinds, one sacred, the other vulgar; the former, which respected the ceremonies of religion, and the duties of the priests, was written in the sacred books of Hermes, but too carefully concealed to pass down to posterity. The latter consisted of maxims and rules of prudence, virtue, or policy. But it appears by ample evidence, that superstition blended itself with their notions of morals and corrupted them. Indeed, it is in vain to look for accurate principles of ethics among an ignorant and superstitious people.

The Egyptians paid particular attention to the education of their children, accustoming them betimes to a frugal diet, and instructing them in two sorts of letters, those called sacred, and those in which their common learning was written. The Egyptian youth were taught betimes to behave with great respect to their elders. In different parts of Egypt they inculcated abstinence from several sorts of animals, according to the different deities they worshipped; and they all agreed in their aversion to swine's flesh, which was accounted impure. Their animal food consisted of birds and fishes, those excepted which were deemed sacred, and of bread made of vegetables, and particularly the lotus and the lower items of the papyrus. Their common drink was the water of the Nile; and their better sort of drink or wine, as Herodotus calls it, was made of barley, so that we are probably indebted to this nation for the invention of beer.

The Egyptians still make a fermented liquor of maize, millet, barley, or rice, pleasant to the taste, but in the hot season it will not keep above a day. This is drank in considerable quantities in Cairo and in the Said. The native Christians distil for themselves, from dates, a liquor called by the general name "Araki;" it is also made from currants, or the small grapes, imported from Cerigo. The ancient Egyptians used frequent ablutions and purifications; they scrupulously avoided eating with strangers as unclean; and the custom of circumcision, which remains to this day, and which was extended to women as well as men, was observed by them from time immemorial, and esteemed by them so necessary, that Pythagoras, in order to obtain the liberty of conversing with the Egyptian priests and entering into their temples, was obliged to submit to this operation. In many of their manners and customs they seemed to act in contradiction to the rest of mankind; for with them it was the custom for the women to be employed in trade and business abroad, while the men staid at home to spin and mind domestic affairs; and this practice, perhaps, gave occasion to the extraordinary law; by which the sons were not obliged to provide for their parents, but the daughters were. They kneaded dough with their feet, and tempered mortar with their hands: and though in other countries, the places destined for cattle were separated from those of the men, in Egypt men and beasts dwelt together. Gratitude was a virtue which the Egyptians held in high estimation; hence they were led to honour their princes, whom they considered to be possessed of power and will to do good to mankind, as gods, and hence also proceeded the great respect manifested by them to the remains of deceased ancestors. The mourning for the dead, and funeral rites in Egypt, were anciently performed with peculiar solemnity. When any eminent person died, all the women of the family, having their heads and faces besmeared with dirt, their breast bare, and their waists girt, left the body at home, and marching in this garb, attended by all their relations of the same sex, through the streets of the city, lamented the deceased, and beat themselves in the most cruel manner. The men formed another company and mourned in the same manner. This ceremony they continued till the corpse was interred, abating from the bath, from wine, and delicate meats, and from the use of their best attire. The body was afterwards embalmed (See EMBALMING), delivered to the relations, and put into a wooden coffin, which was placed upright against the wall of the edifice appropriated to this purpose. At the time prefixed for the interment, the judges and friends were invited, and sat in a certain place beyond the lake (supposed to be that of Mœris) which the body was to pass. The vessel, whose pilot was called Charon, being hauled up to the shore, before the body was suffered to embark, every one was at liberty to accuse the deceased. If any accuser made good his charge that the deceased had led a bad life, the body was denied the customary burial, but if the accuser charged the deceased unjustly, he incurred a severe punishment. If no accuser appeared, or the accusation could not be supported, the relations recited the praise of the deceased, and the attendants joined their acclamations to this funeral oration. The body was then deposited in the family sepulchre. Those, who for their crimes or for debt were forbidden to be interred, were deposited privately in their own houses. This institution of the Egyptians relating to their treatment of dead bodies, was well adapted to the encouragement of virtue and the discouragement of vice; and from this practice the Greeks evidently deduced all their fables concerning the infernal judges, and the recompence or punishment of men after death. The sepulchres of the dead were adapted to the

EGYPT.

the rank and character of the deceased. See CATACOMBS and PYRAMIDS.

It appears, by very ancient testimonies, that the Egyptians were distinguished by their wisdom and learning, and that they were the inventors of many arts and sciences. Geometry is generally allowed to have been first found out in Egypt. Arithmetic and algebra, and also astronomy, were also diligently cultivated in this country. The science of medicine seems to have owed its origin to the Egyptians; and their physicians had a public provision made for them by the law. Herodotus relates, that, in his time, there were distinct physicians for different diseases; which they classed according to their seat in the human body. From Dioscorus Siculus we learn, that, instead of prescribing medicines, according to the judgment and experience of the practitioner, every physician was obliged to follow a written code; and if, in adhering to this, he was unsuccessful, he was free from blame; but if he ventured to depart from the prescribed forms, though the patient recovered, the physician was to lose his life. In administering medicines, they called in the aid of magical incantations, and pretended that supernatural virtues were thus communicated to certain plants. Upon the whole, medical practice was entirely empirical, and artfully connected with superstition, to secure the purposes of priestcraft. Anatomy was likewise cultivated at an early period in Egypt. The invention of music, as far as it comprehends the first elements of melody, is ascribed to the Egyptians. For astrology and magic the Egyptians were particularly famous; the art was very ancient among them; and we find many references to it in the sacred writings. We need not here take notice of their skill in architecture, mechanics, painting, and sculpture. The art of alchemy is said to have been known to the ancient Egyptians; and from the imagined founder of the Egyptian philosophy, it has been called the Hermetic art. (See the several articles above-mentioned). As to the manner in which the Egyptians preserved their knowledge, and transmitted it to posterity, we may here observe, that their priests were the depositaries of all their learning. They had the charge of their philosophy, and other sciences, as well as of their religion and sacred rites; and they were the persons to whom those who desired to be instructed were to apply. For this purpose they had colleges, or academies, in several parts of the kingdom. One of these, at Heliopolis, is mentioned by Strabo, who visited the apartments, where Eudoxus and Plato had studied for several years. The Egyptian learning was partly inscribed on columns, and partly committed to writing in their sacred books. Of their columns, the most famous were those of Hermes, mentioned by several credible authors, from which the Greek philosophers and Egyptian historians deduced much information, and to which Pythagoras and Plato are said to have been partly indebted for their philosophy. Sanchoniatho and Manetho made use of these monuments, which stood in certain subterraneous apartments near Thebes. But it should be considered, that the Egyptians, like others among the ancients, had two sorts of learning, the vulgar, open to all, and the secret, which was veiled and disguised, written in a character not commonly understood, and guarded by the priests. Hence it happened, that Pythagoras is said to have found great difficulty in gaining access to the sources of Egyptian knowledge and learning. The chief method which the Egyptians adopted for concealing their doctrine, was that of wrapping it up in hieroglyphics, symbols, enigmas, and fables. In their inscriptions and writings, they made use of three different sorts of characters. The first and most ancient sort was that of *hieroglyphics*; which see. They also used literal characters,

of which they had two kinds, *viz.* the sacred letters, in which their public registers, and all matters of an higher nature, were written; and the other the vulgar, used by every one in their common business. How far the Egyptians were concerned in the invention of letters is a question to which our attention will be directed under the articles LETTERS and WRITING.

The Egyptian language is, without doubt, one of the most ancient in the world, and, as some have imagined, an original, or mother-tongue. See LANGUAGE, and the article COBETS.

We shall close this article with a concise sketch of the history of Egypt. This country consisted originally of a narrow tract on the borders of the river Nile. The region, afterwards called Lower Egypt, and the Delta, was, in those early ages, a gulf of the sea. The date of the population of Egypt is uncertain. Some learned men have conjectured that, not long after the division of the earth among the sons of Noan, Ham with his family retired to this fertile tract; and that his son Mizraim peopled the country with his own issue, which inhabited several parts of it, under the names of Mizraim, Pathrusim, Caluhim, and Capthorim. Some have added, that after the death of Mizraim, Egypt was divided into several small principalities, which were governed by their respective sovereigns. It is not probable, however, that Mizraim should establish a monarchy in Egypt; but it is more likely, that the world was at first planted by tribes, or colonies, composed of different families blended together without distinction; and that every tribe should remain separate and independent, in its settlement, till it was constrained to yield to some powerful invader, and that thus the monarchical form of government was established. The sources of information concerning the ancient state of Egypt are those with which we are furnished by Syncellus, Manetho, and Eratosthenes. But these are so fabulous, defective, and inconsistent, that it is needless for us to recite them. The reader may find them stated and examined, or rather exposed in the 1st volume of the Ancient Universal History. The result, however, from an examination of these sources is, that in Egypt there were 30 dynasties, consisting of 36,525 years, and that, after a period of somewhat more than 34,200 years, during which their gods and demi-gods reigned, the cynic circle succeeded. The duration of this dynasty is fixed to 443 years, after which their kings began to reign; the first of whom is Menes. In Blair's tables, the kingdom of Egypt is said to commence under Mizraim, the son of Ham, in the year 2188 B. C., and to have lasted for 1663 years, to the conquest of Cambyses, in the year 525 B. C. Sir Isaac Newton places Menes after Sesostris, supposed by him to be Osiris, and in opposition to other chronologers who wrote before him, he thus transposes the series of the kings of Egypt mentioned by Herodotus. According to his account, Menes was the same with Amenophis and Memnon, and was about 300 years older than Plammethichus, with whom the Egyptian chronology begins to be unravelled, and to acquire a certain degree of clearness and consistency. Sir Isaac holds it irrational to suppose, that there was any king of Egypt till after the expulsion of the shepherds.

Menes, supposed to be the first mortal who reigned over Egypt, is said to have found the whole country, except Thebas, a morass, so that no land appeared between the lake Meris and the Mediterranean. He diverted the course of the Nile, which before washed the foot of the sandy mountain, towards Libya, and built the city of Memphis within the ancient bed of the river. On the north side he made a lake, and on the west another, both without the walls,

EGYPT.

walls, and both fed by the Nile, which flowed along the east side of the town; and in the city itself he built the famous temple of Vulcan. He is said to have been the first who instructed the Egyptians in religious matters, that introduced magnificence and luxury, and that instituted the pomp of feasts. After an unascertained succession of kings, the peace and felicity of the country were disturbed by the approach of a large body of adventurers, distinguished in history by the appellations of Auritæ, Hycfos, and Shepherds. Sir John Marsham places this event 157 years before the exodus of the children of Israel. Sir Isaac Newton places their expulsion in the year 1070 B. C. Their irruption happened, according to archbishop Usher, in the year 2048 B. C., and their expulsion in 1825 B. C.; the reign of Salatis, their first king, and his five successors, as marked by Manetho, amounting to 259 years. Ancient and modern writers have entertained different opinions concerning these enterprising people. Manetho, quoted by Josephus, supposes that they came from Arabia, and held the whole of Lower Egypt in subjection for 259 years, at the end of which period they were obliged, by a king of Upper Egypt, named Amosis, and Thethmosis, to quit the country, and retire elsewhere. When the Shepherds withdrew from Egypt with their families, their number amounted to 240,000; and, taking the way of the desert, they entered Syria; but, fearing the Assyrians, who were then very powerful, they built for themselves, in the land now known by the name of Judea, a city capable of holding so great a multitude, and called it Jerusalem: such is the account of Manetho. Others, as Tatian, Justin Martyr, Clemens of Alexandria, suppose, that the expulsion of the Shepherds and the exodus of the children of Israel were the same event. The ingenious and learned Bryant maintains that these Shepherds were Cushites, who had been expelled from Babylon by the sons of Shem, at the second dispersion; and that, abandoning a region, which they could no longer possess in tranquillity, they precipitated themselves into Egypt, drove the disunited tribes of Ham from the most fertile part of their territories at the upper end of the Delta, and settled there. This invasion happened soon after the Assyrians had become formidable by the conquests of Ninus; for we are told that the Auritæ fortified the eastern borders of their new settlements towards Arabia and Chaldaea. About this time, as ancient historians assert, the Delta had acquired the consistency of a morass. Drained by the Shepherds, it soon became a temperate and beautiful, as it naturally was a fertile region. For the space of 2½ centuries, that bold and enterprising race kept possession of Middle and Lower Egypt. In the course of this period, as we are told, they discovered many useful arts and inventions, and sent out colonies, from time to time, in quest of new settlements. Two hundred and sixty years after their arrival in Egypt, the posterity of the original natives, not finding sufficient accommodation in Upper Egypt, to which they had been confined, or envying the success of their fortunate invaders, commenced hostilities against them. After a long, doubtful, and bloody contest, the Auritæ were compelled to retire. They separated into several bodies, and migrated into Phœnicia, Syria, Greece, and other regions, carrying with them their inventions and improvements. (See AURITÆ and SHEPHERDS.) This memorable revolution happened not long before the descent of Jacob, 1706 B. C. The land of Goshen, that had been evacuated by the expulsion of the shepherds, was allotted as a settlement to him and his family. His posterity possessed this province for a period of 215 years; and in the year 1491 B. C. they were permitted to depart. Soon after their departure the Egyptian monarch pursued them with a powerful army, determined either to bring them

back to servitude or to destroy them, unarmed and defenceless, in the wilderness. Providence, however, conducted and preserved them: and overthrew Pharaoh with his whole host in the Red sea. Soon after this event, which happened, as some say, in the reign of Amenophis, this king was succeeded (1485 B. C.) by his son, as some have thought, Sesostris, the Sefac or Shishak of scripture, according to sir John Marsham, who says that the more ancient kings of Egypt are styled Pharaoh. Whiston has laboured to shew, that Sesostris is the Typhon of the mythologists, and the same Pharaoh who perished in the Red sea. Sir Isaac Newton, as we have already said, maintains, that Sesostris is the Osiris of the Egyptians, the Bacchus of the Greeks, and the Sefac or Shishak of the scriptures. However this be, his reign, which lasted 68 years according to Blair's tables, formed the most extraordinary part of the Egyptian history. He is represented as having been very powerful, both by sea and land, wise, just, generous, valiant, and magnificent, but ambitious. (See SESOSTRIS.) After the death of Sethon, about 675 years B. C., Egypt was divided into 12 kingdoms, and as many of the Egyptian lords were appointed rulers or sovereigns, who entered into the strictest association for the public welfare. The sea-coasts fell to the lot of one of them, called Psammeticus, who, encouraging commerce with the Greeks and Phœnicians, not only accumulated great wealth, but acquired the favour and friendship of several foreign kings and nations. The other sovereigns became jealous and envious, and declared war against him. Finding himself unequal to the conflict, he hired an army of mercenaries, consisting chiefly of Ionians, Carians, and Arabians, and repelling force by force, he at length subdued the other kings, and put an end to the duodecimirate, after it had subsisted 15 years. In the year 660 B. C. he became master of the whole kingdom of Egypt, and reigned with as much wisdom, magnanimity, and splendour, as any of his predecessors had ever displayed. After a long and prosperous reign, he was succeeded (616 B. C.) by his son Pharaoh-Necho, who was defeated by Nebuchadnezzar king of Babylon. Soon after this defeat, Nebuchadnezzar returned to Egypt with a powerful army, laid waste the kingdom, dethroned Apries, Necho's successor, (587 B. C.) invested Amasis with the supreme power (569 B. C.), and carried an incredible quantity of captives and spoils to Babylon. Amasis, consulting his own safety, entered into an alliance with the Grecian states, and with Crœsus, king of Lydia. About this time the Persian empire had been much elevated by the victories and triumphs of Cyrus. Twenty-three years after the conquest of Lydia, Cambyses, the son of Cyrus, reduced Egypt, and made it tributary to Persia, 525 years B. C. In the second year of Artaxerxes Longimanus (463 B. C.) Egypt revolted from the Persians, under Inarus, who procured for them the assistance of the Athenians; but they were again compelled to submission. In the 10th year of Darius Nothus (414 B. C.) another revolt took place; and Egypt had for a short interval its own kings, the last of whom was Nectanebus, when it was compelled to submit to the Persians in the 6th year of Artaxerxes Ochus, 350 years B. C. In a few years Alexander the Great, having subdued Persia (331 B. C.) marched towards Egypt, and the whole kingdom submitted without resistance to his victorious army. After his death Ptolemy, one of his generals, took possession of it, 323 years B. C.; and his posterity maintained themselves upon the throne for about 280 years. Upon the defeat of Antony, and the death of Cleopatra, Egypt shared the fate of other kingdoms, and was reduced by Augustus into a Roman province, in the 2d year of his reign, 30 B. C. Augustus divided the government among several persons of equestrian

order; not venturing to confide in senators, who were already too powerful. No circumstances pertaining to Egypt of sufficient moment to be here recited, occurred during the reigns of the first emperors: but in that of Gallienus, (about A. D. 254) Emilian, who had been prefect for some years, assumed the imperial purple, and gratified the people by delivering them from the yoke of Gallienus, who was hated and despised. The people and the soldiers concurred in acknowledging his sovereign authority, and he governed the country for some time with prudence and vigour. At length, however, he was taken by Theodotus, and sent to Gallienus, who ordered him to be strangled in prison. Under Claudius (A. D. 260) Zenobia, who called herself a descendant of the kings of Egypt, and decorated her pedigree with the names of the Ptolemies and Cleopatras, from whom she pretended to derive her origin, took possession of Egypt; but whilst Aurelian made war upon this ambitious sovereign in the East, his lieutenant Probus re-conquered Egypt and annexed it to the Roman empire. In the year 640 Egypt was subdued by Amrou, the famous general of Omar, caliph of the Saracens. (See ALEXANDRIA.) Under the administration of Amrou Egypt prospered; and his genius renewed the maritime communication, which had been attempted or achieved by the Pharaohs, the Ptolemies, and the Cæsars; and a canal, at least 80 miles in length, was opened from the Nile to the Red sea. This inland navigation, which would have joined the Mediterranean and the Indian ocean, was soon discontinued as useless and dangerous. Amrou's letter to Omar exhibits in glowing colours the riches and populousness of this country. The Saracens retained possession of this country, until Saladin, A. D. 1174, established the empire of the Turks in Africa. In the year 1250, the Turkish government gave way to that of the Mamlouks. (See MAMLOUKS.) This dynasty terminated in 1517, when Selim, sultan of the Ottomans, annexed the kingdom of Egypt to the Turkish dominions. It still remains in subjection to the Sultans, and is governed by Pachas or Bashaws, and Beys, who, as we have already seen, have reduced it to extreme misery. (See BASHAW and BEY.) Of the attempts that have been lately made both by the English and French, to take possession of this country, it is unnecessary to take notice, as they have terminated by alternate victories and defeats between the contending parties, and in the withdrawal of the forces of England and France from this scene of contest. *Anc. Un. Hist. vol. i. Savary's Travels in Egypt, vol. ii. Volney's Travels in Egypt and Syria, vol. i. Sonnini's Travels in Egypt. Browne's Travels in Egypt. Brucker's Hist. Philos. of Enfield, vol. i.*

EGYPTIAN GNOSTICS. See GNOSTICS.

EGYPTIAN *Pebble*. See JASPER.

EGYPTIAN *Year*. See YEAR.

EGYPTIANS, popularly *Gypsies*, in our statutes, impostors and jugglers, forming a kind of commonwealth among themselves, who disguise themselves in uncouth habits, smearing their faces and bodies, and framing to themselves a canting language, wander up and down, and, under pretence of telling fortunes, curing diseases, &c. abuse the common people, trick them of their money, and steal all that they can come at.

The origin of this tribe of vagabonds is somewhat obscure; at least, the reason of the denomination is so. It is certain, the ancient Egyptians had the character of great cheats, and were famous for the subtlety of their impostures, whence the name might afterwards pass proverbially into other languages, as it is pretty certain it did into the Greek and Latin; or else, the ancient Egyptians being much versed

in astronomy, which in those days was little else but astrology, the name was on that score assumed by these tellers of good fortune.

Be this as it will, there is scarcely any country of Europe but has its Egyptians, though not all of them under that denomination: the Latins call them *Ægyptii*: the Italians, *Cingani* and *Cingari*; the Germans, *Zigeuner*; the French, *Bohemiens*; others, *Saracens*; and others, *Tartars*, &c.

Münster, *Geogr. lib. iii. cap. 5.* relates, that they made their first appearance in Germany, in 1417, exceedingly tawney and sun-burnt, and in pitiful array, though they affected quality and travelled with a train of hunting-dogs after them, like nobles. The above date should probably have been 1517, as Münster himself owns, he never saw any till 1524. He adds, that they had passports from king Sigismund of Bohemia, and other princes. Ten years afterwards, they came into France, and thence passed into England. Pope Pius II., who died A. D. 1464, mentions them in his history as thieves and vagabonds, thus wandering with their families over Europe, under the name of Zigari; and whom he supposes to have migrated from the country of the Zigi, which nearly answers to the modern Circassia. Several historians inform us, that when sultan Selim conquered Egypt, in the year 1517, several of the natives refused to submit to the Turkish yoke; but being at length subdued and banished, they agreed to disperse in small parties over the world, where their supposed skill in the black art gave them an universal reception, in that age of superstition and credulity. In a few years the number of their proselytes multiplied, and they became formidable in most of the states of Europe. Pasquier, in his *Recherch. liv. iv. chap. 19.* relates a less probable origin of the Gypsies, thus: on the 17th of April 1427, there came to Paris twelve penitents, or persons, as they said, adjudged to penance, *viz.* one duke, one count, and ten cavaliers, or persons on horseback: they took on themselves the character of "Christians of the Lower Egypt," expelled by the Saracens; who, having made application to the pope, and confessed their sins, received for penance, that they should travel through the world for seven years, without ever lying on a bed. Their train consisted of 120 persons, men, women, and children, which were all that were left of 1200, who came together out of Egypt. They had lodgings assigned them in the chapel, and people went in crowds to see them. Their cars were perforated, and silver buckles hung to them; their hair was exceedingly black, and frizzled; their women were ugly, thievish, and pretenders to telling of fortunes. The bishop soon afterwards obliged them to retire, and communicated such as had shewn them their hands.

Ralph Volaterranus, making mention of them, affirms, that they first proceeded or strolled from among the Uxii, a people of Persia or Persia. Mr. Grellman, in a German "Dissertation on the Gypsies," of which an English translation by Matthew Raper, esq. was published in 1787, has given a circumstantial and connected account of these wandering tribes and their manner of living in different parts of Europe. Having collected the opinions of several writers on the origin of the Gypsies, and, as he conceived, refuted the arguments alleged in support of them, he asserts, that they came from Hindoostan: this hypothesis he grounds chiefly on the similarity of the Gipsy language to the Hindoostanic; and upon a comparison it must be acknowledged that many words are the same, whilst many are different. Many of these words, as Sir William Jones has observed (*Asiatic Res. v. iii. p. 7.*) are pure Sancerit, scarcely changed in a single letter. Mr. Grellman, moreover, supposes, that the Gypsies are of the lowest class of Indians, *viz.* "Parrias," or, as they are called in Hindoostan, "Suders." He

He compares the manners of this class with those of the Gypsies, and enumerates many circumstances in which they agree; but some of his comparisons are frivolous, and prove nothing. In answer to the question, How and when did the Gypsies migrate from Hindoostan, he replies, that there is no cause to be assigned for their retreat from thence by any means so plausible as the war of Timur Beg in India. The date of their arrival, he says, marks it very plainly. It was in the year 1408 and 1409 that this conqueror ravaged India; and his progress was so alarming and destructive, that these, among other terrified inhabitants, saved themselves by flight. Accordingly this author endeavours to trace their route from Hindoostan to Europe; but he acknowledges that nothing can be said on this subject beyond mere surmise. Sir W. Jones (*ubi supra*) suggests, that, in some piratical expedition, they might have landed on the coast of Arabia, or Africa, whence they might have rambled to Egypt, and, at length, have migrated, or been driven into Europe. A race of banditti, resembling them in their habits and features, is found among the Troglodytes, in the rocks near Thebes.

Mr. Grellman estimates the number of these wanderers in Europe to be between 7 and 800,000. As to the favourite food of these people our author says, that they are so far from being disgusted with the carrion of a sheep, hog, cow, or other beast, horse-flesh only excepted, that their fill of such a meal is with them the height of epicurism. He has then described their dress, their family-economy, their occupations and trades, their marriages and education, their diseases and burials, their political regulations and religion. In these particulars we cannot follow him. With regard to their character he says, that they are lively, and uncommonly loquacious, extremely fickle and inconstant in their pursuits, and faithless to every body even of their own cast, destitute of gratitude, and frequently recompensing benefits with the most insidious malice: slavish when intimidated, and cruel when unapprehensive of danger, revengeful and violent in their resentments; so addicted to drinking as to part with any necessary for spirits; and exceedingly vain and fond of fine clothes. Such are the levity and insensibility of a Gipsy's temper, that in the space of an hour he forgets that he has been just released from the whipping post.

But there are other traits of character much more atrocious than any we have already mentioned. The depravity of their manners, with regard to the intercourse of the sexes, is extreme. The mother, says our author, endeavours, by the most scandalous arts, to train up her daughter for an offering to sensuality, and the daughter is scarcely grown up to maturity, before she becomes a seducer of others. Laziness is so predominant among them, that if they were to subsist merely by their own labour, they would hardly have bread for two days in the week. This indolence increases their propensity to stealing and cheating. It is not matter of surprise, if this picture be fairly drawn, that almost every European state has exerted its utmost power to get rid of these noxious intruders. Mr. Grellman enumerates several edicts that have been passed for the banishment of the Gypsies out of Spain, France, Italy, England, Denmark, Sweden, the Netherlands, Holland, and Germany. He disapproves of these laws, and recommends other methods for making them useful subjects in the several kingdoms, where they are now dangerous and mischievous vagabonds. One of the means which he proposes is not likely to answer any valuable purpose. The civilization of a savage must be effected by gentle treatment, and not by corporeal punishment, which he recommends.

By an ordinance of the states of Orleans, in the year 1560, it was enjoined all these impostors, under the name of

Bohemians and Egyptians, to quit the kingdom, on penalty of the galleys. Upon this they dispersed into lesser companies, and spread themselves over Europe. They were expelled from Spain in 1591. The first time we hear of them in England was in the year 1530, when they were described by the statute 22 Hen. VIII. cap. 13. as "an outlandish people, calling themselves Egyptians, using no craft nor feat of merchandize, who have come into this realm, and gone from shire to shire and place to place in great company, and used great, subtle, and crafty means to deceive the people; bearing them in hand, that they by palmistry could tell men's and women's fortunes; and so many times by craft and subtlety have deceived the people of their money, and also have committed many heinous felonies and robberies." Wherefore they are directed to avoid the realm, and not to return under pain of imprisonment, and forfeiture of their goods and chattels; and upon their trials for any felony which they may have committed, they shall not be entitled to a jury "de Medietate lingue." And afterwards, it is enacted by statutes 1 and 2 Ph. and M. c. 4, and 5 Eliz. c. 20, that if any such person shall be imported into this kingdom, the importer shall forfeit 40*l.* And if the Egyptians themselves remain one month in this kingdom, or if any person, being fourteen years old, (whether natural born subject or stranger,) which hath been seen or found in the fellowship of such Egyptians, or which hath disguised him or herself like them, shall remain in the same one month, at one or several times; it is felony without benefit of clergy: and Sir Matthew Hale informs us, that at one Suffolk assizes no less than 13 Gypsies were executed upon these statutes, a few years before the Restoration. But to the honour of our national humanity, there are no instances more modern than this of carrying these laws into practice. Now, indeed, by stat. 23 Geo. III. c. 51. the said act of 5 Eliz. c. 20. is repealed: and the statute 17 Geo. II. c. 5. regards them only under the denomination of rogues and vagabonds. See VAGRANTS.

EHENHEIM, or UPPER EHENHEIM, relatively to the village of the same name, called *Lower Ehenheim*, in *Geography*, is a small town of France, in the department of the Lower Rhine, on the river Ergel, or Ergers; 15 miles S.W. of Strasbourg. It was anciently a free imperial city.

EHINGEN, a small town of Germany, in the kingdom of Wirtemberg, situated on the Danube; 12 miles S.W. of Ulm, remarkable for a very ancient nunnery.—Also, a small town of Germany of the same kingdom, situated on the Necker; 6 miles W. of Tubingen.

EHLE, a river of Germany, in the circle of Upper Saxony, which runs into the Elbe, near Magdeburg.

EHRENBERG, a small town of Germany, in the kingdom of Bavaria, situated in the Tyrol, on the frontiers of Suabia, in the lordship of the same name. It is remarkable for an ancient castle, which formerly was considered as very strong. It is 30 miles S.E. of Kempten.—Also, a small town of Germany, in the former principality of Fulda, with a chapel dedicated to the Virgin Mary on the top of a very high hill, which its termination *berg*, the German for mountain, denotes.

EHRENBREITSTEIN, (*the broad rock of honour*,) an important fortress of Germany, near the Rhine, on a high mountain opposite Coblenz, at the place where the river Moselle falls into the Rhine. The rock is so steep, and the fortifications are so strong, that it can be reduced only by famine. It surrendered to the French in 1793, after a blockade of eighteen months. The electoral palace of the archbishops and electors of Trèves, whose territory was ceded to France by the peace of Lunéville, is at the foot of the rock, and surrounded with works of defence. Ehrenbreitstein is now in the territory of the grand duke of Nassau.

faul Weiburg, one of the princes of the Confederation of the Rhine.

EHRENBURG, a town of Germany, in the kingdom of Westphalia, and county of Hoya; 18 miles W.S.W. of Hoya.

EHRENFRIEDERSDORF, anciently **IRBERSDORF**, a small town of the kingdom of Saxony, in the circle of the Erzgebirge, on a small rivulet, which, after having received several other brooks, takes the name of Wilfch, and falls into the Zschopau near Griebach. It is chiefly inhabited by miners occupied in the adjacent mines; its population amounts to 1300 individuals, and its chief manufacture is that of thread, lace, and yarn.

EHRENSTEIN, a town and castle of Germany, in the circle of Upper Saxony, and principality of Schwartzburg Rudolstadt; 10 miles N.W. of Saalfeld.

EHRETIA, in *Botany*, so named by Browne, in honour of George Dionysius Ehret, a German, much celebrated for his beautiful botanical drawings, which now fetch a high price among collectors. Mr. Ehret was the friend of Miller, as well as a correspondent of Linnæus. He drew from dried specimens the excellent plates of Browne's *Natural History of Jamaica*, and after residing long in England, where he had many pupils, even among the nobility, who highly respected him, he died about 40 years ago, and was interred near his friend Miller, in the burial ground of the King's-road, Chelsea. He was born in 1703. Browne's *Jam.* 168. t. 16. f. 1. Linn. *Gen.* 102. Schreb. 139. Willd. *Sp. Pl.* v. 1. 1077. Mart. *Mill. Dict.* v. 2. Juss. 128. Clafs and order, *Pentandria Monogynia*. Nat. Ord. *Asperifolia*, Linn. *Borraginea*, Juss.

Gen. Ch. Cal. Perianth of one leaf, bell-shaped, small, permanent, divided half-way down into five obtuse segments. *Cor.* of one petal; tube twice as long as the calyx; limb in five, nearly ovate, recurved, obtuse segments. *Stam.* Filaments five, inserted into the base of the tube, awl-shaped, spreading, the length of the corolla; anthers roundish, incumbent. *Pist.* Germen superior, roundish; style thread-shaped, swelling upwards, the length of the filaments; stigma obtuse, cloven. *Peric.* Berry, according to Jussieu, of four cells, but separable into two hemispheres, each of two cells. *Seeds* one in each cell, convex on one side, angular on the other.

Obs. *E. Beurreria* has the fruit separable into four parts, each of which has two cells and two seeds. *Juss.* Hence Linnæus's paradoxical account, that each *seed* is of two cells in that species.

Eff. Ch. Corolla of one petal, inferior. Berry of four or eight cells. Seeds solitary. Stigma cloven.

This genus in Willdenow consists of seven species. *E. tinifolia* is the original one. "Leaves oblong-ovate, entire, smooth. Flowers panicled."—Figured in Browne as above-said, and in *Trew's Plantæ Scelctæ*, t. 25, where it is represented as hexandrous, with six segments to the corolla, which the editor erroneously terms to many petals. This tree grows in Jamaica "in the lower lands," and is from 16 to 20 feet high. The *flowers* are white, not remarkable for beauty. *Berries* yellowish, about the size of currants. Browne says they serve to feed poultry, and are sometimes eaten by the poorer sort of people. The plant having not much to recommend it to general notice, is only occasionally cultivated in the English hives. Miller introduced it in 1734.

E. Beurreria is still more unfrequent in our collections. "Leaves ovate, entire, smooth. Flowers somewhat corymbose. Calyx smooth."—Native of Jamaica, figured in Browne t. 15. f. 2, who describes it as growing in the Savannahs, to the height of 14 or 15 feet only. The *flowers* are white,

fewer, but much larger, than in the former. *Berries* saffron-coloured, with eight seeds.

E. busifolia, Roxburgh *Coromand.* v. 1. t. 57, is an East Indian species, unknown to Linnæus, and as yet a stranger in England. "Leaves clustered, obovate, besprinkled with callous points, obscurely three-toothed at the summit. Stalks many-flowered." A rigid shrub, remarkable for the white callosities on its *leaves*. From three to fix white small *flowers* grow on each flower-stalk. *Berry* red, the size of a pea.

Jussieu suspects this genus may be the same with the *Menais* of Linnæus; but the latter has been seen by Loefling and Aymon only, and we know not how the question is to be clearly determined.

If it should prove so, the name of *Ehretia* has a prior claim, in point of time, to *Menais*, not to mention the greater inconveniences of changing it. If, however, the calyx of *Menais* be correctly described, as "of three loosely spreading leaves," this genus must be distinct, and the linear and sessile anthers moreover abundantly mark it as such.

EHRFELDEN, in *Geography*, a town of Germany, in the circle of the Upper Rhine, and principality of Hesse Darmstadt; 8 miles W. of Darmstadt.

EHRHARTA, in *Botany*, named by Thunberg and the younger Linnæus after their friend Frederick Ehrhart, a Swiss botanist of great diligence and acuteness, who studied at Upsal, and settled as an apothecary at Hanover, where he died some years since. He published several collections of dried plants, with authentic names, for the use of the medical practitioner as well as botanist, and a miscellaneous work, entitled *Beiträge*, in 7 vols. Svo. in German, full of excellent botanical remarks, with some peculiarities of opinion and style. He bestowed great and commendable attention upon many common garden trees and flowers, which other botanists had confounded or neglected, as well as on cryptogamic plants. Being employed to superintend the printing of the *Supplementum Plantarum*, he introduced some of his own genera of molles, with new, affected, and unauthorized terms, which gave so much displeasure to Linnæus, that the sheet was cancelled. *Thunb.* Stockholm *Transf.* for 1779, 216, t. 8. Linn. *fl. Nov. Gram. Gen.* 32. fig. Suppl. 28. Smith *Pl. Ic. fac.* 1. t. 9. Schreb. 236. Willd. *Sp. Pl.* v. 2. 246. Juss. 32. Mart. *Mill. Dict.* v. 2. Swartz *Tr. of Linn. Soc.* v. 6. 40. t. 3, 4. (*Trochera*; *Rozier Journ.* for 1779, 225.) Clafs and order, *Hexandria Digynia*. Nat. Ord. *Gramina*, near *Oryza*.

Gen. Ch. Glume of two valves, single-flowered; valves usually shorter than the corolla, ovate, acute, concave, channelled, beardless, a little spreading, unequal; the outer generally smaller, ovato-lanceolate, embracing the inner by its base; inner rather larger, ovate, broad, acute. *Cor.* double, longer than the calyx, scarcely gaping. Outer of two-folded, compressed, unequal valves, embracing each other, often furnished with one or two tufts of hairs at the base; the inner valve narrower, with a notch at each side of its base; outer valve in an early state almost concealing the other, and connected with it by a sort of joint at the very bottom. Inner corolla compressed, two edged, of two valves, which are folded, membranous, keeled, unequal; the outer valve broadest, embracing the opposite glume of the outer corolla with its base, at the notched sides of that glume; inner valve tapering, somewhat incurved. At the base of the interior corolla, adjoining to the inner valve of the outer corolla, is a sessile, roundish, uneven tubercle; perhaps the rudiment of another floret. Nectary of two minute membranes, thickened at their base, very thin at the summit, enfolding the organs of impregnation. *Stam.* Filaments fix, very short, inserted round the germen; anthers linear, erect,

notched at the base, cleft at the summit, of two cells, each of which bursts obliquely at the top. *Pist.* Germen superior, ovate, minute, smooth; styles two, very short, erect, contiguous; stigmas long, approaching each other, at length divaricated, each consisting of two opposite, feathery rows. *Peric.* none, except the permanent valves of the corolla. *Seed* solitary, smooth.

The above description is taken from Dr. Swartz's paper, the only correct history of this curious and elegant genus, in which the contrarieties and errors of preceding authors are explained and corrected. Dr. Swartz remarks, that in those species where the tubercle, or rudiment of a floret, is wanting, a petal-like scale is found in its stead, on both sides, where the inner valve is notched.

Eff. Ch. Calyx a glume of two valves, single-flowered. Corolla double, each of two valves; the outer corolla notched at the base.

The celebrated Thunberg first founded this genus upon a single species in 1779; about the same time the abbé Rozier published a description of another species by Richard, under the name of *Trochera*. The name of Thunberg however was adopted by Linnaeus in the *Supplementum* who described his original *E. capensis*, by the name of *E. Mnemateia*, a name probably suggested by Ehrhart himself, who was partial to words of Greek derivation. Dr. Smith first distinguished these two species, and added three others to the genus, in his *Plantarum Icones*. Finally, Professor Swartz has investigated the whole, and ascertained four more species, making nine in all. Professor Willdenow was not acquainted with this excellent treatise when he described the genus in his *Sp. Plantarum*; and this popular work being therefore deficient, as well as the subject very curious, we shall briefly elucidate all the species. They all grow, as far as is at present known, near the Cape of Good Hope only. In habit they most resemble *Melica*, but the flowers have a singular and elegant aspect, especially such as have the outer corolla transversely wrinkled. Some bear terminal awns on that part, others none.

* *Beardless.*

1. *E. mnemateia*, Sw. in Tr. of L. Soc. v. 6 44. f. 1. Linn. Suppl. 209. Thunb. Prod. 66 (*E. capensis*; Thunb. Stockh. Transf. for 1779, 216. t. 8. *E. cartilaginea*; Sm. Pl. Ic. fasc. 2. sub t. 33. Willd. Sp. Pl. v. 2. 246. *E. nutans*; Lamarek Encycl. v. 2. 346.) "Outer corolla rugose, obtuse, beardless. Panicle simple, lax. Stem simple. Margin of the leaves cartilaginous and crisped."—The leaves have a cartilaginous edge, very elegantly notched and crisped. *Flowers* tinged with purple, on capillary drooping stalks.

2. *E. panicea*, Sw. 47. f. 2. Sm. Pl. Ic. fasc. 1. t. 9. Willd. Sp. Pl. v. 2. 247. (*E. erecta*; Lamarek 347) "Outer corolla smooth, somewhat rugged, obtuse. Panicle slightly branched, drooping. Stem subdivided."—Cultivated in the stoves at Kew and Cambridge, flowering in June and July. It has the habit and small green flowers of a *Panicum* or *Poa*, but the slightest inspection shews its true genus.

3. *E. ramosa*, Sw. 49. f. 3. (*Melica ramosa*; Thunb. Prod. 21. Willd. Sp. Pl. v. 1. 383.) "Outer corolla rough, abrupt. Panicle close. Stem much branched, rather shrubby."—Dr. Swartz informs us this is also the *Ehrharta digna* of Thunberg, the only botanist who seems to have found it; and that the flowers somewhat resemble *Festuca decumbens* of Linnaeus. The calyx is nearly as long as the corolla. The stem jointed, branched, and almost woody.

4. *E. melicoides*, Sw. 51. f. 4. (*Melica capensis*; Thunb.

Prod. 21. Willd. Sp. Pl. v. 1. 383) "Outer corolla very smooth and obtuse. Panicle widely spreading."—Much resembling a *Melica*. Glumes of the corolla peculiarly bare and rounded, and panicle very much branched. Sw.

5. *E. calycina*, Sw. 53. f. 5. Sm. Pl. Ic. fasc. 2. t. 33. Willd. Sp. Pl. v. 2. 247. (*Aira capensis*; Linn. Suppl. 108) "Outer corolla somewhat hairy, obtuse with a short point. Panicle close, nearly simple. Stem branched."—Sparman was the discoverer of this species, whose pointed hairy glumes distinguish it from the last, as well as its close panicle.

** *Awned.*

6. *E. geniculata*, Sw. 55. f. 6. (*Melica geniculata*; Thunb. Prod. 21. Willd. Sp. Pl. v. 1. 382.) "Outer corolla hairy; one valve awned. Panicle close. Stem decumbent, bent at the joints."—Habit of the last, but its crisped leaves, and pointed awned corolla distinguish it.

7. *E. longiflora*, Sw. 56. f. 7. Sm. Pl. Ic. fasc. 2. t. 32. Willd. Sp. Pl. v. 2. 246. (*E. aristata*; Thunb. Prod. 66.) "Outer corolla rugged, hispida, both valves awned. Panicle rather lax, branched."—A large species, with the habit of an *Avena*. Dr. Swartz found six stamens, Dr. Smith but three, in the flowers they severally examined. The length of the awns varies.

8. *E. gigantea*, Sw. 58. f. 8. (*Melica gigantea*; Thunb. Prod. 21. Willd. Sp. Pl. v. t. 382. *Aira villosa*; Linn. Suppl. 109.) "Outer corolla hairy, both valves awned. Panicle close, somewhat whorled. Stem remotely jointed. Leaves involute."—One of the largest species, being six feet high. The flowers also are larger and more hairy than in any other. *Calyx* very membranous, half as long as the corolla.

9. *E. bulbosa*, Sw. 60. f. 9. Sm. Pl. Ic. fasc. 2. sub t. 33. (*Trochera striata*; Richard in Rozier's Journal, v. 13. 225. t. 3.) "Outer corolla with obovate, emarginate, rugged, short-awned glumes. Panicle lax."—The root is more bulbous in this than in some others. It was described by Richard from a plant in some of the French gardens, and he attributes "but three stamens to the flowers." We have found four, with appearance of abortive filaments, so that the number probably varies. This most resembles the first species, with which indeed Lamarck confounded it.

EHRHART GROSS, in *Geography*, a town of Germany, in the circle of Upper Saxony, and county of Schwartzburg; 4 miles W. of Greußen.

EHRNAU, a town of Germany, in the duchy of Stiria; six miles N. of Knittelfeld.

EHRNHAUSEN, a town of Germany, in the duchy of Stiria, at the conflux of the Salm and the Muebr; 10 miles N. of Mahrburg.

EHRNSPRUNN, a town of Germany, in the archduchy of Austria; 8 miles S. of Laab.

EIA, a river of Russia, which runs into the sea of Azoph, at Eskoi.

EIA, or *Ey*, in our *Old Writers*, are used for an island. Hence the names of places ending in *ey*, denote them to be islands. Thus, Ramsley, the isle of Rams; Sheppey, the isle of Sheep, &c.

EIA is also sometimes used for water; and hence the names of places near waters or lakes, terminate in *ey*.

EJACULATION, in *Medicine*, the act of emitting seed, from the Latin, *ejaculare*, to cast outwards. See EMISSION.

EJACULATOR SEMINIS, in *Anatomy*, a muscle of the urethra, called also accelerator urinæ; which see.

EJACULATORY DUCTS, a term which has been applied to the openings of the vasa deferentia in the urethra. See GENERATION, *Organs of*.

EIBESWALD, in *Geography*, a town of Germany, in the duchy of Soria; 16 miles S. of Voitsberg.

EICËTE, called also *Hiceta* and *Hiceta*, heretics of the seventh century, who made profession of the monastic life.

From that passage in Exodus, where Moses and the children of Israel are said to have sung in praise of the Lord, after they had passed the Red sea, wherein their enemies had perished, the Eicete concluded, that they must sing and dance, to praise God a night; and as Mary the prophetess, sister of Moses and Aaron, took a drum in her hand, on the same occasion, and all the women did the like, to testify their joy, by playing, beating, and dancing, the Eicete, the better to imitate their conduct herein, endeavoured to draw women to them to make profession of the monastic life, and assist in their mirth.

EICHENBUHL, in *Geography*, a town of Germany, in the circle of the Lower Rhine, and electorate of Mentz; 3 miles S. E. of Milkenberg.

EICHHOLZ, a town of Germany, in the circle of Upper Saxony, and principality of Anhalt Zerbst; 3 miles S. W. of Zerbst.

EICHMED, a town of Prussia, in the province of Naugard; six miles S S E. of Rastenburg.

EICHNER, M. in *Biography*, an eminent performer on the bassoon, and an excellent composer, not only for his own instrument, but for the harpichord and piano-forte. He was in this country about five and twenty years ago, and introduced a style between that of Schobert and the present; with less fire than Schobert, and more taste and expression. He was accused by the critics of his own country of being too modern. He was in a bad state of health during his residence in England, and played but little in public; yet from that little it was easy to discover a style, taste, and expression, of the most refined and polished kind. His pieces for keyed-instruments, printed by Bremner, were elegant, correct, and extremely pleasing. He died at Berlin the beginning of 1778.

EICHSFELD, in *Geography*, frequently but improperly called the *Eisfeld*, is a country of Germany, situated in the Electoral Rhenish circle, bounded by Hanover, Hesse, and Thuringia, about 35 miles in its greatest length from south to north, and 24 miles in breadth from east to west, having altogether a territorial extent of 185 square miles. It is divided into Lower and Upper Eichsfeld, the Lower being the northern, and the Upper the southern part. The latter is very mountainous, and gives birth to several rivers, as the Leine; the Lutter, which first runs into the Wiesel, and then conjointly with this into the Werre; the Unstrut; and the Wipper, and the Rume.

The Eichsfeld contains four cities, three boroughs, and one hundred and fifty villages. Duderstadt, in the Lower Eichsfeld, was considered as the capital. Its population, at the peace of Luneville, was about 120,000 individuals.

Anciently the Eichsfeld belonged to Thuringia. The Upper Eichsfeld was ceded by Henry, count of Gleichen, in the year 1294 to Gerhard II. elector of Mayence; the remaining parts of this country were successively added to the electorate in 1334, 1563, and 1692. But at the peace of Luneville, the archbishop of Mayence was secularized, and the Eichsfeld given as an indemnity to Prussia for the Prussian provinces on the west side of the Rhine. This cession was confirmed by the convention of the 26th of December 1802, between Austria, Russia, and France. But Prussia lost the Eichsfeld again at the peace of Tilsit in 1807, and by Napoleon's decree of the 18th of August of the same year, the Eichsfeld was constituted a part of the new kingdom of Westphalia.

EICHSTAEDT, **EICHSTETT**, or *Aiehsadt*, an ancient town of Germany, in the circle of Franconia, formerly the chief city and episcopal residence of the bishopric of the same name, is situated in a fertile valley on the river Alt-Üd. 45 miles S. of Nuremberg, in a tract of country called the Nordgau. The place on which the town of Eichstett stands, belonged anciently to the counts of Hirschberg, one of whom ceded it to St. Boniface, and the latter to his sister's son Willibald, who founded a convent, near which houses were gradually built, and this assemblage of buildings obtained the name of Eichlett from the number of large oaks with which it was surrounded. In 745 Boniface consecrated Willibald bishop of Eichlett.

The bishopric of Eichlett, which was nearly 54 miles long and about 21 in breadth, contained 10 towns and one borough: but it was secularized at the peace of Luneville, and first given to the king of Bavaria, who still retains a small portion of it. The principal part, together with the town of Eichlett, was afterwards transferred as part of his indemnities to the grand duke of Tuscany, who was created elector of Salzburg, and whose possessions in Germany are now known by the name of the grand duchy of Salzburg. They are considered as under the protection of Austria.

EIDA, in *Modern History*, a Mahometan spring festival, celebrated annually by the Nawab of Lucknow, in Hindoostan, on the 11th of March, after the new moon becomes visible, and kept, as it is said, in commemoration of Abraham's sacrifice. A camel is here substituted for a ram. The princes of Hindoostan march in procession, at this ceremony, with all their courtiers, and a large military escort. On such occasions, the oriental taste for show and gaudy magnificence is displayed with extraordinary attention. The howdahs, palanquins, and harnessing of the elephants, are so contrived, as to exhibit a blaze of gold, in which the numerous ornaments cannot be well distinguished. After the pomp and ostentation of the procession, during which aims are distributed, when the first part of it arrives on the ground, the ceremony consists in a solemn invocation of the Deity for plenty and prosperity during the ensuing season. It is observed, however, that the transitions from outward acts of devotion to the grossest crimes is short and frequent. This festival seems to resemble the feast of Tabernacles among the Jews, which, as we learn from the complaint of the prophet, was observed by that people with as little moral effect, or purity of intention, as this is by the Mussulmans. Both Jews and Mussulmans have, in too many instances, equally regarded superstitious observances, as a substitute for every moral virtue, and a compensation to the Deity for the violation of his laws.

EIDE, in *Geography*, a town of Norway; 36 miles E. S. E. of Bergen.

EIDER, a river, which, in a great part of its course, divides the duchy of Sleswick from that of Holstein, and runs into the German ocean; 12 miles W. S. W. of Lunden.

EIDER-Duck, in *Ornithology*. See **Duck**.

EIDWALD, in *Geography*, a town of Bohemia, in the circle of Leitmeritz; 16 miles W. N. W. of Leitmeritz.

EJECT INFRA TERMINUM. See **QUARE Eject**.

EJECTION, the act of throwing out, or discharging any thing at some of the emunctories, as by stool, vomiting, or the like.

EJECTIONE CUSTODIÆ. *Ejectment de Garde*, in *Law*, a writ which lies against him that calls out the guardian from any land during the minority of the heir. See **GUARDIAN**.

EJECTIONE FRMÆ, a writ that lies for the lessee for years, who

EJECTMENT.

who is ejected before the expiration of his term, either by the lessor, or a stranger.

Also ejectment may be brought by a lessor against the lessee, for rent in arrears, or holding over his term, &c. Reg. Orig. 227. This writ of *ejectione firmæ*, or action of trespass in *ejectment*, lieth where lands or tenements are let for a term of years, and afterwards the lessor, reversioner, remainder-man, or any stranger, doth eject, or oust the lessee of his term. (1 Inst. 45.) In this case, he shall have his writ of *ejection*, to call the defendant to answer for entering on the lands so demised to the plaintiff for a term that is not yet expired, and ejecting him. And by this writ the plaintiff shall recover back his term, or the remainder of it, with damages. Ejectment is now become an action in the place of many real actions, as writs of right, formedons, &c. which are very difficult, as well as tedious and chargeable; and this is the common action for trying of titles, and recovering of lands, &c. illegally kept from the right owner. However, all titles cannot be tried by this action. This method seems to have been settled as early as the reign of Edward IV. (7 Edw. IV. 6.); though it hath been said (F.N.B. 220.) to have first begun under Henry VII., because it was then first applied to its present principal use, that of trying the title to the land. In order to apprehend the contrivance, by which this end is effected, it should be recollected, that the remedy by ejectment is, in its original, an action brought by one, who hath a lease for years, to repair the injury done him by dispossession. For the purpose of converting it into a method of trying titles to the freehold, it is first necessary that the claimant do take possession of the lands, to empower him to constitute a lessee for years, that may be capable of receiving this injury of dispossession. For it would be an offence, called in our law "Maintenance," to convey a title to another, when the grantor is not in possession of the land. When, therefore, a person, who hath right of entry into lands, determines to acquire that possession, which is wrongfully withheld by the present tenant, he makes (as by law he may) a formal entry on the premises; and being so in possession of the soil, he there, upon the land, seals and delivers a lease for years to some third person or lessee; and, having thus given him entry, leaves him in possession of the premises. This lessee is to stay upon the land, till the prior tenant, or he who had the previous possession, enters thereon afresh and ousts him; or till some other person (either by accident, or by agreement, before-hand) comes upon the land, and turns him out or ejects him. For this injury the lessee is entitled to his action of ejectment against the tenant, or this "casual ejector," whichever it was that ousted him, to recover back his term and damages. But where this action is brought against such a casual ejector, before-mentioned, and not against the very tenant in possession, the court will not suffer the tenant to lose his possession, without any opportunity to defend it. Accordingly, it is a standing rule, that no plaintiff shall proceed in ejectment to recover lands against a casual ejector, without notice given to the tenant in possession (if there be any), and making him a defendant, if he pleases. In order to maintain the action, the plaintiff must, in case of any defence, make out four points before the court; *viz.* title, lease, entry, and ouster. He must, first, shew a good title in his lessor, which brings the matter of right entirely before the court; then, that the lessor, being seised or possessed by virtue of such a title, did not make him the lease for the present term; thirdly, that he, the lessee, or plaintiff, did enter, or take possession, in consequence of such lease; and, lastly, that the defendant ousted, or ejected him. Whereupon he shall have judgment to recover his term and damages; and shall, in

consequence, have a writ of possession, which the sheriff is to execute, by delivering him the undisturbed and peaceable possession of his term.

This is the regular method of bringing an action of ejectment; and this method must still be continued in due form and strictness, except only as to the notice to the tenant, whenever the possession is vacant, or there is no actual occupant of the premises; and also in some other cases. But, as much trouble and formality were found to attend the actual making of the lease, entry, and ouster, a new and more easy method of trying titles by ejectment, when there is any actual tenant, or occupier of the premises in dispute, was invented above a century ago by the lord chief justice Rolle, who then sat in the court of upper bench, so called during the exile of king Charles II.

This new method entirely depends upon a string of legal fictions: no actual lease is made, no actual entry by the plaintiff, no actual ouster by the defendant; but all are merely ideal, for the sole purpose of trying the title. To this end, in the proceedings, a lease for a term of years is stated to have been made by him who claims title, to the plaintiff, who brings the action, as by John Rogers to Richard Smith, which plaintiff ought to be some real person, and not merely an ideal fictitious one, as is frequently, though unwarrantably, practised (6 Mod. 309.): it is also stated, that Smith, the lessee, entered; and that the defendant, William Styles, called the "casual ejector," ousted him; for which ouster he brings this action. As soon as this action is brought, and the complaint fully stated in the declaration, Styles, the casual ejector, or defendant, sends a written notice to the tenant in possession of the lands, *e. g.* George Saunders, informing him of the action brought by Richard Smith, and transmitting him a copy of the declaration; assuring him that he, Styles, the defendant, has no title at all to the premises, and shall make no defence; and therefore advising the tenant to appear in court, and defend his own title; otherwise, he, the casual ejector, will suffer judgment to be had against him; and thereby the actual tenant, Saunders, will inevitably be turned out of possession. On receipt of this friendly caution, if the tenant in possession does not, within a limited time, apply to the court to be admitted a defendant in the stead of Styles, he is supposed to have no right at all; and, upon judgment being had against Styles, the casual ejector; Saunders, the real tenant, will be turned out of possession by the sheriff.

But, if the tenant in possession applies to be made a defendant, it is allowed him upon this condition; that he enter into a rule of court to confess, at the trial of the cause, three of the four requisites for the maintenance of the plaintiff's action, *viz.* the lease of Rogers the lessor, the entry of Smith the plaintiff, and his ouster by Saunders himself, now made the defendant instead of Styles; which requisites being wholly fictitious, should the defendant put the plaintiff to prove them, he must of course be non-suited for want of evidence; but by such stipulated confession of lease, entry, and ouster, the trial will now stand upon the merits of the title only. When this is done, the declaration is altered by inserting the name of George Saunders instead of William Styles, and the cause goes down to trial under the name of Smith, the plaintiff, on the demise of Rogers the lessor, against Saunders, the now defendant. And herein the lessor of the plaintiff is bound to make out a clear title: otherwise his fictitious lessee cannot obtain judgment to have possession of the land for the term supposed to be granted. But if the lessor makes out his title in a satisfactory manner, then judgment and a writ of possession shall go for Richard Smith, the nominal plaintiff, who by this trial has

proved the right of John Rogers his supposed lessor. Yet to prevent fraudulent recoveries of the possession, by collusion with the tenant of the land, all tenants are obliged by statute 11 Geo. II. c. 19. on pain of forfeiting three years' rent, to give notice to their landlords, when served with any declaration in ejectment: and any landlord may, by leave of the court, be made a co-defendant to the action, in case the tenant himself appears to it; or if he makes default, though judgment must be then signed against the casual ejector, yet execution shall be stayed in case the landlord applies to be made a defendant, and enters into the common rule:—a right, which indeed the landlord had, long before the provision of this statute; in like manner as (previous to the statute of Westminster. 2. c. 3.) in a real action the tenant of the freehold made default, the remainder-man or reversioner had a right to come in and defend the possession; left, if judgment were had against the tenant, the estate of those behind should be turned to a naked right. (Bracton, l. 5. c. 10. § 14.) But if the new defendants, whether landlord or tenant, or both, after entering into the common rule, fail to appear at the trial, and to confess lease, entry, and ouster, the plaintiff Smith must be non-suited, for want of proving these requisites; but judgment will in the end be entered against the casual ejector Styles; for the condition, on which Saunders, or his landlord, was admitted a defendant, is broken, and therefore the plaintiff is put again in the same situation as if he never had appeared at all; the consequence of which would have been, that judgment would have been entered for the plaintiff, and the sheriff, by virtue of a writ for that purpose, would have turned out Saunders, and delivered possession to Smith. The same process, therefore, as would have been had, provided no conditional rule had been ever made, must now be pursued as soon as the condition is broken.

The damages recovered in these actions, though formerly their only intent, are now usually (the title being considered as the principal question) very small and inadequate; amounting commonly to one shilling or some other trivial sum. In order, therefore, to complete the remedy, when the possession has been long detained from him that had the right to it, an action of trespass also lies, after a recovery in ejectment, to recover the mesne profits which the tenant in possession has wrongfully received. This action may be brought in the name of either the nominal plaintiff in the ejectment, or his lessor, against the tenant in possession; whether he be made party to the ejectment, or suffers judgment to go by default. (4 Burr. 668.) In this case the judgment in ejectment is conclusive evidence against the defendant, for all profits which have accrued since the date of the demise stated in the former declaration of the plaintiff; but if the plaintiff sues for any antecedent profits, the defendant may make a new defence.

This is the modern way, now universally adopted, of obliquely bringing in question the title to lands and tenements. It is founded on the same principle as the ancient writs of assize, being calculated to try the mere possessory title to an estate, and hath succeeded to those real actions, as being infinitely more convenient for attaining the ends of justice; because the form of the proceeding being entirely fictitious, it is wholly in the power of the court to direct the application of that fiction, so as to prevent fraud and chicane, and vivificate the very truth of the title. The writ of ejectment, and its nominal parties, as was resolved by all the judges (Mich. 52 Geo. II. 4 Burr. 668. Stra. 54.) are judicially to be considered as the fictitious form of an action, really brought by the lessor of the plaintiff against the tenant in possession: invented, under the controul and power of the

court, for the advancement of justice in many respects; and to force the parties to go to trial on the merits, without being entangled in the nicety of pleadings on either side."

But a writ of ejectment is not an adequate means to try the title of all estates; for on those things, whereon an entry cannot in fact be made, no entry shall be supposed by any fiction of the parties. Therefore an ejectment will not lie of an advowson, a rent, a common, or other incorporeal hereditaments. (Brownl. 129. Cro. Car. 492:) except for tithes in the hands of lay appropriators, by the express purview of stat. 32 Hen. VIII. c. 7., which doctrine hath since been extended by analogy to tithes in the hands of the clergy (Cro. Car. 301. 2 Lord Raym. 789.): nor will it lie in such cases, where the entry of him that hath right is taken away by descent, discontinuance, twenty years' dispossession, or otherwise.

The action of ejectment is, however, rendered a very easy and expeditious remedy to landlords, whose tenants are in arrears, by statute 4 Geo. II. c. 28, which enacts, that every landlord, who hath by his lease a right of re-entry in case of non-payment of rent, when half a year's rent is due, and no sufficient distress is to be had, may serve a declaration in ejectment on his tenant, or fix the same upon some notorious part of the premises, which shall be valid, without any formal re-entry or previous demand of rent; and a recovery in such ejectment shall be final and conclusive, both in law and equity, unless the rent, and all costs, be paid or tendered within six calendar months afterwards. Blackk. Comm. B. iii. c. 17. For the practice relating to ejectments, see Jacob's Dict. by Tomlins, art. *Ejectment*. See also Bull. Ni. Pri. and Gilbert's *Ejectments* by Runnington.

EIGHT-FOIL, or *Double Quarter foil*, in *Heraldry*, a modern difference, denoting the ninth son of the first house.

EIGHT, *Piece of*. See **PIECE OF EIGHT**.

EIGHTH Pair of Nerves, in *Anatomy*, the same with the par vagum. See **NERVES**.

EIGHTH, in *Music*, is, next to the unison, the most perfect concord, and the boundary of the present musical system; it includes 12 semitones, which produce 24 keys, 12 major and 12 minor; it contains all the intervals, concords and discords; as all beyond the octave are but replicates, or recurrences of the same sounds: the flat 6th being but the octave of the flat 2d, and the major 9th of the major 2d; the 10th of the 3d, &c. It is an essential note of the triad or common chord, and is so near unison in its effects, that when a male and female, or a man and an adolescent sing the same melody together, it seems, to persons ignorant of music, as if they sung in the same pitch of voice. In instrumental music, as well as in the accompaniment to vocal, the tenor often plays *Oct. Basso*; that is, an octave above the base; and the 2d violin playing an octave below the first, has sometimes a beautiful effect. See **OCTAVE**.

EIGNE, from the French *eigne*, in *Lava Books*, is used for eldest, or first-born. Thus we say, bastard eigne, and mulier puifne, for the elder bastard, and the younger lawfully born.

EIGNOTZ, in *Modern History*, the name of a party which sprung up in Geneva about the year 1530, denoting a confederacy in defence of liberty, so called in opposition to another, reproachfully denominated *Mamelukes*, or slaves. When the protestant opinions began to spread among the citizens, A. D. 1532, these opinions inspired such as embraced them with a bold enterprising spirit, which always accompanied, or was naturally produced by them in their first operations. As both the duke of Savoy and the bishop were, from interest, from prejudice, and from political considerations, violent enemies of the reformation, all the new converts

converts joined with warmth the party of the Eignotz; and zeal for religion, blended with the love of liberty, added strength to that generous passion. The rage and animosity of two factions, shut up within the same walls, occasioned frequent insurrections, which terminated mostly to the advantage of the friends of liberty; and therefore they daily gained ground.

EIKON BASILIKÆ, a posthumous publication bearing this anonymous title, is generally supposed to have been the composition of king Charles I. and to have been written by his own hand. It was entitled *Eikon Basilike*, that is, *the royal image*, "or portraiture of his sacred majesty in his solitude and sufferings," because intended to represent the religious disposition of that unfortunate monarch, and depict the unmerited treatment he experienced at the hands of his subjects. It was first printed in the year 1649, and passed through 50 editions in different languages within 12 months. By the friends of royalty it has been considered as the king's pious meditations and confessions, during the long period of his trying perils, and unavailing struggles against the usurped power of his parliament: and by the sponsors of republican principles, as an apology in which he vindicates his own character, endeavours to support the justice of his cause, and to shew the unprecedented and unjustifiable conduct of his opponents. The book comprises twenty-seven sections; the first containing the king's thoughts on calling his last parliament, and the last, meditations on death. This work produced an animated and severe reply from a most able writer, entitled *Eikonoklastes*; for which title the author in his preface gives the following reason: "In one thing I must commend his openness, who gave the title to this book, *Εικον Βασιλικη*, that is to say, the king's image; and by the shrine he dresses out for him, certainly would have the people come and worship him. For which reason this answer also is entitled *Εικονοκλαστης*, the famous surname of many Greek emperors, who in their zeal to the command of God, after long tradition of idolatry in the church, took courage and brake all superstitious images to pieces." Whatever sentiments the reader of the work and its answer may entertain, there can exist but one opinion, as to which performance should be assigned the palm of victory. Indeed, whatever cause such a writer as the author of *Paradise Lost* were induced to defend, leaving the merits of the question totally out of consideration, he would not fail, by logical subtlety and eloquent elucidation, to make it appear incontrovertibly the best. After the work made its appearance, the question was strongly agitated, whether the *Eikon Basilike* was the production of the deceased monarch, and the honour or disgrace attached to the writing of it was affixed to different persons among the abettors of the royal cause:—Lord Clarendon, author of the "History of the Rebellion;" bishop Burnet, who in his youth accompanied prince Charles in his exile; bishop Juxon, the king's chaplain, who possessed his confidence, was his secret adviser, and attended the monarch in his last moments, &c. &c.

The grounds and evidences of the spuriousness of the book are these: 1. That lord Clarendon, in his History of the Grand Rebellion, makes no mention of it. 2. Bishop Burnet says, the duke of York, afterwards king James II., told him in the year 1673, that the book called *Eikon Basilike* was not of his father's writing, but that Dr. Gauden writ it: that after the restoration, the doctor brought the duke of Somerset to the king and to the duke of York, who both affirmed that they knew it to be his (the doctor's) writing, and that it was carried down by the earl of Southampton, and shewed the king during the treaty of Newport, who read and approved it. 3. The earl of Anglesey gave it

under his hand, that king Charles II. and the duke of York declared to him, in the year 1675, that they were very sure the said book was not written by the king their father, but by Dr. Gauden, bishop of Exeter. 4. Dr. Gauden himself, after the restoration, pleaded the merit of this performance in a letter to lord chancellor Hyde, who returned for answer, that the particular he mentioned (*i. e.* of his being the author of that book.) was communicated to him as a secret: I am sorry, says his lordship, that it was told me, for when it ceases to be a secret it will please nobody but Mr. Milton. 5. Dr. Walker, a clergyman of the church of England, after invoking the great God, the searcher of hearts, to witness the truth of what he declares, says, in his treatise entitled "A True Account of the Author of *Eikon Basilike*," I know and believe the book was written by Dr. Gauden, except chap. 16th and 24th by Dr. Duppa. "Dr. Gauden, says he, acquainted me with his design, and shewed me the heads of several chapters, and some of the discourses. Some time after the king's death I asked him, whether his majesty had ever seen the book? He replied, I know it certainly no more than you; but I used my best endeavours that he might, for I delivered a copy of it to the marquis of Hertford, when he went to the treaty of the Isle of Wight." Dr. Gauden delivered the MS. to this Walker, and Walker carried it to the press; it was copied by Mr. Gifford, and both the doctor's son and his wife affirm, that they believe it was written in the house where they lived. Notwithstanding all this evidence, Mr. archdeacon Eachard says, the book is incontestably the king's; and bishop Kennet adds, that those who pretend *Eikon Basilike* was a sham put upon the world, are a set of men that delight to judge and execute the royal martyr over again by murdering his name. Dr. Hollingworth, Dugdale, Wagstaffe, and others, have endeavoured to invalidate the above-mentioned authorities, by shewing that Dr. Gauden was not capable of writing such a book; but the evidence already produced is as strong and convincing as any thing of this nature can possibly be. Neal's Hist. of the Puritans, vol. ii. p. 369, &c. 4to.

When the *Eikonoklastes* was published the writer was not known, or it would doubtless have been mentioned. The author of that treatise was in doubt, and still "stat nominis umbra." Whoever was the writer, there can no doubt remain as to the scope and tendency of the facts produced, and the arguments used in the *Eikon Basilike*. It appears to have been written, not merely as an apology for the past, but a vindication of the then present measures, and to further the cause of royalty. In this view it has been considered by the favourers of a republican form of government. To counteract the effects likely to be produced by it on the minds of the public, Milton was assigned the task of drawing up a confutation. In the light above stated he saw it; for "it appears manifestly the cunning drift of a factious and defeated party, to make the same advantage of his (the king's) book, which they did before of his regal name and authority; and intend it not so much the defence of his former actions, as the promoting of their own future designs; and that by publishing, dispersing, commending, and almost adoring it, seem to place therein the chief strength and nerves of their cause. For how much their intent, who published these over-late apologies, and meditations of the dead king, drives to the same end of stirring up the people, to bring him that honour, that affection, and, by consequence, that revenge to his dead corpse, which he himself living could never gain to his person; it appears both by the concerted portraiture before his book, drawn out to the full measure of a masking scene; and set these to catch fools and silly gazers; and by those Latin words after the end, "Vola dabunt quæ bella negarunt:"

negarunt;" intimating, "that what he could not compass by war, he should achieve by his meditations." See preface to Milton's *Eikonoklastes*, edition by Baron.

EILAMIDES, from *ελας*, *I involve*, a word used by Hippocrates, to express the meninges, or membranes of the brain, and dura mater and pia mater.

EILENBURG, in *Geography*, in old times called Ile-burck, Ileburg, Ilinburg, Juungenburg, Iliburg, is a very ancient town of the kingdom of Saxony, in the circle of Leipzig, on the high road leading to Breslau, 15 miles from Leipzig, pleasantly situated in an island formed by the river Mulde, over which there is a wooden bridge. Brewing constituted its chief industry before and some time after the thirty years' war, during which it suffered severely. It is now chiefly remarkable for its hops, which are reckoned the best in Saxony. Eilenburg has about 3500 inhabitants. There is close to the town an ancient castle, in which Margaret, the widow of the elector of Saxony, Frederick II. surnamed the Mild, resided 22 years, from 1464 to 1486.

EMBECK, or EINBECK, anciently *Embike*, a town of Germany, in the principality of Grubenhagen, which constituted part of the electorate of Hanover, and now, by Napoleon's decree of the 18th of August, 1807, forms part of the new kingdom of Westphalia, is situated on the river Ilme, which, at a small distance from the town, falls into the river Leine, 15 miles N. of Goettingen, and 30 S. W. of Hildesheim. It contains about 5000 inhabitants, and is remarkable for its manufactures of woollen cloth, flannel, serge, crape, dimity, and other cotton stuffs. Eimbeck is surrounded with mountains, part of the Hartz or Hercynian forest, which yield silver, copper, iron, and lead.

EIMËO, or IMAO, one of the Society Islands, in the south Pacific ocean; about four leagues W. from the N.W. part of Otahete. It has two harbours, *viz.* Taloo and Parowroah; the former is situated upon the north side of the island, in the district of Oboonohoo or Poonohoo, S. lat. $17^{\circ} 30'$ E. long. $210^{\circ} 0'$. It runs in S. or S. by E. between the hills above two miles. This is not inferior, says Capt. Cook, for security and goodness of its bottom, to any harbour belonging to the islands in this ocean; and it has this advantage over most of them, that a ship can sail in and out with the reigning trade-wind, so that the access and egress are equally easy. There are several rivulets that fall into it. Wood and water are to be procured here with great facility. The harbour of Parowroah, on the same side of the island, is much larger within, than that of Taloo, but the entrance is much narrower, and lies to leeward of the harbour. The inhabitants of this island were anxious to trade in bread-fruit, cocoa-nuts, and hogs, which they exchanged for hatchets, nails, and beads. Eimëo supplies abundance of fire-wood. There is little difference between the produce of this island and that of Otahete; but there is a striking difference in their women. Those of Eimëo are of low stature and dark hue, and their features are generally forbidding. The general appearance of this island is very different from that of Otahete. The latter rises in one steep hilly body, has little low land, except some deep valleys, and a flat border that surrounds it, towards the sea. Eimëo, on the contrary, has hills running in every direction, which are steep and rugged, inclosing large valleys, and covered almost to their tops with trees. Near the harbour where Capt. Cook lay, in October 1777, were two large stones, or rather rocks, concerning which the natives have some superstitious notions. They consider them as "Eatooas" or divinities, saying that they are brother and sister, and that they came, by some supernatural means, from Ulieca. Cook's Third Voyage, vol. ii.

EINABI, a town of Asiatic Turkey, in the province of Natolia; 26 miles N. of Dognizlu.

EINBLINDER, in *Ichthyology*, the name of a sort of lamprey, without eyes, called by the writers on these subjects the *lampetra caca*, or blind lamprey. See *PETRONIXON branchialis*.

EINECIA, in our *Old Writers*, is used for primogeniture. It is sometimes writ *esuecia* and *esuecy*. See *ESNECY*.

EINICH, in *Geography*, a town of Asiatic Turkey, in the province of Natolia; 44 miles S.W. of Artaki.

EINSIEDLEN, or EINSTEDL, a small town of Switzerland, in the canton of Surtz, remarkable for the ancient and rich abbey of the same name.

This abbey, which is also called "St. Meinrad's Cell in the Dark Forest," in Latin *Erems Disparæ Matris; Eremsus Divæ Virginis; Monasterium Eremitarum; Eremitarium Cœnobium in Helvetiis*; in ancient records *Monasterium in Silva, Megiradi Cella*; in French, *Notre Dame des Hermites*; in Italian, *La Madonna di Waldo*, is situated in a thick gloomy forest, to which St. Meinrad or Megirad is said to have retired. In 838, the first abbot of the *Frauenmünster* at Zurich, caused a chapel and cell to be built for him, but after the murder of the hermit in 863, they fell to ruin. About the year 906 St. Benno laid the foundation of the abbey, which is the second of the Benedictine order in Switzerland. In 1704 the convent was rebuilt, and is now a large splendid edifice. It has an extensive library, and rooms for the reception of strangers. The church of our Lady was rebuilt in 1719. In a chapel is an image of the Virgin, which particularly used to attract a great number of pilgrims, and which has been productive of considerable wealth to the abbey. The manors of Erlibach and Manndorf, in the canton of Zurich, the lordships of Sonnenberg, Gachrang, and Freudenfels, in the canton of Thurgau, the parish of Oberkirch, and several villages in Germany, belonged to Einsiedlen.

EINVILLE, a small town of France, in the department of the Meurthe, in the district of Lunéville, 3 miles N. of that place, remarkable for a palace which king Stanislaus of Poland built here during his retreat at Nancy.

EINZELLE, one of the Persian havens of the Caspian, which, though it be only a wretched village, is the most frequented through the Persian commerce. Formerly vessels ventured through the channel into a bay; but this bay being choaked up, they are now obliged to lie at anchor in the road. Einzelle is situated on the south-western coast, a few miles N. of Reshd, capital of the province of Ghilan: it consists of Old and New Einzelle; the former inhabited by the Persians and Armenians, under the jurisdiction of the sophy; the latter by the Russian merchants, and those Armenians who are subject to Russia. A garrison of 30 soldiers is stationed under the command of the consul. It contains a Russian and Armenian church, and about 300 houses, mostly formed with mud. The refuse only of the Persian and European commodities is exposed to sale at Einzelle: the great mart being at *Reshd*, which see.

EION, in *Ancient Geography*, a town of Thrace, near the mouth of the river Strymon; four miles from Amphipolis and its port.

EIRE. See *EYRE*.

EIRESSIONE, *Eiresson*, from *ειρε*, *peace*, in *Antiquity*, an olive branch, bound about with wool, and crowned with all sorts of first fruits, which was carried in procession in the Athenian festival, called *Pyanesia*. Pott. *Archæol. Græc. lib. ii. cap. 20. tom. i. p. 428*.

EIRON, in *Geography*, a river of South Wales, in Cardigan-shire,

diganhire, which, descending through a narrow vale between steep impending hills, falls into the sea, a little below a picturesque bridge at Aberciron, in the road from Cardigan to Aberystwith.

EISENACH, in Latin *Isenacum*, a town of Germany, in the duchy of Saxe Weimar, formerly the chief city of the principality of Saxe Eisenach, which devolved to the dukes of Weimar in 1741, is situated in an agreeable fertile valley on the small river Nesse, 45 miles S.W. of Erfurt, and has an ancient palace, which has been converted into stables. Eisenach contains between 8 and 9000 inhabitants; it has several manufactures of woollen cloth, serge, and woollen and cotton stuffs, which are considerably benefited by an excellent fuller's earth, that abounds in the neighbourhood. The grammar school, which was founded by the duke John-William in 1707, has a very extensive and valuable library. The town has been much improved of late, the streets are regular, well paved, and well lighted. The vicinity of Eisenach is also remarkable for hops and madder. At a distance of two miles is an ancient castle, called the Wartburg, in which Luther was confined in the year 1521; and at nearly the same distance is the summer-palace of Wilhelm's Thal (William's Dale) with a large park, founded in 1729, by the duke John-William.

EISENBACH, a small town of Hungary, near Schemnitz, remarkable for a warm bath, and surrounded by limestone rocks.

EISENBERG, a small town of Germany, in the duchy of Saxe Gotha, principality of Altenburg, 6 miles from Zeitz, with an ancient ducal palace, and a good grammar school. It contains 3500 inhabitants, and has a brisk timber and deal trade, besides several manufactures of chairs, waggons, woollen stuffs, and leather.—Also, a small town of Germany, with an old ruined castle, in the principality of Waldeck.

EISENHARTZ, a town of Germany, in the duchy of Stiria, enriched by iron mines, discovered in 702; 10 miles N. of Leoben.

EISENSTADT, a small town of Hungary, three miles to the left of the road from Vienna to Oedinburgh, with a palace, which is the residence of prince Esterhazy, who has large estates in its neighbourhood.

EISETERIA, *Ἐισητηρία*, from *εἰσέρω*, I enter, in *Antiquity*, the day on which the magistrates at Athens entered upon their office; upon which it was customary for them to offer a solemn sacrifice, praying for the preservation and prosperity of the commonwealth, in the temple of Jupiter *Ἐισητηριος*, and Minerva *Ἐισητηρία*, i. e. the Counsellors. Pott. *Archæol. Græc. lib. ii. cap. 20. tom. 1. p. 385.*

EISEFELD, anciently *Afffeld*, *Eisfeld*, *Eiffelfeld*, or *Efsfeld*, in *Geography*, a small town of Germany, in the duchy of Saxe Cobourg, on the river Werra, 9 miles from Cobourg, with a good grammar school and an old ducal palace, usually the residence of the dukes's dowager, if any.

EISKOI, a town of Russia, in the government of Caucasus, situated at the mouth of the river Eia, on the east coast of the sea of Azoph; 50 miles S.W. of Azoph.

EISLEBEN, or EISZLEBEN, in Latin *Isleba*, an ancient and considerable town of the kingdom of Saxony, chief city of the county of Mansfeld, situated on a hill near a brook, called the Klippenbach, 15 miles E. of Halle, 20 of Merseburg, and 30 of Leipzig, containing 993 houses, and a population of 5000 individuals. It is divided into the Old and New Town. The former, which was known as a flourishing city in 1024, has an ancient castle, three parish churches, and an excellent grammar school, attended by seven professors. Brewing was the principal occupation of the inhabitants in former times. They brewed a strong

beer called *krappel*, which used to be exported to a great part of Germany; they are now chiefly employed in agriculture, and in the making of saltpetre and potash. There are also some mines of importance in the neighbourhood. The New Town has only one parish church.

But Eisleben derives its principal celebrity from being the birth-place of Martin Luther. The house in which he was born has been rebuilt, after the great conflagration of 1594, and is still visited by travellers. The furniture of the room in which this eminent reformer first saw the light, is reported to have been saved from the fire, and is shewn as a curiosity, to which the superstition of the vulgar attaches the faculty of a relic, and the power of healing certain diseases. Since the year 1772 a part of the house has been converted into a charity school, than which nothing could have been more appropriate, to honour the memory of him who restored the freedom of conscience, and enforced the extension of a more enlightened instruction in the sacred records of revealed religion to all and every member of the community.

EISTEDDFOD, in *Antiquities*, was an annual session of the British bards. The learned Mr. Owen, in his Sketch of Bardism, prefixed to his translation of the Heroic Elegies, by Llywarc Hen, observes, that the bards generally held annual assemblies, called *Gorseddau*; at which the traditions of the bardic system were rehearsed, and all matters respecting their religion and policy transacted. But, subsequent to the introduction of Christianity, genuine bardism declined. A schism took place in the bardic body, not, as he supposes, from the two systems clashing with each other; but through the introduction of superstitions from the practice of the Romish church. A prince, by the name of Belus, proposed numerous deviations from the tenets of the original institution, with which most of the order complied. Among many of the privileges of which they were deprived on that occasion, *eligibility to the priesthood* appears to have been one. But from the tenor of history, it is most probable, that the nonjuring bards were such as were tenacious of their Ethnic opinions; and that the *Beirdd-Beli*, *Over-veirdd*, or *Pseudo-bards*, on the other hand, were such as complied with the institutes of Christianity. This schism took place in the 5th century. After which, the dissenting party continued to hold *gorseddau*, and propagate their tenets, till the death of the last Llywelyn; when, by the cruelty of the English monarchs, bardism was nearly annihilated. From the time of the schism, the character of the bardic orders, generally acknowledged as such, was materially changed; and their occupations became widely different. They appear, however, to have been divided into three classes, or orders, as poets, minstrels, and singers; and, in imitation of their ancient assemblies, or *gorseddau*, they held annual meetings, which, from the spirit of party, they termed *Eisteddfodau*. The learned author of the *Welsh Dictionary*, however, considers them as a spurious race, and although they were an incorporated society, governed by peculiar laws, yet they were not bards. The *eisteddfod*, or congress, was held under the sanction of the Welsh princes; and as North Wales was the last part of the country which preserved its independency, and with that its peculiar laws; the most authentic vestiges are there to be traced of the ancient usages of Cambria. At this meeting the princes and chieftains, as well as bards, attended. It was usually held at one of the royal residences, *Aberffraw*, *Mathralaw*, or *Caerwys*; which circumstance has induced some to suppose it a triennial, rather than an annual meeting. For the calling of these assemblies, a special commission was issued by the Welsh princes, while they continued masters of the country, and afterwards by royal authority under the English monarchs,

sarchs. At these British olympics were collected in a focus the scattered rays of musical and poetic genius. British bards pour'd forth their most animated strains, and minstrels tuned their fascinating harps to melody. This was considered not only as an opportunity of displaying skill, but as a college of harmony, where genius was registered, and merit rewarded with honours and emoluments. Candidates for bardic professions were admitted, others were assigned precedence, and the bard most distinguished for his talents on the occasion was solemnly chieft, and had awarded to him, as the highest mark of respect, the badge of merit, the *silver harp*. Without an examination at this public meeting, and receiving a diploma in consequence of being approved, none was qualified to exercise the profession, either of bard, or minstrel. The last eisteddfod convened by royal authority was held in the reign of Elizabeth. The commission for the purpose was granted to sir Richard Bulkeley, and other persons of distinction, October 20th, in the year 1567. In pursuance of that, an eisteddfod was held at the town of Caerwys, in Flintshire, the requisite notice having been previously given to the principality. The assembly was numerous, and many persons of eminent genius displayed extraordinary talents, both in music and poetry. Fifty-five bardic degrees were conferred; seventeen in vocal, and thirty-eight in instrumental music. From that period, the eisteddfod was discontinued, bards and minstrels sunk into insignificance; and bardism may now be said to have expired. The cruelty of Edward was the preparatory step to the downfall of the institution, and the subjecting of the Welsh to the jurisprudence of England, in the reign of Henry VIII, has been operating to accomplish it. A public spirited society in London, associated under the name of the Gwyneddigion, determined to revive a practice calculated to elicit genius; and, by rivalry, to produce poetical and musical excellence. The ancient notice of a year and a day was given previous to the meeting, and the enthusiasm of the country was increased by the aid of locality. Caerwys was appointed as the place of meeting, and the old town-hall was fitted up on the occasion, for the reception of the company. It was numerously and respectfully attended, and many excellent performers on the harp, as well as poetical composers, and others of great vocal powers, displayed abilities; which evinced, that however the genius of harmony had been neglected, or the bardic spirit suppressed, it was not extinguished among the inhabitants of North Wales. The number of bards in attendance was twenty, of minstrels twelve, and of dateciniaid, or singers, eighteen. Having elected a proper person to fill the *ceder*, or chair, the first day was occupied in hearing the poetical compositions recited; and on the second, the vocal and instrumental candidates displayed their respective abilities. The distinguishing honours of bardic braint, or principal bard; penceidd dant, or chief performer on the harp; and penceidd dafod, or chief of vocal powers,

“ Who gave to song resistless powers to charm,”

were then conferred: and the meeting, which had been highly gratifying to the lovers of genuine music and poetry, then adjourned. *fine die.* Evans's Tour in North Wales.

EITHON, or YTHON, in *Geography*, a river of Scotland, which runs into the German sea; 26 miles N. of Aberdeen.

EITIAI, a town of Africa, in the empire of Morocco, and province of Tadia, defended with walls, and containing about 3000 inhabitants.

EKA, a town of Sweden, in the province of Smoland; 11 miles N. of Wexio.

EKANGA, a river of Russia, which runs into the Frozen sea; 140 miles E. of Kola.

EKARMA, one of the smaller Kurile islands, in the North Pacific ocean. N. lat. 49° 30'. E. long. 154° 29'.

EKASTROV, a town of Russia, in the government of Archangel; 80 miles S. of Kola.

EKATERINENBURG. See CATHERINENBURG.

EKATERINOGRAD, a town of Russia, in the government of Caucasus, on the Malva; 265 miles S.E. of Azoph. N. lat. 44° 15'. E. long. 43° 38'.

EKATERINOSLAV. See CATHARINENSLAV.

EKATERINOSLAVSKOI, a province of Russia, in the government of Ekaterinoflav, comprehending what was formerly called Budzinc Territory, and the Ukraine, now part of the government of Ekaterinoflav. See CATHARINENSLAV.

EKATERINSKAIA, a bay of the North sea, in Russian Lapland, near Kola. N. lat. 68° 50'. E. long. 32° 24'.

EKEBERGIA, in *Saxony*, named by Sparrmann after fir Charles Gultavus Ekberg, knight of the order of Wafa, captain of a Swedish Indiaman, who took him to China for the purpose of making inquiries in natural history, and who first brought the tea plant alive to Europe. (See Amoen. Acad. v. 7. 498.) Sparrmann finding this tree, of a new genus, during their visit to the Cape of Good Hope, jolly dedicated it to his friend and patron, and has described it, with a figure, in the *Stockholm Transactions for 1779*, 282. t. 9. Thunb. Nov. Gen. 43. Murray in Linn. Syst. Veg. ed. 14. 399. Schreb. 284. Willd. Sp. Pl. v. 2. 549. Juss. 265. Mart. Mill. D. C. v. 2. Clafs and order, *Decandria Monogynia*. Nat. Ord. *Tribilites*, Linn. *Melie*, Juss. Gen. Ch. *Cal.* Perianth of one leaf, bell-shaped, downy, in four or five deep, ovate, obtuse segments. *Cor.* Petals four or five, oblong, obtuse, rather larger than the segments of the calyx, being about a line long, externally downy. Nectary a ring encompassing the base of the germen. *Stam.* Filaments ten, inserted into the nectary, broad and short, downy, somewhat cohering together; anthers erect, oblong, acute, much longer than the filaments. *Pistl.* Germen superior, round; style cylindrical, very short; stigma large, capitate, umbilicated. *Peric.* Berry globose, mealy. *Seeds* from two to five, oblong, angular.

Eff. Ch. Calyx in four or five segments. Petals four or five. Nectary a ring round the germen, bearing the stamens. Berry superior, with from two to five seeds.

Obs. Jussieu doubts, with great reason, that the corolla can really be of four petals, while the stamens are ten, and accordingly we find on dissection that the flowers are, sometimes at least, five-cleft, the stamens being twice as numerous as the petals. From the hairiness and minuteness of the parts, it is difficult to ascertain precisely the mode of connection between the filaments and the nectary, or to define the limits of each, but analogy seems to have rightly guided Jussieu to improve the descriptions of Thunberg and Sparrmann.

E. capensis, the only known species, is reported by Thunberg to grow in the woods of Hauteniquas and Essenboch at the Cape. The Dutch colonists call it Essen or Esschenboom, and Hauteniquas Essen, from its resemblance to the European ash. It forms a tall tree, with greyish bark, and a hard wood used for many utensils. *Branches* alternate, knotty, rugged, scarred, downy when young. *Leaves* clustered about the tops of each branch, alternate, much resembling those of the ash in general appearance, being pinnate and smooth, but the leaflets are entire. The panicles of whitish small flowers come forth in November and the

following

following months, and are axillary, much shorter than the leaves. Spartman describes the fruit as about half an inch in diameter, mealy and rather bitter, with five seeds resembling those of an orange. Thunberg observes that they vary from two to five, probably from partial abortion, and not from any original diversity of number in the germs.

EKENAS, in *Geography*, a sea-port town of Sweden, in the province of Nyland, on the north coast of the gulf of Finland, with an indifferent harbour; 50 miles S.E. of Abo.

EKERDEN, a town of Asiatic Turkey, in the province of Natolia; 16 miles E. of Irbateh.

EKESIO, a town of Sweden, in the province of Smoland; 60 miles N.W. of Calmar.

EKHONT, GERBRANT VANDEN, or rather ECKHONT, in *Biography*, a painter born at Amsterdam in 1621. He is better known by the excellence of the manner in which he imitated the peculiarities of his master Rembrandt, than for original genius in thought, or execution. He is esteemed as one of the most perfect disciples of that great man; but he never obtained that just perception of truth and tasteful arrangement of the materials composing his pictures, which was Rembrandt's grand characteristic; although many of his pictures are highly esteemed for their force and colour. He painted portraits principally; but oftentimes he attempted historical compositions, in which he was not so successful. He died in 1674, aged 53.

EKHONT, ANTHONY VANDEN, a fruit and flower painter, born at Brussels in 1656. His works are much esteemed for the peculiarities of their composition, more than for the truth of their execution. He travelled to Lisbon, where he was married to a young lady of quality and great fortune: this success and affluence excited the envy of some abandoned ruffians, who shot him in his carriage, in 1695, and remained undiscovered.

EKIE, in *Geography*, a town of Asia, in Tibet; 55 miles S. of Tesson-Hutun.

EKKI-TEKKI, a town of Africa, in the country of Commodo.

EKRAD, a town of Egypt; 10 miles S.E. of Monfalout.

EKRON, in *Ancient Geography*. See ACCARON.

EKSAS, in *Geography*, a town of Egypt; 21 miles S. of Cairo.

EKSENIDE, a town of Asiatic Turkey, in Natolia; 84 miles S. of Degnizla. N. lat. 35° 27'. E. long. 28° 55'.

ELABORATION, the act of finishing or perfecting any thing with labour and time.

The term is chiefly used in *Medicine*, where the chyle, blood, and semen, are said to be well elaborated, when they are well conditioned, have undergone all the secretions, mixtions, impregnations, and circulations, necessary to bring them to perfection.

If the chyle went directly from its receptaculum to the breasts, it would not be sufficiently elaborated to afford good milk. See MILK.

ELABORATORY. See LABORATORY.

ELABUGA, in *Geography*, a town of Russia, in the government of Viatka, on the Bielaja; 156 miles S. of Viatka.

ELACATEUM, in *Ancient Geography*, a mountain of Greece in Thessaly.

EL-ADDA, in *Zoology*. See EL ADDA.

ELÆA, in *Ancient Geography*, a maritime town of Asia Minor, in the Eolide, at the mouth of the river Caicus, opposite to the S.E. part of the isle of Lesbos.—Also, a town of Ptoconia, between Tyre and Sidon.—Also, a promontory in the eastern part of the isle of Cyprus, S.E. of Serapis.

Ptolemy.—Also, an island of the Propontis, so called on account of its oives. Pliny.—Also, a mountain of Palestine, six stadia E. of Jerusalem. Josephus.—Also, a town and sea-port of Asia Minor, in Bithynia, near Myfia. Steph. Byz.—Also, a part of Ethiopia. Id.

ELÆAGNUS, in *Botany*, *ελαιγιος* of Theophrastus, from *ελαι*, the olive, and *γιος*, the chaff tree. Linn. Gen. 62. Schreb. 85. Willd. Sp. Pl. v. 1. 688 Mart. Moll. Dict. v. 2. Juss. 75. Tourn. t. 489. Clafs and order, *Tetrandria Monogynia*. Nat. Ord. *Calycifloræ*, Linn. *Eleagni*, Juss.

Gen. Ch. Cal. Perianth of one leaf, four-cleft superior, erect, bell-shaped, rough on the outside, coloured within, deciduous. Cor. Petals none. Nectary in the bottom of the flower, globose, four-cleft at its summit, surrounding the base of the style. Stam. Filaments four, very short, inserted below, and alternate with, the segments of the calyx; anthers oblong, incumbent. *Pist.* Germen inferior, oblong; style simple, rather shorter than the calyx; stigma simple. *Peric.* Drupa ovate, obtuse, smooth, with a minute point at the top. *Seed.* Nut solitary, oblong, obtuse, of one cell. Some flowers, according to Adanson, are male.

Ess. Ch. Corolla none. Calyx four-cleft, bell-shaped, coloured. Drupa inferior.

A genus of shrubs, elegant for their white scaly silvery pubescence, which is most copious on the under side of the leaves, the upper being nearly smooth and naked. Flowers axillary, solitary, or clustered, small, externally scaly, yellow or greenish within, the calyx partaking of the nature of a corolla. The fruit is usually reddish, pulpy, but useles. Willdenow enumerates ten species, six of which are natives of Japan.

E. angustifolia, Linn. Sp. Pl. 176. Sm. Prod. Fl. Græc. v. 1. 105. Pallas, Ross. v. 1. 10. t. 4. DuRoi Arb. v. 1. 213. t. 89. (*ελαι καθυπτιαν* Desc. book 1. chap. 137.) "Leaves lanceolate." Native of the eastern and southern parts of Europe; it is very hardy in our gardens, but seldom bears fruit. The flowers have a strong scent, especially at night, and are yellow. Tournefort and Pallas describe the fruit as sweetish. The ancients thought this tree barren of fruit. The leaves they celebrate as astringent. Its natural soil, according to Pallas, is moist and sandy.

E. orientalis and *spinosa* are very nearly akin to the above; the thorns appear to be a variable character of the latter species, as in *Amygdalus*, *Pyrus*, &c.—*E. latifolia*, "leaves ovate," is a native of Ceylon, of which we know little, and still less of the six Japanese species described by Thunberg and partly by Kempter.

ELÆAS, in *Ancient Geography*, a port of Greece, in Epirus.

ELÆGNON. See AGNUS CASTUS.

ELÆIS, in *Botany*, so named by Jacquin from *ελαι*, the olive, in allusion to its oily fruit. Jacq. Amer. 288. t. 172. Linn. Mant. 21. Schreb. 776. Juss. 38. Gært. t. 6. Mart. Mill. Dict. v. 2. Clafs and order, *Dioclea Hexandria*, Thunb. and Gærtner. (*Monoclea*, Jacq.) Nat. Ord. *Palmeæ*.

Gen. Ch. Male, Cal. Perianth of six concave upright leaves. Cor. of one petal, the length of the calyx, with six acute upright segments. Stam. Filaments six, awl-shaped, the length of the corolla; anthers oblong, acute.

Female, Cal. as in the male. Cor. of six petals. *Pist.* Germen superior, ovate, of three cells; style thickish, triangular; stigma three, obovate, depressed, reflexed. *Peric.* Drupa ovate, somewhat angular, internally fibrous and oily, of one cell. *Seed.* Nut solitary, ovate, obscurely triangular, thick and hard, of one cell, without any valves, with three pores at the base. Embryo at the base of the seed.

Ess. Ch. Male, Calyx of six leaves. Corolla six-cleft. Female,

Female, Calyx of six leaves. Corolla of six petals. Stigmas three, dilated. Drupa fibrous. Nut solitary, stony.

Gærtner has improved Jacquin's description of the fruit, but we apprehend the latter to be most correct as to the female flower.

E. guineensis, Linn. Mant. 137. Gærtner. v. 1. 17. (Palma foliorum pediculis spinosis, fructu pruniformi luteo oleoso; Sloane Jam. v. 2. 113. t. 214.) The Oily Palm. Native of Guinea, from whence it is said to have been carried to America. Jacquin found it cultivated, though rarely, in the gardens of Martinico. The tree he described and figured was 30 feet high, and, as he conceived, 10 years old. *Trunk* erect, beset with the remains of old leaf-stalks, and crowned by a tuft of long, pinnated, leaves, unarmed, but having hooked spines on the edges of their stalks; leaflets sword-shaped, a foot and half long, entire. *Spadices* axillary, solitary, large, repeatedly compound, and very dense; their stalks imbricated, compressed, covered, (except their naked triangular points,) with flowers, which in the evening especially exhale a strong anise-like smell. *Fruit* about the size of a pigeon's egg, yellowish variegated with black and red, its pulp abounding with oil, which exudes on the slightest pressure between the fingers. *Nut* very black, marked with whitish, longitudinal, interrupted streaks.

Gærtner describes and figures the fruit of an *E. melanococca* which he esteems a mere variety of the above. It is smaller, more oblong, and internally blacker, but no clear specific mark of distinction appears.

ELÆOCARPUS, compounded of *ελαιον*, the olive, and *καρπος*, fruit, the drupa bearing some resemblance to an olive. Burm. Zeyl. 93. t. 40. Linn. Gen. 268. Schreb. 356. Willd. Sp. Pl. v. 2. 1169. Mart. Mill. Dict. v. 2. Juss. 258. Gærtner. t. 43. (Dicera; Forst. Gen. 40.) Class and order, *Polyandria Monogynia*. Nat. Ord. Akin to *Guttifera*, Juss.

Gen. Ch. *Cal.* Perianth of one leaf, inferior, permanent, divided to the base into five linear-lanceolate, concave, acute segments. *Cor.* Petals commonly five, with claws, three-cleft, and usually deeply lacinated, equal, scarcely longer than the calyx, inserted at the base of the nectary; their ultimate segments often capillary. Nectary an orbicular, depressed, fleshy, lobed, villous gland, in the centre of the calyx. *Stam.* Filaments from 20 to 30, capillary, short and slender, erect, inserted into the nectary; anthers shorter than the corolla, erect, linear, rough, taper-pointed, of two cells, opening by two common reflexed valves, usually more or less unequal in length. *Pistl.* Germen somewhat globose, hairy, seated on the nectary; style thread-shaped, longer than the stamens; stigma acute. *Peric.* Drupa oblong or globose, smooth and polished. *Seed.* Nut oblong or roundish, furrowed and tuberculated, with an imperfectly three-valved shell, and one cell; kernel bluntly triangular.

Obs. The number of segments of the calyx, as well as the petals, and the segments of the latter, vary from three to five. The number of stamens also is from 3 to about 30, some say 40.

Ess. Ch. Petals three to five, torn. Anthers with two valves at the summit. Calyx in three to five deep segments. Drupa superior, with a furrowed crisped nut.

The species of this genus are so ill defined by authors, that although we are not furnished with sufficient materials to elucidate them all as we could wish, we will not withhold such information as we have. In arranging the known species we find new specific characters requisite, in order to explain the new ones.

1. *E. ferrata*. Linn. Sp. Pl. 734. Fl. Zeyl. 92. Burm. Zeyl. 93. t. 40.—Leaves elliptical, obtuse, bluntly serrated,

smooth; divarications of their veins glandular, anthers with nearly equal valves, bearded. Native of Ceylon, where it is called Weralu. We have a specimen from thence whose leaves are two or three inches long, with veins glandular only at their base. Petals three-cleft, and beautifully lacinated. Calyx in five downy segments. The fruit is said to be oval. Another, either from the same island or some other part of the East Indies, sent by Koetig to David Van Royen, has leaves but half as long as the former, with veins much subdivided, and glandular at most of their subdivisions, as well as at the base. The petals are fallen, but all the other parts agree. Both these plants have a pair of glands at the base of the leaves, as described in *Fl. Zeyl.* or rather at the summit of their footstalks, and both have long simple axillary clusters of flowers. We cannot refer any synonym of Rumphius or Rheede with satisfaction to either, nor dare we assert, that the two specimens are distinct species.

2. *E. oblonga*. Gærtner. v. 1. 202. t. 43. (Ganitrum oblongum, Catuampam; Rumph. Amb. v. 3. 163. t. 102.)—Leaves elliptic-oblong, pointed, with shallow serratures; veins downy underneath. Anthers with nearly equal valves, scarcely bearded. Fruit oval. Sent by Dr. Buchanan from the East Indies, by the name of *E. ferrata*. It is nevertheless manifestly distinct from the genuine Weralu above described. The leaves are five or six inches, or more, in length, sharp-pointed, with numerous shallow, though acute, serratures; smooth above, but the veins, which are numerous and strong, destitute of glands, are downy and rusty at the under side, which gives that softness to the touch mentioned by Rumphius. As to the size, they accord with his description, and it must always be remembered that his figures are diminished. The footstalks, which are bi-glandular at their summit, are likewise downy, as well as the flower-stalks. The latter grow from above the scars left by the last year's leaves, not as in *E. ferrata* (the genuine Ceylon plant at least) from the bosoms of the foliage of the present season. Each cluster is five or six inches long, simple, much resembling those of *Prunus lusitana*, or Portugal Laurel. Calyx in five downy segments, shorter and rather blunter than in the first species. Petals five, each in five moderately deep and equal divisions, cut into various capillary points. Stamens 20 or more; anthers with nearly equal valves, only very slightly and occasionally bearded at their points. Germen oblong, furrowed, bristly; style hairy; stigma naked. The nectary seems to swell into five hairy globose glands. Fruit oblong, according to Rumphius and Gærtner. Their synonyms depend on each other, and we have no doubt of their belonging to our plant.

3. *E. elliptica*.—Leaves elliptical, entire, smooth on both sides; veins destitute of glands. Anthers slightly bearded. This is the specimen described by Linnæus Mant. 2. 401, which Willdenow copies. It is a very miserable specimen, apparently from the East Indies, and if the flowers have, as he says, but three petals and eight stamens, which we cannot correctly verify, they confirm that specific difference from both the foregoing, which the leaves sufficiently evince. The latter are about three inches long, smooth all over, as well as their footstalks, which have no glands at their summit, neither are the veins glandular. Flowers small. Calyx acute. Germen globose, silky, with five large swellings of the nectary under it; style silky near the base only, and longer in proportion than the last, though the flowers are not above half so large.

4. *E. integrifolia*. Lamarck Encycl. v. 2. 604. Willd. Sp. Pl. v. 2. 1170, excluding the synonym.—Leaves obovate, obtuse, entire, smooth; divarications of their veins glandular. Petals silky on both sides. Anthers with equal valves.

valves. Gathered by Commerfon in the ifland of Mauritius, and given by Thouin to the younger Linnæus, among the duplicates of his whole herbarium. The *leaves* are about $2\frac{1}{2}$ inches long, obovate, obtufe at each end, either quite entire, or very rarely and flightly ferrated here and there, fmooth on both fides, fhining above, paler beneath, cluftered about the points of the branches. At the origin and fubdivifions of each vein is a glandular tubercle, open at the top on the under fide of the leaf, and projecting much more on the upper, where each forms a globose red fwelling. *Foot-ftalks* thick and flout, fmooth, without glands. *Clufter*s axillary, flout, rather longer than the l-aves, with finely downy ftalks. *Flowers* fewer than in *E. oblonga*, and twice as large. *Calyx* four-cleft, broad and bluntifh. *Petals* four, filky on both fides, not very deeply three-cleft, obtufely jagged. *Antbers* with equal beardlefs valves. *Nectary* very large and wrinkled. *Germen* roundifh, hairy, like the lower half of the ftyle. *Fruit* unknown. Lamarck quotes with a doubt, and Willdenow abfolutely, the fynonym of Rumphius, which we refer, without any fcruple, to our *E. oblonga*, and which has no affinity to the fpecies before us.

5. *E. grandiflora*.—Leaves elliptic-lanceolate, undulated, obtufe, without glands. *Petals* filky. One valve of the anthers elongated, awl fhaped. Communicated to the writer of this article by the late fir G. L. Staunton, bart. who collected it in his voyage to China, but in what country is not mentioned. This is the fineft fpecies we have feen of its genus, the *flowers* being twice as large as thofe laft defcribed, and diftinguifhed from all the foregoing by the long taper points of the anthers, formed by the elongation of one of their valves. The *calyx* has five linear acute downy fegments. *Petals* five, filky on both fides, except the jagged part. The *clufter*s confift but of few flowers, with fmooth flender ftalks, and grow among the long, crowded, fmooth, crenate or undulated *leaves*, about the extremities of the branches.

6. *E. reticulata*. Leaves lanceolate, ferrated, reticulated with interbranching veins, which are glandular at their origin. *Petals* lacinated, fmooth. One valve of the anthers taper-pointed. Gathered near Port Jackson, New South Wales, by Dr. White. *Leaves* about three inches long, on fmooth fomewhat glandular foot-ftalks, lanceolate, pointed, ftrongly ferrated throughout, fmooth, fhining above, reticulated on both fides with innumerable veins, which have ufually a fmall gland, or pore, at their origin on the back of the leaf. *Clufter*s axillary, fhorter than the leaves, of eight or ten white flowers, not half fo large as the laft, with fmooth ftalks. *Calyx* in five or fix fmooth, linear-lanceolate fegments. *Petals* fmooth, three-cleft, fcarcely half-way down, finely jagged. One valve of each *anther* terminates in a flender point, at length recurved, but much fhorter than in *E. grandiflora*. *Germen* ovate, fhort, quite fmooth, as well as the furrowed annular *nectary* beneath it, and the whole *ftyle*. *Fruit* globofe, larger than a pea, blue. *Nut* curioufly tuberculated and wrinkled. This fpecies would prove a great acquisition to our greenhoufes and conservatories, and poffibly may be in fome collections already; but we have not heard of its flowering, till which it would hardly be juftly appreciated, and might be miftaken for an *Olea*, or fome unobftrufive flrub of the clafs *Pentandria*.

7. *E. dentata*, Willd. Sp. Pl. v. 2. 1169. (*E. ferratus*; Linn. Suppl. 269, but not, as Willdenow rightly remarks, Syft. Veg. ed. 13. 410. It may poffibly be what Murray meant as *E. monogynus*, Syft. Veg. ed. 14. 494. *Dicera dentata*; Forft. Gen. 40. t. 40. Prod. 41.) Leaves obovato-lanceolate, obfcurly toothed; veins glandular and pouched at their origin. *Petals* fimpfy three-lobed-

anthers with taper-pointed valves. Gathered by Forfter in New Zealand. From his fpecimen given to the younger Linnæus, though a poor one, it is eafy to perceive its clofe affinity to our *E. reticulata*, with which it agrees altogether in habit, but differs in the following particulars. The *leaves* are inclining to obovate, finely filky beneath, though not perceptibly fo till examined with a high magnifier, crenate, or flightly dentate; the bafe of their lateral veins not merely glandular, but forming a deep triangular pouch, very prominent on the upper fide. We are aware, however, that this part may, in the different fpecies, vary, according to the age of the leaf, or other circumftances, though it appears, in fome fhape or other, to be almoft univerfal in the genus before us. *Clufter*s much like thofe of the laft, but the *flowers* are effentially different, having *petals* only fimpfy three-lobed; the central lobe broader, and longer than the other two, and all of them entire and undivided, not jagged, or torn, as in all the foregoing fpecies. The *anthers* appear to us to have one of their valves awned, as in the laft; but Forfter defcribes them, from this very plant, as having two equal capillary points, or horns. A ftill greater contrariety occurs in his account of the *fruit*, which we have never feen. He defcribes and figures it as a “capfule of two cells, containing numerous feeds.” This, if true, would make the plant a moft diftinct genus from *Elæocarpus*, and the petals would ftrengthen its character. But the authority of fir J. Banks and Dr. Solander, marked by Linnæus the younger in his own copy of Forfter’s work, declares it an *Elæocarpus*, and therefore Forfter muft have fallen into an unaccountable error. The fame authority makes a new genus of the following fpecies; but, as Forfter and all his followers have called it a *Dicera*, or *Elæocarpus*, we fhall defcribe it under this laft name, in hopes that Mr. Brown, or fome fuch original obferver, will difpofe of it better.

8. *E. Dicera*. Linn. Fil. Suppl. 266. Murray Syft. Veg. ed. 14. 494. Willd. Sp. Pl. v. 2. 1170. (*Dicera ferrata*; Forft. Gen. 40. Prnd. 41.) Leaves oppofite, ovate inclining to heart-fhaped, unequally ferrated. *Clufter*s compound. *Petals* fimpfy three-lobed. *Styles* four. Native of New Zealand. The *leaves* are oppofite, (not alternate, as in all the foregoing), on flender flightly hairy ftalks, ovate, broad, pointed, unequally and fharply ferrated, thin and pliant, apparently deciduous, fmooth on both fides except the rib and veins. Small glandular pores are plentifully fcattered over the under fide, generally adjoining to the veins, but feldom at their divarications. Thefe foon become perforations with a white membranous border. *Clufter*s two, from the bafe of the prefent year’s fhoot, oppofite, much fhorter than the leaves, compound, but of few flowers, with flightly hairy ftalks, and oblong *bractææ* in the lower part. *Flowers* fmall, greenifh. *Petals* fmooth, and, as far as we can difcern, divided into three obtufe entire lobes. *Antbers* hairy; we cannot perceive any horns, or terminal bristles. *Styles* four, fmooth, recurved, with obtufe ftigmas. *Fruit*, according to Forfter, a berry with four cells, and two feeds in each cell. The ftudy of botany would be truly fatisfactory, and extremely eafy, were every genus as eafily defined as this plant is diftinguifhable from *Elæocarpus*, and even from that fpecies with which Forfter affociated it. We beg leave to remark, that it muft not, when eftablifhed as a genus, be called *Dicera*, with the characters of which, and the name thence derived, it has nothing in common, merely agreeing in its three-lobed petals only with Forfter’s real *Dicera*, which is, according to all appearance, an *Elæocarpus*. Even the fpecific name, therefore, which we have been forced to retain, for the prefent, is falfe; nor

could we adopt that of Forster, *sevrata*, as belonging to the first *Elæocarpus*, however excellent, for this plant, when established as a separate genus.

We have purposely omitted *E. integerrima* of Loureiro, being uncertain of its genus and species. Still less reason do we find to follow Retzius and Vahl in reducing *Vateria indica* of Linnæus, a plant, indeed, we have never seen, to this genus. S.

ELÆOCOCCA, from *ελαιον*, an olive, and *κοκκος*, a berry, a name given by Commerçon to a tree called in French *arbre d'huile*, or oily tree. This, Jussieu tells us, is a species of *Dryandra*, possibly the very same plant as *D. cordata*; which see.

ELÆODENDRUM, from *ελαιον*, an olive, and *δενδρον*, a tree. Jacq. jun. in Nov. Act. Helvet. v. 1. 36. Jacq. Ic. Rar. v. 1. t. 48. Murray Syst. Veg. ed. 14. 241. Schreb. 152. Willd. Sp. Pl. v. 1. 1148. Mart. Mill. Dict. v. 2. Ait. Hort. Kew. v. 1. 278. Gärtner. t. 57? (Rubentia; Juss. 378, and 452.) Class and order, *Pentandria Monogynia*. Nat. Ord. *Rhamnif.* Juss.

Gen. Ch. Cal. Perianth inferior, of five small, deep, roundish, obtuse, concave, widely spreading, permanent, segments. Cor. Petals five, roundish, obtuse, concave, widely spreading, twice as long as the calyx. Nectary a gland beneath the germen. Stam. Filaments five, awl-shaped, recurved, inserted under the nectary; anthers roundish, erect. Pist. Germen roundish, pointed, standing on the nectary; style conical, short; stigma obtuse, cloven. Peric. Drupa ovate, obtuse. Seed. Nut ovate, of two cells, with a very hard thick shell, and two oblong compressed kernels.

Eff. C. Calyx in five deep segments. Petals five. Drupa superior, ovate. Nut of two cells.

1. *E. orientale*. Jacq. as above. "Without thorns. Leaves lanceolate, acute." A shrub, native of the isles of Mauritius and Bourbon, where it is called Bois d'Olive, or Bois Rouge. The branches are spreading, and, at length, pendulous. Leaves lanceolate; those of the lower branches entire, longest, and narrowest, elegantly marked with a red nerve; the upper ones broader, crenate, with a pale nerve. In the bosoms of these last stand small stalked clusters of greenish sweet-smelling flowers. Fruit a reddish drupa, usually perfecting but one seed, from which an oil is expressed.

2. *E. Argan*. Retz. Obs. Fasc. 6. 26. Willd. Sp. Pl. v. 1. 1148. (Rhamnus pentaphyllus; Jacq. Obs. v. 2. 17. Murray Syst. Veg. ed. 14. 233. R. ficulus; Linn. Syst. Nat. v. 3. 229. R. ficulus pentaphyllus; Bocc. Sic. 43. t. 21. Raii Hist. 1626.) "Branches spinous. Leaves obovate, obtuse." Native of Sicily and Morocco, in which last country it is called Argan, and the expressed oil of the seed is used for food and other purposes. It forms a thorny bush. The leaves grow usually about five together, on long stalks. Flowers in dense clusters. Linnæus describes five barren filaments between the stamens. Fruit ovate, generally perfecting but one seed.

ELÆOMELI, in the writings of the ancient Physicians, the name of a substance, thus described by Dioscorides. In Palmyra, a country of Syria, the elæomeli, which is an oil thicker than honey, and of a sweet taste, flows from the trunk of a tree. Two cyathi of this oil, he adds, drank with a hemina of water, evacuate crude and bilious humours by stool. There was much good obtained from the giving of this medicine; but it had this remarkable effect, that those who took it were seized with a torpor, and privation of strength for a time: this was, however, of no ill consequence, but people knew of and expected it, and used

always to keep those persons awake who had taken it, and the symptoms soon went off. The same author also adds, that the oil was sometimes prepared from the buds of the tree; and such of this kind was esteemed the best that was old, thick, fatty, and not foul, or turbid. It was judged of a heating nature, and frequently applied externally to the eyes, with good effect in the cure of dimness of sight, and contributed to the cure of leprosy, and pains of the nerves. Hermolæus Barbarus has a strange conjecture in regard to the substance, which is, that it was the same with the manna mentioned in Scripture, only used in medicine instead of food: but the account which Dioscorides gives of the effects of it is a very sufficient answer to the absurdity of such an opinion. Dioscorides, lib. i. cap. 37.

ELÆON, in *Ancient Geography*, a mountain of Palestine, one stadium from Jerusalem. See *Mount of Olives*.—Also, a maritime town of Greece, on the coast of Bœotia.

ELÆOSACCHARUM, in *Pharmacy*, is the term given to a powder composed of sugar rubbed with a little essential oil, or other aromatic matter, so as to give it the fragrant smell and aromatic taste when dissolved in any watery liquid, in which the sugar promotes the solution of the essential oil.

As an example, the *elæosaccharum anisi* is composed of an ounce of white sugar candy, or, in the room of it, of the finest and driest loaf sugar, rubbed into fine powder, with 20 drops of oil of aniseed. About a dram of this, dissolved in barley-water, or any other watery liquid, may be taken for a dose, and it is a convenient and elegant way of exhibiting this essential oil.

The *elæosaccharum citri corticis*, or sugar imbued with the oil of lemon-peel, is commonly in use in confectionary, and is prepared by rubbing a lump of hard loaf sugar upon the rind of a whole lemon, by which the cells in which the flavory essential oil is contained are broken down, and the sugar absorbs it. In this way a very perfect extemporaneous lemonade may be made by the elæosaccharum of lemon peel, and the concrete acid of lemons mixed with water, when wanted, and the dry materials will keep unimpaired for any length of time.

ELÆOTHESIUM, *Ελαίοθησιον*, in *Antiquity*. See **ALIPTRERIUM**.

ELÆUS, in *Ancient Geography*, a town of Asia Minor, in Lycia.—Also, a town of the Thracian Chersonesus, on the bank of the Hellepont; now a castle on the strait of the Dardanelles.—Also, a town placed by Strabo and Pliny in the gulf of the Doride.—Also, a town of the Peloponnesus, in the Argolide. Steph. Byz.—Also, a town of Greece, in Epirus, according to Ptolemy; probably the same with that placed by Polybius in Calydoonia, a country in the vicinity of Epirus.

ELÆUSSA, an island situated upon the coast of Cilicia, near *Corycos*. It was small according to Strabo, who says, that Archelaus made it his place of residence.—Also, an island of Asia Minor, near Smyrna. Pliny and Livy, the latter of whom calls it *Elæa*.

ELAGABALUS. See **HELOGABALUS**.

ELAHAJAN, in *Geography*, a town of Arabia, in the country of Yemen; 100 miles S. E. of Amazarifdin.

ELAIS, in *Ancient Geography*, a town of Phœnicia, between Joppa, Gaza, and Tyre.

ELAITIS, a small country of Asia Minor, in the Eolide, adjoining to the territory of Pergamus, and watered by the Caius.

ELAIUS, a mountain of Arcadia, S.W. of Megalopolis, and N. of Phigalia. In this mountain Ceres had a grotto, in which sacrifices were offered to her, at which a female presided,

presided, who had for her assistant one of the priests, called "Hierothytes." The grotto was situated in the midst of a sacred wood.

ELAM, in *Scripture History*, one of the sons of Shem, and grandson of Noah, who is supposed to have settled in the southern tract beyond the Tigris or Euphrates. This is inferred not only from the authority of Scripture, in which the inhabitants of the said tract are plainly and frequently denoted by the name of Elam; but also from the testimony of heathen writers, who mention a country in this tract called Elymais, and a city of the same name. The name Elam, however, is sometimes taken in a stricter sense, as when it is distinguished from Susiana and the adjoining provinces, and sometimes in a larger sense, so as to include Susiana and other adjacent provinces. Hence Pliny and Ptolemy mention the Elymaei, as a people inhabiting on the Persian gulf; and hence the prophet Daniel speaks of Shushan, the chief city of Susiana, as lying in the province of Elam. (Dan. viii. 2.) The Elamites were a warlike people, living by rapine, and fighting with bows and arrows, (Is. xxii. 6. Jer. xliii. 35.) and they were joined to Susia, as Strabo says, and there was an ingress to them from Persia, and the Susians and Elamites are mentioned apart. (Ezra iv. 3.)

ELAM, in *Ancient Geography*, a city of Edom, on the Elanitic gulf of the Red sea. It was taken by David when he subdued the Edomites; and again, after they had recovered their liberty and independence, by Uzziah or Azariah. (2 Kings, xiv. 23.) But Rezin, king of Syria, drove the Jews out of it. Elam is by the ancients named Elana, Elalh, Elas, Alan, or Elon: and hence the gulf near the isthmus of Suez is called the Elanitic gulf. Strabo places it 1260 furlongs from Gaza. St. Jerom says, that Elam lies at the extreme of Palestine; and Procopius places it at the eastern extremity of Palestine.

ELAN, in *Geography*, a town of Russia, in the country of the Cossacks, on the Don; 68 miles S.W. of Achadialtaia.

ELAN of *Buffon*, in *Zoology*. See CERVUS *Alces*. See also TAPIR.

ELANITIC GULF. See ELAM.

ELAPHEBOLIA, *Ελαφεβόλια*, in *Antiquity*, a festival kept in honour of Diana *Ελαφεβόλος*; i. e. the Huntress, for which reason, a cake, made in form of a deer, and upon that account called *ελαφος*, was offered to her. For a farther account of it, see Pott. *Archæol. Græc.* lib. ii. cap. 20.

ELAPHEBOLION, *Ελαφεβόλιον*, in *Ancient Chronology*, the ninth month of the Athenian year. It consisted of thirty days, and answered to the latter part of our February and beginning of March. See MONTH.

It was thus called from the festival *Elaphebolia* kept in it.

ELAPHIS. See ELAPS.

ELAPHITES, in *Ancient Geography*, islands on the coast of Illyria, so called on account of the deer, with which they abounded. Pliny enumerates three of them, which he places 15 miles from Melita.

ELAPHITIS, an island of the Ionian sea, in the vicinity of Ephesus. Pliny.

ELAPHOCAMELOS, in *Zoology*, a name by which several authors have called the Peruvian camel, usually called *glama*, and employed there as a beast of burden. See CAMELUS.

ELAPHONESUS MARMOR, a name used by the ancients to express a species of marble used in statuary, and called also *Proconnesius marmor*; it was of a bluish white, variegated with slender veins of black. See PROCONNESIUS.

ELAPHONNESUS, in *Ancient Geography*, an island of the Propontide, over-against the town of Cyzicus. *Heuce* was obtained the marble to which it gave name.

ELAPHUS, a mountain of Asia, in the island of Arginussa.—Also a river of the Peloponnesus, in Arcadia, called lake *Elatum* by Pliny.—Also, a rapid stream of Arcadia, N.E. of Megalopolis.

ELAPHUS. See CERVUS.

ELAPHUSA, an island of the Ionian sea, near that of Coreyra. Pliny.

ELAPS, or ELAPHIS, by some called also *elaps*, the name of a serpent described by many authors, and met with by Bellonius in the island of Lemnos: it grows to about three feet long, and is on the back of a dark grey, with three longitudinal black lines, running from the head to the tail, and on the belly of a bright yellow, according to Aldrovandus. The people of Lemnos call it *lophiat*.

ELARABAD, or EL HARABAD, in *Geography*, a town of Spain, in the province of Seville; 20 miles N.W. of Seville.

ELASERE, a town of Arabia, in the country of Yemen; 28 miles N. of Chamir.

ELASMIS, in *Natural History*, the name of a genus of fossil bodies, of the talc class, the distinguishing characters of which are, that they are composed of small plates, in form of spangles, each of which is either single, and not farther fissile; or, if complex, fissile only to a certain degree, and that into somewhat thick laminae.

The word is derived from the Greek *ελασμος*, a *lamina*, or *plate*: the several component parts of these masses being so many small plates.

The bodies of this genus have been used to be named mica, glimmer, and cativer, by authors, in the same manner with the bractæaria. There are only four known species of this fossil.

ELASTIC, (from the Greek *ελαστις*, *impulsor*, of *ελαστις*, to *impel*, *push*, &c.) springy, viz. having the power of returning to the form from which it has been forced to deviate, or from which it is withheld. Thus a branch of a tree, the blade of a sword, &c. are said to be elastic, because if they are bent to a certain degree, and then let go, they will of themselves return to their former situation.

ELASTIC Bodies are such as will suffer their form to be altered by the application of a force or pressure, and will recover it on the removal of that pressure. In this respect all the bodies which come within our knowledge are comprehended under the following distinctions. If two bodies, when pressed towards each other, suffer an alteration of their forms, and if afterwards, on removing that pressure, they recover their original forms, then they are said to be *elastic*; if, when pressed, their forms are not altered in the least, or if their forms, when once altered by pressure, are never afterwards recovered, then the bodies are said to be *non-elastic*, and the former are called *perfectly hard*, whilst the latter are called *perfectly soft*. So that a hard body is that whose parts do not yield to any pressure or percussion; but retains its original form unaltered; a body *perfectly elastic*, is that whose parts yield to any stroke or pressure, but recover their original form as soon as the pressure is removed; and a body *perfectly soft*, is that whose parts yield to any stroke or pressure, but does not after the removal of the pressure in the least endeavour to recover its original form.

As far as we know, there do not exist in nature bodies that are perfectly hard or perfectly soft; for they all seem to be elastic in a greater or less degree. With respect to perfect elasticity, perhaps air alone may be said to possess it; for a long continued pressure does not seem to affect its elasticity. A quantity of air has been left for several years, much compressed in proper vessels, wherein there was nothing that could have any chemical action upon it; and afterwards on removing that pressure, and replacing it in the same tem-

perature, under the same barometrical altitude, as it had before; that air has been found to recover its original bulk without any perceptible difference. Most other aerial fluids, or gasses, as far as they have been tried, seem to be equally elastic; but they have not been submitted to trials equally long.

Glass, certain metals, ivory, moist woods, feathers, and a few others, are the most elastic bodies, next to the aerial fluids. Soft clay, wax mixed with oil, butter, and some other bodies, in a temperate degree of heat, come nearest to a state of perfect softness. It has long been doubted whether water had any elasticity or not; but Mr. Canton's discovery of the compressibility of water, determined the question, by shewing that by the application of force, water may be compressed in a small degree. See the article COMPRESSION.

The form of an elastic body may be altered by force, three different ways; *viz.* by compression, by distension, and by bending, which last mode, in fact, is only a combination of the other two; for when an oblong straight body is bent, those particles of it which are on the concave side are compressed, whilst those of the convex side are distended. In an elastic body the change of form is greater when the pressure is greater, and *vice versa*; but it is not always exactly proportionate to it, excepting in the case of air and other aerial fluids, the bulk of which is always inversely proportional to the compressing force.

In the recovery of their form from a state of compression, after the removal of the compressing force, elastic bodies exert a greater power at first than at last, so that the whole progress of restoration is a retarded motion. Thus, let a quantity of air be condensed in a strong metallic vessel, and then let the stop-cock, or any other small orifice, be opened, and it will be found that the air rushes out of it with great violence at first, but it slackens its power gradually, until at last it can hardly be perceived to move.

The elasticity of moist bodies, especially of long and slender forms, may be easily shewn, but even in very hard and compact bodies their elasticity may be manifested without much difficulty; for instance, let a marble slab, or a flat and smooth iron, be covered with black-lead, or with printing ink, then drop an ivory ball upon it successively from different heights, and the degree of compression will be indicated by the magnitude of the spot which will be found upon the ivory ball.

The elasticity of solids appears to be more perfect when they are subjected to a low degree of compression, than when they are exposed to a higher degree of it. Or, in other words, an elastic solid in general will recover its full original form after having been little delected from it; but not after a violent distortion; for in the latter case its parts suffer another sort of derangement, from which they are not capable of recovering. Thus, take a watch spring, bend it in a moderate degree, and afterwards on removing the band, the spring will be found to recover its original direction without any perceivable deviation; but if you bend it to a sharp angle as far as it will bear without breaking, then it will remain considerably bent, or delected from its original direction. Thus also, if a musical chord be struck gently, it will express a certain sound which is produced by its vibrations, and these vibrations are performed in consequence of its elasticity. And if it be thus repeatedly struck, it will express the same sound precisely; but if it be struck violently, then, on being struck again, it will express a lower sound, which shews that it has suffered an elongation, that is, a derangement of its parts.

Elastic bodies are either solid or fluid, and it is necessary to consider them separately on account of their possessing

some remarkable peculiar properties. The elastic solids are very numerous; for all solid bodies are more or less elastic; but some of them are elastic in so small a degree as almost to deserve the appellation of *soft*, whilst others possess that property in an eminent degree, on which account they are extremely useful in the arts, in civil economy, and, above all, in mechanics; for there is hardly a machine, wherein the elasticity of one or more solids is not essentially concerned. The principal bodies of this latter sort are certain metallic bodies, moist kinds of wood, glass, bones, ivory, dry membranes, and feathers, caout-chouc, and a few others.

The metallic bodies, in the state in which they remain after fusion, are not very elastic, but they may be rendered so, more or less, by various operations. Steel, whether perfectly hard, or of the softest temper, resists flexure with equal force, when the deviations from the natural state are small; but at a certain point of the steel, if soft, it begins to undergo an alteration of form; at another point it breaks if much hardened: but when the hardness is moderate, it is capable of a much greater curvature without either permanent alteration or fracture. In order to give it the above-mentioned degree of hardness, a piece of steel is first of all rendered quite hard and rigid by plunging it, when red or white hot, in cold water, and it is then heated to about the 500th degree of Fahrenheit's thermometer, which gives it what the workmen call a *spring temper*; for by heating it more or less, steel, that has been hardened in the above-mentioned manner, may be rendered more or less elastic. Platinum, gold, silver, copper, and steel, may be rendered elastic to a considerable degree, by hammering, or by treatments of the like nature, such as wire-drawing, milling, &c. Amongst all the other metallic bodies, there are few which will acquire any moderate degree of elasticity by any known method. Metallic alloys generally are (or they may be rendered, by hammering, milling, &c.) much more elastic than any of the simple metals which enter into their composition. Thus, brass may be rendered much more elastic than either the zinc or the copper, which are its component simple metals.

The elasticity of solids is apt to be diminished by heat; and a high temperature softens metallic bodies so as to deprive them of all the hardness and elasticity which had been given them by any of the above-mentioned means. But the presence or absence of air does not appear to affect the elasticity of solids.

Thus much relates to the bending and unbending of elastic solids; but with respect to distension and compression, it has been found by experiment, that the measure of the extension and compression of uniform elastic bodies is simply proportional to the force which occasions it, at least when the forces are comparatively small. Thus, if a weight of 100lbs. lengthened a rod of steel one hundredth of an inch, a weight of 200 would lengthen it very nearly two hundredths, and a weight of 300lbs. three hundredths. The same weights, acting in a contrary direction, would also shorten it one, two, or three hundredths respectively. The former part of this law was discovered by Dr. Hooke, and the effects appear to be analogous to those which are more easily observable in elastic fluids.

The elasticity of the same metallic body seems to be greater or less, according as that metal is more or less compact; thus, by hammering or milling, a piece of silver is rendered more elastic and more compact; for its specific gravity is thereby increased; but this is not the case with steel hardened and tempered, as appears from the following statement. The specific gravity of soft steel is 7.833; that of steel hardened in water is 7.816. Mr. Cavallo mentions the following experiment of Mr. R. Pennington, as a confirma-

tion

ELASTIC.

tion of the expansion of steel by hardening. Mr. Pennington found, that a piece of steel, which when soft measured in length 2.760 inches, after having been hardened by plunging it, when red hot, in cold water, was found to measure 2.7785 inches; and after having been let down to a blue temper, it measured 2.768 inches. Cavallo's Philosophy, vol. ii. P. 77.

The elastic fluids have a tendency to expand, when at liberty, with an elastic force which is proportional to their density, and of contracting when pressed into a space which is inversely proportional to the pressing force. It has been questioned, however, whether this rule holds good in all degrees of rarefaction or of condensation. But no limit has been found to the rarefaction or condensation of air (See the articles AIR and ATMOSPHERE.) Not only common air, but all the gasses, or permanently elastic fluids, follow the same law, as also those which are not permanently so, such as vapour, or the steam of water, and of other substances, provided they be kept in the same temperature. (See the articles GAS and PNEUMATICS.) The elastic power of these fluids (contrary to that of solids) is increased by heat, viz. by an elevation of temperature, and is diminished by cold. The bulk of common air becomes augmented of 412 thousandths, or (according to more recent experiments,) of 375 thousandths, by the heat of boiling water above that of freezing. The elastic power of steam is capable of being raised to a prodigious degree by the application of heat. Thus, in distilleries the vapour of spirit of wine has often occasioned terrible explosions; the vapours of mercury have burst an iron box; and those of nitrous acid, muriatic acid, and various others, when confined in vessels, have burst forth with great violence. In founderies a small quantity of water accidentally poured over the melted metal, has often occasioned the total destruction of the foundery. It is in consequence of this property, that the elasticity of steam has been employed with wonderful success in steam-engines; and that it has been supposed to be the cause of earthquakes, of volcanoes, &c. since, by the increase of heat, its force may be rendered superior to any obstacle.

The elastic force of steam, or the vapour of water, in different temperatures, has been examined by various philosophers, and their interesting experiments, which have been conducted different ways, do not materially disagree in their results. The principle upon which these experiments are in general conducted is as follows; though the peculiar construction and application of the apparatus may be varied at pleasure. An inverted glass siphon is connected with a close vessel containing some water, viz. one extremity of the siphon is cemented tight into the vessel, and some mercury is poured into the arched part of the siphon. Now, in a natural state, viz. when the pressure of the atmosphere only acts upon the siphon, the mercury must have the same altitude in both legs; but if the vapour of water begins to press upon the surface of the mercury in that leg which communicates with the above-mentioned vessel, then the surface of the mercury must descend in the said leg, and must rise in the opposite one; therefore the altitude of the surface of the mercury in the latter, above the level of the former, indicates, or measures, the elastic power of the steam; and hence that power is expressed in perpendicular altitudes of mercury: and when that altitude is about 29.89 inches, then the elastic force of steam is said to be equivalent to the ordinary pressure of the atmosphere, because, at a mean, the pressure of the atmosphere balances a perpendicular column of quicksilver 29.89 inches high in a common barometer. The principal results of the experiments of the Chev. de Bettancourt (De Prony's Archit.

Hydraul. vol. i. p. 557.) are concisely expressed in the following table; the first column of which contains the temperature of the water in degrees of Fahrenheit's scale; and the second contains the correspondent altitudes of mercury in inches and decimals, which the steam of the water can sustain, supporting the barometer to stand at its mean altitude, viz. 29.89.

50°	0.106
100	1.000
150	6.715
160	8.740
170	11.405
180	14.709
190	18.227
200	22.703
212	29.89

Beyond the boiling point, the Chev. de Bettancourt found that every additional 30° of heat nearly double the elastic force of steam; so that at the temperature of 242°, that elastic force is equal to twice the pressure of the atmosphere; at 272° it is equal to four times the pressure of the atmosphere; at 302° it is equal to eight times the pressure of the atmosphere, and so on.

The following table contains the results of Mr. Dalton's valuable and accurate experiments, together with those of other experimenters. The first column contains the degrees of heat according to Fahrenheit's scale; the second shews the corresponding elastic powers of steam according to Dalton; and the third contains promiscuous observations made by various philosophers.

We shall not in this article take any notice of the elastic powers of the electric fluid, of the magnetic fluid, of light, or of caloric, because the nature of those powers is merely hypothetical, and their properties will be described elsewhere.

The contemplation of the elastic powers of bodies, so common, so evident, and so useful, naturally induced philosophers to enquire into the cause of it; and accordingly various hypotheses have been formed and published in explanation of those phenomena. But as yet no satisfactory information has been obtained either from conjecture, or from the result of the numerous experiments that have been instituted expressly for that purpose. Air being one of the most elastic substances known, the speculations of philosophers were principally directed towards it; but of the hypotheses previous to Sir I. Newton's, we need not take any particular notice, since their insufficiency is too evident to need any formal refutation; it was thought, for instance, that the particles of air were like water springs coiled up, or that they were a kind of elastic fibres, &c. Newton contented himself with saying, that the phenomena of the air's elasticity could not be solved on any other supposition, but that of a repulsive power diffused all round each of its particles, which became stronger as they approached, and weaker as they receded, from each other. And he farther supposed, that this repulsive power was increased by heat.

A similar uncertainty exists with respect to the elastic power of solids; it being absolutely unknown how the particles

ticles of a solid can approach one another on one side of it, and recede from each other on the opposite side of the same body; (for this must actually take place when an elastic body is bent;) and then recover their former position when the pressure is removed. Or how the pores of the elastic body can undergo an alteration, and a subsequent restoration of their forms. The Cartesian account for it from the effort of a *materia subtilis*, to pass through pores that are too narrow for it. But as neither the mechanical action of this effort, nor the existence of their *materia subtilis* is at all known, we need not delineate their hypothesis more at large. Other philosophers have endeavoured to modify the Cartesian hypothesis by substituting an ethereal elastic fluid to the *materia subtilis*; but if the elastic property of a solid is said to depend upon the elasticity of that ether; and the cause of elasticity still remains unexplained. But the existence of this ether is merely hypothetical. The pressure of the atmosphere certainly is unconcerned in it; for the elastic power of bodies is the same either in vacuo, or in the open air. Malebranche's idea of the elasticity being caused by vortices of matter included within all bodies, is too strange to require long examination. The particles of all solid bodies have been supposed to be endowed with a sort of polarity somewhat like magnets; so that they are disposed to attract each other with their friendly poles or extremities, and to repel each other with their opposite extremities; and this indeed seems to be corroborated by the phenomena of crystallization; for the particles of almost all bodies, in the act of assuming a solid form, arrange, or endeavour to arrange, themselves in particular orders. Thus all metallic substances, after fusion, shew that tendency;—earthy and saline particles, slowly deposited from their solution in water, shew the same tendency;—the same thing takes place in sublimations; and even water, in the act of freezing, (which may be considered as a deposition from its solution in caloric,) assumes a peculiar crystallized form. This tendency, however, of the particles of bodies to arrange themselves in certain orders, will go a very short way towards elucidating the phenomena of elastic bodies; for, in the first place, it is not applicable to those bodies which become elastic by hammering, or by being put in a state of tension; and secondly, it would, even in the most favourable cases, go no further than to explain the cause of elasticity by another unintelligible property; meaning the attraction and repulsion between the friendly or unfriendly poles of the particles of bodies. See Desaguliers on the Cause of Elasticity. Phil. Transf. vol. xli. for 1739.

Upon the whole it must be acknowledged, that the cause or causes, upon which the elastic property of bodies depends, are utterly unknown. Various useful particulars have been ascertained with respect to the variety, the powers and the durability of elastic bodies; and whilst we remain satisfied with the knowledge and the application of those important facts, we must leave the investigation of their cause to future exertions.

Several other observations respecting the elastic property of bodies, will be found under the articles STEEL, SPRINGS, and TENSION.

ELASTIC Bitumen. See BITUMEN.

ELASTIC Curve. See CATENARIA.

ELASTIC Gum. See CAOUTCHOUC.

ELASTICITY, or ELASTIC Force, is that property in natural bodies, in consequence of which they are said to be elastic; it being a disposition to have their form altered by pressure, and to recover it on the removal of that pressure. See ELASTIC Bodies.

ELASTICITY of Air. }
 ELASTICITY of Fluids. } See ELASTIC Bodies.
 ELASTICITY of Solids. }
 ELASTICITY of Steam. }
 ELASTICITY of Springs. } See SPRINGS, and ELASTIC Bodies.

ELASUS, in *Ancient Geography*, a river of Asia Minor, in Bithynia, the mouth of which is placed by Ptolemy between that of the Hypius and the town of Diopolis.

ELATAS, a river of Asia Minor, in Bithynia, which discharged itself into the Euxine sea, near Parthenium.

ELATE, in *Botany*, ("so named *παρὰ τὸ ελατῶν*, from its great height; *ελατὴν οὐρανοειδέως*, Homer. Supposed to be a fir. It is however put for a palm, or perhaps rather the fruit or spathe of a palm, in Galen and Dioscorides." Martyn.) Linn. Gen. 564. Schreb. 777. Willd. Sp. Pl. v. 4. 403. Ait. Hort. Kew. v. 3. 477. Mart. Mill. Dict. v. 2. Juss. Gen. 38. Class and order, *Monocotyledon Hexandria*. Nat. Ord. *Palme*.

Gen. Ch. Male, *Cal.* Spathe of two valves; spadix branched; perianth with three teeth. *Cor.* Petals three, roundish. *Siam.* Filaments none; anthers six, sessile. Female in the same spadix, *Cal.* Spathe as above; perianth with three teeth. *Cor.* Petals three, roundish, permanent. *Pist.* Germen superior, roundish; style awl-shaped; stigmas three, *Peric.* Drupa ovate, pointed. *Seed.* Nut ovate, marked with a furrow.

Ess. Ch. Common spathe of two valves; common spadix branched. Male, Calyx three-toothed. Petals three, anthers sessile. Female, Calyx three-toothed. Petals three. Stigmas three. Drupa with one nut.

E. sylvestris. Linn. Sp. Pl. 1659. (Katou-indent; Rheede Malab. v. 3. 15. t. 22—25. Kämpf. Amen. 667.) Native of the East Indies. Described in the *Hortus Malabaricus*, where, like other palms, it is illustrated with splendid and ample figures, as of a moderate height, about 14 feet. Wood white and very hard. Leaves pinnate, spinous in their lower part; leaflets opposite, lanceolate, acute, keeled, entire. Spathe thick and coriaceous; spadix with a thick compressed base, very much branched upwards, bearing innumerable, small, greenish-white, scentless flowers. Fruit oval, the size of a sloe, sharp-pointed, blackish and shining; its pulp white, sweet, farinaceous, and astringent. Nut red, with a white bitter kernel. The natives of Malabar wear hats of the leaves. Elephants are fond of the fruit stalks.

ELATEA, in *Ancient Geography*, a town of Greece, which was only inferior to Delphi. It was situated on a plain, over which passed the Cephalus, near Amphiclia; and is said to have been founded by Elatus, who came from Arcadia to assist the Delphians against the Phlegians, in their attempt to plunder the temple. Elatea was one of the towns burned by the Persians; but though it afterwards repulsed the enterprises of the Macedonians, it was subdued by Demetrius. It continued faithful to the Macedonians when Titus Flaminus was sent from Rome to rescue the Greeks from slavery, and sustained a siege. The inhabitants were afterwards reconciled to the Romans, and recovered their liberty. Esculapius had a temple in this place, and his statue exhibited him with a long beard. Here were also a theatre and a bronze statue of Minerva, which appeared to be very ancient. Minerva Carneia had a temple situated on a craggy rock, at the distance of 20 stadia from Elatea. The goddess was represented in the attitude of combat.

ELATER, in *Entomology*, a genus of coleopterous insects. The antennæ are filiform, and situated in a groove under the head and thorax; under side of the thorax terminating

minating in an elastic spine, placed in the cavity of the abdomen.

The species of this genus are generally of an elongated and subcylindrical form, and spring to a considerable distance by means of the spine at the extremity of the thorax; when placed on the back, these insects strike the spine forcibly against the body, and by the sudden jerk turn over and recover their natural position. Many of this genus afford also a strong phosphoric light in the night-time, like the glow-worm, but of greater lustre. A number of the species are found in Europe, chiefly those of small size, the larger kinds being mostly natives of hot climates.

Species.

FLABELLICORNIS. Brown; antennæ with fan-like tuft of eight large lamina. Linn.

Native of India, and one of the largest species.

FASCICULARIS. Thorax mouse-colour; wing-cafes pale, with brown undulated streaks; antennæ with fan-like tuft. Oliv.

The antennæ are black; wing-cafes striated; body mouse-colour; legs pitchy. An American species.

SPECIOSUS. White, spotted with black. Linn.

Native of the East Indies. In this species the antennæ are short and black.

LURIDUS. Downy, cinereous; wing-cafes somewhat striated; end of the legs black. Olivier.

A large species found in Coromandel.

FOVEATUS. Black; thorax with two impressed white dots; wing-cafes striated. Fabr.

Inhabits Guinea. This is a large species, entirely black; the thorax smooth; wing-cafes immaculate.

OCULATUS. Thorax with two black ocellate spots; body black, spotted with white. Olivier.

Native of North America.

LUSCUS. Thorax with two black ocellate spots; body black and immaculate. Olivier.

Inhabits the same country as the preceding.

COECUS. Black; thorax with two ocellar spots; wing-cafes with two arched streaks, and a ferruginous dot behind. Fabr.

An African insect. The thorax is marked each side with a large oblong ferruginous ring; wing-cafes smooth.

LINEATUS. Black; thorax and wing-cafes with rufous lines. Oliv.

A Brazilian insect of large size, described by Olivier from a specimen in the museum of the late French king.

NOCTILUCUS. Sides of the thorax with a glabrous yellow spot. Oliv.

This species inhabits South America, and emits from the two glabrous spots on the thorax a vivid phosphoric light.

PHOSPHOREUS. Thorax with two yellow spots behind. Linn.

Possesses the same luminous property as the last. The species inhabits South America.

IGNITUS. Fuscous; thorax black, with yellow margin. Oliv.

Native of Cayenne.

FUSCIPES. Black; antennæ and legs brown. Oliv.

A large species found in the East Indies.

4-MACULATUS. Cinereous; thorax with four black dots; wing-cafes with two. Fabr.

Native of Africa.

RUBIGINOSUS. Blackish, spotted with grey; large spot on the wing-cafes. Fabr.

Inhabits Sierra Leone. The head of this species is black; breast black, with the sides rust-coloured; legs black.

LIGNEUS. Ferruginous; wing-cafes mucronate; antennæ black. Oliv.

Native of South America.

RUFUS. Ferruginous; head and thorax darker. Fabr.

Inhabits Germany. The head is brown; antennæ ferruginous; thorax brown, ferruginous at the sides; wing-cafes striated.

FERRUGINEUS. Thorax and wing-cafes ferruginous; body and posterior margin of the thorax black. Oliv.

Found in Europe.

PORCATUS. Brassy-green; wing-cafes with villous white grooves. Fabr.

The future of the wing-cafes black and polished. Oliv. Inhabits South America.

SULCATUS. Covered with whitish down; wing-cafes with three elevated black glabrous lines. Fabr.

Native of South America.

VIRENS. Body downy, blackish-green; antennæ black. Oliv.

Inhabits American islands.

FULGENS. Blue polished, beneath coppery; wing-cafes pointed. Oliv.

Native of India.

INEQUATUS. Black blue; thorax uneven; wing-cafes striated, red. Fabr.

The antennæ are black; thorax grooved; scutal dusky. An Italian species.

ATERRIMUS. Thorax black, and polished; wing-cafes striated and black-brown. Oliv.

An European species.

NIGER. Black-brown, and opaque; wing-cafes striated; antennæ and legs same colour. Linn.

Found in gardens in Europe.

MURINUS. Thorax dull cinereous; wing-cafes clouded with cinereous; ends of the legs rufous. Linn.

Common in gardens in Europe.

HOLOSERICUS. Dull; thorax and wing-cafes somewhat silky, and clouded with cinereous and brown. Fabr.

Inhabits Germany.

TESSELLATUS. Wing-cafes brassy, with crowded pale spots; claws red. Linn. Oliv. &c.

Found in gardens in Europe.

FASCIATUS. Thorax varied with black and pale; wing-cafes blackish, with an undulated white band. Linn.

Native of Sweden, and most other parts of Europe.

VARIUS. Black; edge of the thorax, band on the posterior part of the wing-cafes and base yellowish downy. Olivier.

Found in the vicinity of Paris.

ÆNEUS. Thorax and wing-cafes brassy; antennæ black and simple. Olivier.

An European species.

GERMANUS. Thorax and wing-cafes black blue; body and legs black. Olivier.

Native of Europe.

IMPRESSUS. Pubescent, black; thorax with an impressed dorsal line and two dots; wing-cafes striated, shining, brassy. Fabr.

Found in Sweden by Schneider.

PECTINICORNIS. Thorax and wing-cafes brassy; antennæ of the male pectinated. Linn. *Elater fuscus viridis æneus*, Geoffr.

Native of Europe.

FURCATUS. Thorax ferruginous, with a black dorsal line; wing-cafes tapering; testaceous with five black streaks; head furcated. Fabr.

Native of Europe.

FURCATUS. Thorax ferruginous, with a black dorsal line; wing-cafes tapering; testaceous with five black streaks; head furcated. Fabr.

Native of Europe.

FURCATUS. Thorax ferruginous, with a black dorsal line; wing-cafes tapering; testaceous with five black streaks; head furcated. Fabr.

Native of Europe.

FURCATUS. Thorax ferruginous, with a black dorsal line; wing-cafes tapering; testaceous with five black streaks; head furcated. Fabr.

Native of Europe.

FURCATUS. Thorax ferruginous, with a black dorsal line; wing-cafes tapering; testaceous with five black streaks; head furcated. Fabr.

Native of Europe.

Inhabits India, and is of the middle size. Described from a specimen in the British Museum.

SUTURALIS. Thorax one-toothed each side; ferruginous, with a black dorsal line; wing-cafes testaceous, with three black fillets. Fabr.

Native of Senegal.

VITTATUS. Brown; band on the wing-cafes and legs testaceous. Fabr.

The antennæ of this species is pitchy; head and thorax somewhat downy; abdomen ferruginous. Found in Germany.

CUPREUS. Coppery; upper half of the wing-cafes yellow. Olivier.

Native of Britain.

LINEARIS. Thorax rufous, in the middle brown; wing-cafes linear and testaceous. Olivier.

LIVENS. Black; thorax red and glabrous; wing-cafes testaceous. Olivier.

This, and the preceding, inhabit Europe, and are supposed by Hoppe to be varieties of the same species.

CRUCIATUS. Thorax black, with ferruginous sides; wing-cafes yellow, with black edge and cross. Fabr.

Native of Europe.

DENTICOLLIS. Linear, black; wing-cafes and thorax rufous. Fabr.

Inhabits Germany.

CASTANEUS. Thorax testaceous and pubescent; wing-cafes yellow, tipped with black; body black. Olivier.

Native of Europe.

OBSCURUS. Piceous; thorax and wing-cafes dull black. Olivier.

Found in Europe, and common in England.

FLAVIPES. Thorax dull black; wing-cafes striated and brown; legs testaceous.

Inhabits Europe.

CASTANIPES. Brown, with cinereous down; antennæ and shanks testaceous. Gmel. *Elater castaneus*, Fabr.

Native of Guadaloupe. The wing-cafes are striated.

MACULATUS. Ferruginous; wing-cafes dotted with black. Olivier.

A South American species.

FILIFORMIS. Brownish-ash, and immaculate. Fabr.

Inhabits Italy.

TRISTIS. Thorax black and polished; base of the wing-cafes and exterior margin livid. Fabr.

Lives in decayed wood in Europe.

MARGINATUS. Thorax brown; wing-cafes testaceous, edged with black. Olivier.

This, and the eleven following species, inhabit Europe.

THORACICUS. Black; thorax entirely rufous. Fabr.

RUFICOLLIS. Black; thorax, at the posterior part, red and polished. Fabr.

BRUNNEUS. Thorax rufous, black in the middle; wing-cafes and body ferruginous. Fabr.

HÆMATONES. Black; thorax pubescent and fulvous; wing-cafes striated and sanguineous. Olivier.

ELONGATUS. Black; wing-cafes testaceous, with the tips black. Fabr.

LATERALIS. Black and dusky; wing-cafes striated, with an oblong yellowish spot at the base. Fabr.

SANGUINEUS. Black; wing-cafes striated, sanguineous and immaculate. Olivier.

EPHIPPUM. Black; wing-cafes striated, sanguineous with a common dorsal black spot. Olivier.

Found on decayed pines.

PRÆVOSTUS. Black; wing-cafes striated, sanguineous with black tip. Fabr.

TESTACEUS. Black; striated; wing-cafes and legs testaceous. Fabr.

BALTEATUS. Anterior half of the wing-cafes rufous; body black. Fabr.

MELANOCEPHALUS. Sanguineous, head, thorax, dorsal line on the wing-cafes, and tips black. Olivier.

Native of Coromandel. Bankian cabinet.

ELEGANS. Black; margin of the thorax and wing-cafes, with the fillet on the latter, and the legs testaceous. Fabr.

An American species. The head is black; antennæ testaceous.

VARIABILIS. Thorax brown dusky; wing-cafes striated and testaceous. Fabr.

Native of Germany. The wing-cafes in this insect are sometimes fulvous.

PALLIPES. Brown; wing-cafes striated; antennæ and legs yellow. Fabr.

A species of small size, and inhabits Tranquebar.

STRIATUS. Black; wing-cafes brown with four pale lines. Olivier.

Native of Sweden.

RUFIPES. Black; thorax polished; wing-cafes striated; legs rufous. Fabr.

Inhabits Saxony. Hybner.

MINUTUS. Thorax deep black, and polished; wing-cafes and legs blackish. Linn.

An European species of small size.

PALLENS. Black; wing-cafes striated, and with the legs testaceous. Geoffr.

Found by Bosc in France.

LIMBATUS. Thorax black, and polished; wing-cafes testaceous. Thunberg.

Inhabits Kiel.

RIPARIUS. Brassy black; wing-cafes striated; legs rufous. Fabr.

Found by Paykull in Lapland, where it inhabits principally the banks of lakes and rivers.

ADVENA. Black; wing-cafes and legs dull cinereous. Fabr.

A small insect, found in Spain.

NITIDULUS. Wing-cafes striated with two yellow spots; antennæ and legs yellow. Fabr.

The head is black and destitute of spots; wing-cafes black. The species is a native of Cayenne.

PULCHELLUS. Head and thorax black; wing-cafes blackish with yellowish spots; legs yellow. Fabr.

Inhabits Europe in gardens.

2-GUTTATUS. Black; wing-cafes striated, with a rufous spot in the middle. Olivier.

Found in the south of France.

2-MACULATUS. Black; wing-cafes testaceous, tip black with a white dot. Olivier.

Inhabits same part of Europe as the preceding.

3-MACULATUS. Black; wing-cafes striated, testaceous, and marked with three black spots. Fabr.

Native of Saxony. Hybner.

4-MACULATUS. Above black; border of the thorax and two spots on the wing-cafes testaceous. Fabr.

Inhabits Italy.

POLITUS. Black, and polished; wing-cafes striated; anterior legs pale. Paykull.

Found on the higher mountains of Dahlikarbia, and is very small.

6-GUTTATUS. Smooth, black; wing-cafes with three white dots. Thunberg.

Native of the Cape of Good Hope.

- BUPRESTOIDES.** Cylindrical, black and immaculate; head retracted. Hybner.
- Inhabits Saxony.
- PYGMÆUS.** Dull black, with the flanks pitchy. Fabr. Native of Germany, and is found in rotten wood.
- NOTATUS.** Thorax rufous, with two black spots; wing-cafes rufous at the base, the tip black with two white spots. Olivier.
- Found in Coromandel.
- FESTIVUS.** Thorax ferruginous; wing-cafes black with two yellowish bands. Forst.
- Native of Egypt.
- TETRASTICHON.** Black spotted with yellow; wing-cafes with confluent spots; abdomen with four dots. Gmel.
- Inhabits Africa.
- DEUSTUS.** Testaceous; thorax and hind part of the wing-cafes with a branched black line. Thunberg.
- Native of Ceylon.
- CLAVICORNIS.** Green, antennæ clavated. Thunberg.
- Native of India.
- GIGANTEUS.** Depressed; wing-cafes brassy green with a yellow spot; breast and abdomen yellow. Schall.
- This and the following inhabit America.
- INDICUS.** Black; thorax convex, punctured with a fulvous margin, sinuate in the middle; wing-cafes black striate punctured. Herbt.
- VULGARIS.** Black; wing-cafes brown with punctured friz; future black; legs pale. Herbt.
- Found at Berlin, as are likewise the three following species.
- GRISEUS.** Dull grey; thorax convex; wing-cafes with punctured friz; beneath black; antennæ and legs brown. Herbt.
- CINEREUS.** Black, with hoary down; thorax convex; tarfi ferruginous. Herbt.
- EQUISETI.** Black, thorax convex; wing-cafes striated; legs yellowish. Herbt.
- MONTANUS.** Somewhat villous, shining black; base of the antennæ and flanks fulvous. Scopoli.
- Inhabits the alpine regions of Italy.
- PULLUS.** Black, polished and pubescent; wing-cafes punctured; legs chestnut brown. Müll.
- Native of Denmark.
- TUBERCULATUS.** Black, opaque; thorax with two tubercles; wing-cafes finely striated with ferruginous dots. Pontopp.
- Inhabits Denmark.
- GUINEENSIS.** Green bronzed; thorax sub-pubescent; antennæ black; wing-cafes striated. Gronov.
- Inhabits America.
- FIMBRIATUS.** Black, thorax edged with red; wing-cafes with two yellow interrupted lines at the future. Lepechin.
- Found in the deserts of Ural.
- AURATUS.** Green-gold; legs black. Gmel.
- Native of China. Drury.
- VITTATUS.** Black, wing-cafes brown with a longitudinal fulvous stripe. Geoffr.
- Native of France.
- PICEUS.** Entirely black, and polished; wing-cafes very smooth. Degeer.
- Native of America.
- LIVIDUS.** Pale reddish-brown; antennæ rufous; legs yellow-testaceous. Degeer.
- Native of America.
- PUNCTULATUS.** Dull testaceous; anterior part of the
- thorax black; wing-cafes with two irregular black spots. Degeer.
- Native of Surinam.
- SEGETIS.** Black; antennæ and tarfi brown; wing-cafes with black and brown longitudinal lines. AÆ. Holm. 1779.
- Destructive in the larva state to the roots of corn.
- Found in Sweden.
- PUNCTATUS.** Elongated, brown; thorax punctured; wing-cafes with crenate frizæ; mouth and legs ferruginous. Lefke.
- This and the following species are natives of Europe.
- PUBESCENS.** Pitchy and pubescent; wing-cafes striated; ends of the legs ferruginous. Lefke.
- VARIANS.** Brown with yellow down; legs rufous; wing-cafes finely striated with brown spots. Gmel.
- CRASSIPES.** Black, wing-cafes finely striated; thighs thick. Gmel.
- CINERASCENS.** Testaceous with cinereous down; thorax brownish; legs rufous. Gmel.
- QUADRISULCUS.** Black; wing-cafes obsoletely striated with four impressed grooves at the base; antennæ, flanks, and ends of the fore legs rusty-brown. Gmel.
- SUTURALIS.** Brown; margin of the thorax ferruginous; wing-cafes testaceous with a brown future. Gmel.
- CAPUCINUS.** Black; wing-cafes, anterior legs, and flanks testaceous. Gmel.
- SORICINUS.** Mouse-colour; thorax gibbous; wing-cafes testaceous; antennæ and legs ferruginous. Gmel.
- FUNEREUS.** Testaceous; wing-cafes striated; head brown. Gmel.
- CHALYBEUS.** Brassy-black, and polished; base of the anterior thighs and flanks rufous. Gmel.
- OBSCURUS.** Ferruginous; head and thorax brown; the latter on the posterior part with the wing-cafes and legs testaceous. Gmel.
- FULIGINOSUS.** Picceous and pubescent; antennæ, legs and wing-cafes testaceous, the latter edged with brown. Gmel.
- PUSILLUS.** Chestnut brown; three last joints of the antennæ lamellate; wing-cafes finely striated and pubescent.
- UNICOLOR.** Entirely rufous-testaceous; eyes black; thorax elongated with an impressed line in the middle. Marsh. Ent. Brit.
- This with the following species are natives of Britain, and have been recently described in the Entomologia Britannica.
- FULVUS.** Entirely ferruginous with eyes black. Marsh.
- LATERALIS.** Thorax ferruginous black; wing-cafes brassy testaceous; margin and future brownish. Marsh.
- RUGOSUS.** Dull black; thorax rugose; antennæ and legs rufous. Marsh.
- NIGRO-ÆNEUS.** Linear, beneath black; above brassy black; thorax polished. Marsh.
- ELONGATUS.** Entirely chestnut; wing-cafes striated. Marsh.
- OBOLETUS.** Brassy black; wing-cafes obsoletely striated; antennæ testaceous. Marsh.
- CYANEUS.** Entirely purple-blue minutely dotted; wing-cafes striated. Marsh.
- NIGRINUS.** Black; thorax punctured; wing-cafes striate downy. Marsh.
- ELATERIUM,** in Botany, (*ἑλάτηριον*, or wild cucumber, of the ancient Greek writers, from *ἑλάω*, to urge, force, or impel, is certainly *Momordica Elaterium* of Linæus, well characterized by its fruit Diolcorides; but the word being unoccupied as a generic name, was adopted by Jacquin for this American genus, whose elastic fruit agrees in that

respect with the original *καρχίνιον*.) Jacq. Amer. 241. Linn. Gen. 477. Schreb. 619. Willd. Sp. Pl. v. 4. 192. Juss. 394. Clafs and order, *Monocia Monandria*, or rather perhaps *Monocia Monadelphica*. Nat. Ord. *Cucurbitacea*, Linn. Juss.

Gen. Ch. Male, *Cal.* none. *Cor.* of one petal, falver-shaped; tube cylindrical, straight, abrupt at the base; limb in five lanceolate, acute, equal, horizontal segments, whose edges are deflexed so as nearly to meet underneath, and whose intermediate notches are each furnished with a little tooth. *Stam.* Filaments simple, columnar, erect, rather shorter than the tube of the corolla; and either linear, continued in a five-fold zig-zag line, so as to make a ring crowning the filament. Female, *Cal.* none. *Cor.* as in the male. *Pist.* Germen inferior, roundish, somewhat incurved, clothed with soft prickles; style columnar, swelling upwards, inclosed within the tube; stigma capitate, large, cylindrical, convex at the summit. *Peric.* Capsule coriaceous, prickly, kidney-shaped, slightly compressed, of one cell and two unequal valves, of one cell filled with pulp; the dorsal valve is furnished with a highly elastic appendage, bearing the seeds, which it scatters at the slightest touch. *Seeds* several, about 18, imbricated, ovate, angular, flattened.

Ess. Ch. Male, *Calyx* none. *Corolla* falver-shaped. Female, *Calyx* none. *Corolla* falver-shaped. *Capsule* inferior, prickly, elastic, of one cell and two unequal valves. *Seeds* numerous, imbedded in pulp.

1. *E. carthagenense*. Jacq. Amer. 241. t. 154. Linn. Sp. Pl. 1375. "Leaves heart-shaped, angular."—Found on the summit of a hill at Carthæna by Jacquin, the only botanist who seems to have seen this plant, and from whom Linnæus adopted it. The root is supposed to be annual. *Stems* diffuse, or climbing by means of tendrils so as to cover all the neighbouring bushes, round, smooth, herbaceous. *Leaves* alternate, stalked, five-angular, heart-shaped, finely serrated; roughish above, smooth beneath. *Flower stalks* axillary, in pairs; one branched, bearing several male flowers; the other simple, with one female flower. *Flowers* white, fragrant in an evening only, not unlike those of Jasmine. It blossoms in October and November, soon ripening its fruit, whose pulp is watery, with the scent of a cucumber.

2. *E. trifoliatum*. Linn. Mant. 123. (*Sicyos foliis ternatis*; Gron. Virg. part 2. 191. "Leaves three-lobed, cut.")—Gathered by Clayton in Virginia. He describes it as a small procumbent plant like a *Convolvulus*. *Leaves* on long stalks, three-lobed, cut, especially the side lobes. *Flowers* white, small, with a five-leaved hairy calyx, which, if true, does not agree with the generic character. *Capsule* brown, slightly hairy, of one cell and two valves bursting elastically when ripe. *Seeds* one or two, ovate. The elastic capsule induced Linnæus to remove this plant from his *Sicyos angulata*, with which he and others had confounded it, to the present genus. He does not appear to have seen any specimens, and he seems to mistake Clayton's description with respect to the leaves being ternate; we presume it rather expresses their being three-lobed.

ELATERIUM is the inspissated juice of the wild cucumber, (*MOMORDICA ELATERIUM*), an extremely violent purgative, which is sometimes employed in medicine, in dropsies, and other visceral disorders. The juice of the momordica has an unpleasant smell, and a nauseous bitter taste; on standing some hours it deposits a thick fecula. According to Baume, 23lbs. of the fruit will yield as much juice as when slowly evaporated to the proper consistence will produce 6½lbs. of the extract or elaterium. The dose of this powerful medicine is from one to three grains, and it generally operates violently.

ELATINE, in Botany, (*ελατιν*) of the Greek writers,

is thought to have been so called from *ελατιν*, a pine, to which neither its form nor qualities, as mentioned by Dioscorides at least, seem to have any reference. Linnæus, however, took advantage of this allusion to apply the name to what Buxbaum had called *Potamoptypis*, or Pond Pine, on account of its aspect.) Linn. Gen. 198. Schreb. 267. Willd. Sp. Pl. v. 2. 472. Sm. Fl. Brit. 433. Mart. Mill. Dict. v. 2. Juss. 307. Gærtn. t. 112. (*Alfinastrum*; Vaill. Par. 5. t. 1. f. 6.) Clafs and order, *Ötandria Tetragynia*. Nat. Ord. *Inundata*, Linn. *Caryophyllæz*, Juss.

Gen. Ch. *Cal.* Perianth of four roundish, flat, permanent leaves. *Cor.* Petals four, ovate, obtuse, sessile, spreading, about the size of the calyx-leaves. *Stam.* Filaments eight, the length of the corolla; anthers simple. *Pist.* Germen superior, large, globose, a little depressed; styles four, erect, parallel, as long as the stamens; stigmas simple. *Peric.* Capsule globose, rather depressed, large, of four cells and four valves, the partitions fixed in the central column, opposite to each suture. *Seeds* numerous, oblong, curved, angular, inserted into the column.

Obs. Sometimes the flowers are only three-cleft, with fix flaments.

Ess. Ch. *Calyx* of three or four leaves. *Petals* three or four. *Capsule* superior, of three or four cells, and as many valves; the partitions opposite to the fissures. *Seeds* many. *Sm. Engl. Bot.* 955.

1. *E. Hydropteris*. Linn. Sp. Pl. 527. Fl. Lapp. ed. 2. 124. Oed. in Fl. Dan. t. 156. Engl. Bot. t. 955. (*Alfinastrum fernyfolium*, flore roseo tripetalo, et flore albo tetrapetalo; Vaill. Par. 5. t. 2. f. 1. 2. *Hydropiper*; Buxb. Cent. 2. 36. t. 37. f. 3.) *Leaves* in pairs.—Found in sandy inundated places throughout Europe, though not observed in Britain till the Rev. Mr. Williams found it in August 1798, on the eastern shore of Bomere pool, near Coudover, Shropshire. Perhaps its close resemblance to *Montia fontana* may often have caused it to be overlooked.

The root is annual, white, and fibrous. *Herb* smooth in every part, generally under water, even the flowers, which remain closed to shelter the flaments. When out of the water, it appears from Vaillant that the petals assume a red tint. Luxuriant flowers are four-cleft, others three-cleft. The stems are procumbent, and take root as they go. *Leaves* opposite, spatulate, entire. *Flowers* on solitary, simple, axillary stalks.

2. *E. Alfinastrum*. Linn. Sp. Pl. 527. Sm. Fl. Brit. 433. Huds. 173. (*Alfinastrum gratiolæ folio*; Tournef. Inf. 244. Dill. in Raii Syn. 346. A. galli folio; Vaill. Par. 6. t. 1. f. 6.) *Leaves* whorled.—Found in France, Switzerland, and Germany, growing in ditches and ponds. Its having been admitted into our British Floras, from whence it must now be excluded, arose from a most unaccountable error of Dillenius, whose memory, it could not be his judgment, misled him so far as to take *Centunculus minimus* for this plant, as his herbarium shews. The real *E. Alfinastrum* is a span or more in height, with hollow, round, straight, leafy stems, branched only at the base. *Leaves* whorled; those under water linear, narrow, about twice in a whorl; those above the surface four, ovate, entire, ribbed. *Flowers* axillary, solitary, sessile, white. It blossoms in August, and is perennial.

What professor Leche found in ditches, near Abo, in Finland, and which Linnæus took for this plant, see Fl. Succ. ed. 2. 133, is the *Hippuris tetraphylla*, Linn. Suppl. 81, as appears from his herbarium; where also we learn that Pallas made the same mistake in Kämtschatka. This may almost excuse the above error of Dillenius. Retzius does

not appear aware of his *Hippuris lanceolata*, fasc. 3. t. 1, being the *tetraphylla* of Linnaeus, any more than the *Elatine* *Alfnsbrum* of Fl. Suec. which last circumstance, one would think, might have occurred to this generally acute writer, when he was mentioning the similitude of the two plants being such as to render a description of his new *Hippuris* superfluous.

ELATINE, in *Medicine*, has been greatly recommended as an aperient, resolvent, and vulnerary. Its simple water has been used for the same purposes, though it retains very little of the virtues of the plant. The infusion is much better, and the expressed juice preferable still. It has been praised by some in leprous and scrofulous cases; also externally for cancerous and other eating ulcers. An ointment was made of it for these purposes. At present, however, it is very little used.

A combination of its active matter with honey, prepared by boiling four pints of the deperated juice with four pounds of clarified honey, was sometimes kept in the shop.

ELATITES, FIRE-STONE, in *Natural History*, a name given by authors to that sort of petrified wood which shows the lineaments of the fir-tree wood, and has been originally either that or some wood of a like kind.

ELATITES was also a name used by the ancients for an iron ore, esteemed a species of hematites: it was of a yellowish white colour, and was more usually called xanthus.

ELATIUM, in *Ancient Geography*, a town of Decapolis, between Jordan to the west and Philadelphia to the east, towards the confines of Arabia Deserta; 60 miles from Damas and as far from Petra. Pliney mentions this town.

ELATMA, in *Geography*, a town of Russia, in the government of Tambou, on the Oca; 132 miles N. of Tambou. N. lat. 55° 2'. E. long. 41° 42'.

ELATOSTEMA, in *Botany*, from *elatos*, elastic, and *stema*, the stem of a plant. Forst. Gen. t. 53. Juss. 403. (Procris; Commenfon MSS. Juss. 403. Willd Sp. Pl. v. 4. 344. Poiret in Lamarck Encycl. v. 5. 627. tab. 763. f. 2?) A genus of plants referred by subsequent writers to *Dorstenia*, for Justieu and Willdenow were not aware of *Procris* being precisely the same genus as Forster's *Elatostema*. How truly all the species comprized under both are really *Dorstenie*, we have not materials sufficient to determine. Their habit is more caulescent than the original ones, leaves undivided, lanceolate, or oblong, alternate, on short footstalks. Flowers in lateral round heads, having in one species, *Procris cephalata* Willd. 346, evidently the habit, structure, and seeds of a *Dorstenia*, but in others, *P. sagifolia* and *maculata*, more the appearance of a compound flower with an imbricated calyx, and scales between the florets. These latter species, however, do not agree with either Forster's or Commenfon's generic description. Poiret has referred to *Procris* several plants still more generically distinct.

ELATRIA, in *Ancient Geography*, a town of Greece, in Thesprotia, a country of Epirus, situated at the mouth of the Aphas, in the lake of Ambracia.

ELATUM, a river of Greece, in Arcadia; the *Elaphus* of Pausanias.

ELATUS, a mountain of the island of Cephalonia. Pliney.

ELAVER, a river of Gaul; the modern Allier.

ELAY, in *Geography*, a river of Wales, in the county of Glamorgan, which runs into the Brittol channel, near Penarth point.

ELBA, *ELBE*, *Elbe*, an island of Italy, which, with the neighbouring islands of Capraja, La Pianosa, Palmarola, and Monte Christo, was added to the territory of France on the 26th of August, 1802, by right of conquest,

and forms now a separate department, administered by a commissary general and a council of administration.

The island of Elba is situated in the Mediterranean sea, between the Etrurian or Tuscan coast, from which it is separated by a channel, 20 kilometres, or about 12 English miles in breadth, and the island of Corsica, which is 50 kilometres, or about 30 English miles distant from its shore. It shape is nearly triangular; its territorial extent 95 kilometres, or about 20 leagues; and its chief towns, are Porto Ferrajo, Porto Longone, Capolibrì, Rio, Marciana, and Campo.

The climate of the island of Elba is milder than that of Etruria or Tuscany, on account of the sea breezes, which moderate its heat; and such is the influence of this climate, that although but 12 miles distant from the Tuscan coast, the soil produces plants and fruits which do not grow in Tuscany.

There is no river in the island, but it has a considerable number of springs. The Rio is the principal brook by which it is irrigated; it has its source near the town of Rio, flows through the celebrated mine also known by the same name, and after a course of a kilometre runs into the sea. It is chiefly remarkable for the abundance of its waters; in its short progress it sets eighteen different mills in motion, and what is very extraordinary, the volume of its waters is increased and diminished with the length of the days; at the summer solstice, when other brooks are almost dried up, its stream is considerable.

The island of Elba is covered with high mountains, which offer a rich and spontaneous vegetation of multifarious odiferous plants and shrubs, by which the atmosphere is perfumed. There are, however, a few extensive plains, of which that of Lacona is the principal. It opens a wide field to agricultural speculations, as the least labour would render it uncommonly fertile.

Grapes, which are plentiful, are converted into a wine resembling that of Spain; there is also a great abundance of figs and olives, Turkey corn, pease, and beans, but little wheat. The trees which thrive best are the cork tree, the green oak, the lemon tree, the orange tree, and all the fruit trees of Europe except the apple tree; it is, however, supposed that the latter would thrive in the northern part of the mountains. Melons, particularly those known by the name of *Pastèques*, are excellent.

Notwithstanding the beauty of its climate and the fertility of its soil, the island of Elba is mostly unimproved by tillage. Pastures are scarce; there are no cattle reared, and there are very few horses and mules. Wood, owing to the carelessness of the inhabitants, is likewise scarce; pines, oaks, and other trees, would grow in the mountains, which are covered with a luxurious vegetation of various shrubs. And, notwithstanding the many flowers and odiferous plants that cover the island, there are no bees. At the foot of the town of Porto Ferrajo is a salt work, but its harbour has a dangerous entrance; many more might be established in other parts of the island.

Nature appears to have heap'd together all the treasures of mineralogy in the island of Elba. It has mines of gold, silver, copper, iron, magnet, lead, sulphur, vitriol, and quarries of marble, granite, slate, and others. But it is its iron, and chiefly the iron mine of Rio, which constitutes its principal riches. According to letters written at Vienna in 1780, on the natural history of the island of Elba, by Mr. Henry Koellin to the Count de Borch, this small island supplied Corsica, Genoa, Tuscany, the Papal dominions, and part of the kingdom of Naples, with iron from the single mine of Rio, which afforded the prince of Piombino, to whom the

island belonged at that time, an annual revenue of nearly 50,000 crowns. The mines are now farmed, and produce annually 500,000 livres to the French government.

The most important branch of industry next to the mines is the Tunny fishery, which is extremely productive; and as its vessels are now protected against the Algerine pirates by the French flag, the commerce of the island must be benefited by this circumstance; its situation renders it, at least, a most important station for the French trade in general.

The whole population of the island of Elba amounts to 12,250 individuals; the electoral assembly is composed of 60 members. It contains three cantons, Porto Longone, Porto Ferrajo, and Marciana, and seven communes. Porto Longone is so called from the harbour, which is long and narrow, and is divided into the Upper and Lower Towns. The latter lies on the shore of the harbour, and the former contains a citadel on the summit of the hill. There is at Porto Ferrajo a court of justice, consisting of seven judges. Near this town, on a steep rock, stands the tower of Voltarajo, which can be reduced only by famine.

During the war, which ended at the peace of Amiens, the island of Elba was a long time occupied by the English; who, from this station, successfully annoyed the trade of their enemies in the Mediterranean sea by their numerous cruizers. Herbin, *Satitigue de la France*.

ELBE, a small town of France, in the department of Lot and Garonne; six miles W. of Villefranche.

ELBE, in Latin *Albis*, and in the Bohemian language *Labe*, is one of the most considerable and important rivers in Germany. It has its source on the confines of Bohemia and Silesia, in that part of the Carpathian mountains which is called the *Riesengebürges*, or the Giants' Mountain, where the Oder and the Vistula likewise take their rise at an inconsiderable distance from each other. Its course is at first through Bohemia, where it receives the river Moldau above Meinick. It begins to be navigable at Leutmeritz, above which place it receives the river Eger, which comes from the Fichtelberg in Franconia. Leaving Bohemia, the Elbe enters the kingdom of Saxony, passes by Dresden, and in the principality of Anhalt Dessau receives the Mulde not far from Dessau; in the duchy of Magdeburg, it receives the Saale above Barby, flows afterwards through part of the German dominions of the king of Prussia, where, near Werben, not far from Havelberg, it receives the Havel, which communicates with the Oder by means of the Spree, through Berlin. The Elbe then pursues its course through the confines of the duchies of Lüneburg and Mecklenburg Schwerin, where it receives the Elmenau, up to Hamburg, in the neighbourhood of which it divides itself into several branches that form several islands: but uniting its waters again below Hamburg, it divides Hanover from Holstein, receives the Stör below Glückstadt, and about one hundred English miles farther runs at last into the North sea, not far from the island of Heligeland or Heligoland. At its mouth, as well as in its course, particularly below Cuxhaven, which may be considered as the port of Hamburg, the Elbe forms several small islands, and has many sand banks, which render its navigation extremely difficult.

The principal places whose commerce is animated by the Elbe, are Dresden, Lauenburg, Magdeburg, and Hamburg. The inland commerce of that great emporium of Germany by means of the Elbe was very considerable, before the occupation of Hanover by the French caused that fine river to be blockaded by an English squadron; it was, indeed, more extensive than the commerce of the Rhine, or of any

other river in Europe, although it laboured under several restrictions and inconveniences, arising from an excessive number of tolls, extravagantly high duties, and absurd staple privileges, such as that of Magdeburg, where all vessels, not under Prussian colours, or not laden with Prussian produce, were obliged to unload, and to re-ship their goods in Prussian vessels, three hundred of which were employed by Magdeburg alone; and besides this detention and loss of time, goods sent, for instance, from Pirna in Saxony to Hamburg had not less than thirty-two tolls to pay. Well might an old English chronicler style the German tolls "Mira infania Germanorum." (Wicke's Chron. ad annum, 1260.) How far the newly created kingdom of Westphalia, through which the Elbe now flows in its progress from the kingdom of Saxony towards Hamburg, is likely to be influenced by more liberal maxims of commerce, and whether the circumstance of both the new kings being members of the confederacy of the Rhine will lead to the adoption of less confined views of policy, it is impossible to conjecture; but the Elbe certainly appears destined to convey the principal commerce of Europe at some future period. The inland communication from Hamburg, by means of this river, extends from the western and northern extremity of Germany, through the kingdoms of Westphalia and Prussia, to Austria, and the interior of Russia, and even down the Dnieper to the Black sea.

Many years ago, a canal was projected between the Elbe and the Weser, to transport goods from Bremen to Stade, and so on to Hamburg. A sluice was built at Stade: but from the nature of the soil the canal itself was found impracticable. However, the Elbe might easily be made to communicate with the Danube by the Moldau, which again might be connected with the Rhine, by either the Mayn or the Necker. (Oddy's European Commerce).

ELBE, a river of Germany, in the circle of the Upper Rhine, which runs into the Eder, two miles S.S.E. of Fritzlar, in the county of Waldeck.

ELBEDOUÏ, a town of Arabia, in the county of Yemen; 14 miles S. of Abu Arich.

ELBENAU, a small town of the kingdom of Saxony, in that part which was formerly called the Electoral circle, (Caurkocis) with a royal hunting seat. Together with the town of Gommern it constituted, in ancient times, the burgraviate of Magdeburg, which was a distinct province from the bishopric of Magdeburg, which was secularized in favour of the electors of Brandenburg, by the title of a duchy, and now forms a valuable part of the new kingdom of Westphalia.

ELBERFELD, or ELVERFELD, a town of Germany, in the grand duchy of Berg, which, since the late accession of Joachim Murat to the throne of Naples, has been annexed to France. It is situated on the Wipper, 18 miles E. of Duffeldorf. The new town, which is called Gemark, is remarkable for the beauty of its buildings. Its principal manufactures, which are very flourishing, are those of linen cloth, thread, and thimbles. There are also some coal mines in its neighbourhood. Elberfeld counts 8700 inhabitants. It has 2500 weaver-looms, and 100 bleaching grounds; these last alone employ 700 individuals.

ELBERT, a county of America, in the Upper district of Georgia, between Tuglo and Broad rivers; the S.E. corner of the county is at their confluence, where stands the town of Peterburgh. On the N.W. it is bounded by Franklin county. It is divided into 17 townships, and contains 10,094 inhabitants, of whom 2816 are slaves.

ELBERTON, a town in the above county, in which are the

the post-office and the seat of justice; 23 miles N.W. of Petersburg.—Also, a post town of Ellingham county, in the state of Georgia, on the N.E. bank of Ogeechee river; about 19 miles W. of Ebenezer, 48 N.W. of Savannah, and 55 S.E. of Louisville.

ELBEUF, a small town of France, in the department of the Lower Seine, chief place of a canton in the district of Rouen, situated on the river Seine, 12 miles south of Rouen, and 78 miles N.W. of Paris, with a population of 5400 individuals. It is particularly remarkable for its manufacture of woollen cloth, which was established here under the administration of Colbert in 1666 by two Protestant gentlemen of the name of Le Monnier and Le Coultre, who, during the religious persecutions, carried this manufacture to Holland. They were, however, replaced by Catholic manufacturers; the number of whom, in 1686, amounted to 28.

In 1687 Elbeuf made 3443 pieces of cloth.

1696	-	-	5538
1750	-	-	18,771
1768	-	-	only 14,059

And this manufacture has declined ever since, and its decline has been much more sensible after the revolution of 1789. The canton of Elbeuf contains eight communes, and 16,096 inhabitants, upon a territorial extent of 50 kilometres.—Also, a small town of France, in the department of Eure, 18 miles N. of Andely, with a fine castle.

ELBING, a considerable town of Prussia, in the circle of Marienburg, on the river Elbing, near a bay of the Baltic sea, called the Frische Hauff. N. lat. $54^{\circ} 12'$. E. long. 20° , in a very fertile district; 36 miles S.E. of Dantzick, 120 miles N. by W. of Warsaw. Its origin dates from the year 1239; its first inhabitants were a colony from Lubeck; and Elbing was in the Hanseatic league till the end of the 16th century. The fortifications have been demolished since the town was ceded to Prussia by Poland, in the year 1772. The population in 1802 amounted to 19,200 individuals, without the garrison, but has probably been reduced by the disastrous war which terminated in the peace of Tilsit in 1807.

The trade of Elbing has always been considerable. From 1577 to 1660, there was an English trading society at Elbing, which owed its dissolution to political circumstances. But it is chiefly from the year 1772, that its commercial importance had been progressively increasing till 1806. Capital warehouses have been erected in an island formed by the river Elbing and a moat. The corn warehouses alone hold 30,000 lasts; and the custom-house, which is in the same situation, keeps all goods that arrive by sea from Pillau, at a moderate rent, till they are disposed of. At the end of 1803, the shipping consisted of 7110 tons, besides 50 coasters and 25 lighters, which take cargoes to the ships loading at Pillau, distant about 50 miles. Vessels of 100 tons may come up to Elbing and load the greatest part of their cargoes at the warehouses. But the trade with fir timber, deals, and staves, is trifling, in comparison with that of Dantzick. Flax is the principal article of exportation. Elbing has also a share of the transit trade to the Russian and Austrian provinces.

Elbing has an extensive manufacture of soap, one of tobacco, two of woad-ashes, two of starch, a sugar-house, and a saw-mill for cutting deals. The district of Elbing includes ten parishes. Oddy's European Commerce.

ELBINGERODE, or **EVELLINGERODE**, *Elvengerode*, *Elgerode*, a handsome town of Germany, in the principality of Grubenhagen, which formed part of the electorate of Hanover, is situated on a rivulet called the Bode, or Bude, in the Hercynian forest, in German the Hartz; 7 miles of

Blankenburg, 5 of Wernigerode, and 15 S.W. of Halberstadt. Its origin dates from the year 1189: but the oldest record which mentions Elbingerode as a walled town is of the year 1571. The walls, however, have long ago been destroyed. The number of houses, which are mostly new and handsome, having been almost all re-built, after a dreadful conflagration that consumed the town on the 17th of May, 1753, amounts to 400. It contains 2500 inhabitants.

The district of Elbingerode is nearly ten miles long, and five miles broad. It abounds with wood and excellent pastures; but is chiefly remarkable for its iron mines, two warm springs, quarries of marble and slate, and ruins of four ancient castles, one of which, called the Königsburg, was a hunting seat of the kings and emperors of Germany of the house of Saxony.

ELBOCORIS, or **ELCORIS**, a town of Spain, in the interior of Lusitania.

ELBONTIS, a town of Africa, between Egypt and Cyrene.

ELBOW, in *Anatomy*, is the joint formed between the humerus, radius, and ulna. See **EXTREMITIES**.

Elbow is also used by the architects, masons, &c. for an obtuse angle of a wall, building, or road, which diverts it from its right line.

Elbow in the Havese, in *Sea Language*, denotes a particular twist in the cables, by which a ship is moored.

Elbow Island, in *Geography*, an island in the north-western part of Lake Superior, in Upper Canada, which lies to the N.E. of the grand Portage, and W. of Isle Maurepas.

ELBUGA, a river of Russia, in the government of Caucasus, which runs into the Kagalinak; 12 miles E. of Azoph.

ELBURG, or **ELBURCH**, a town of Guelderland, seated on the eastern shore of the Zuyder sea; 34 miles N.N.E. of Utrecht. N. lat. $52^{\circ} 28'$. E. long. $5^{\circ} 25'$.

ELCESAITES, **HELCESAITES**, or *Elcesaites*, as Theodoret calls them, ancient heretics, thus denominated from their great prophet Elcesai.

This Elcesai, by others called Elxai, was a Jew, attached to the worship of one god, and full of veneration for Moses, who lived in the time of Trajan, and corrupted the religion of his ancestors, by blending with it a multitude of fictions drawn from the oriental philosophy; pretending also, after the example of the Essenes, to give a rational explication of the law of Moses, he reduced it to a mere allegory. He is likewise said to have adopted the sentiments of the Ebionites, with regard to Jesus Christ; though he altered and reformed them in some things, to denominate himself the author of a sect.

His fundamental doctrines were, that Jesus Christ, who was born from the beginning of the world, had appeared from time to time under diverse bodies; that he was a celestial power, or virtue, called *the Christ*, whereof the Holy Spirit was sister (note the Hebrew word for *spirit* is feminine); and that both of them had descended into Jesus, the son of Mary, who was clothed with a corporeal appearance, but not with a real body.

The Elcesaites, according to St. Epiphanius, were by some also called *Sampsicans*, from the Hebrew word *samses, sun*. Scaliger was notoriously mistaken, in holding that Elxai was no more than Elsai, or Essene; on which supposition he made the Elcesaites the same with the sect of Essenes, which is contrary to all antiquity.

Origen makes mention of the Elcesaites, in one of his homilies, as a heresy newly risen. The retainers hereto, says he, do not admit all the books of the canon, but only some

some of them; they allow some passages out of the Old Testament and the Evangelists, but reject all the Epistles of St. Paul. Add, that they have produced a book, which they pretend descended to them from heaven; and maintain, that whoever perform what is enjoined therein, shall obtain pardon of all their sins. See Eusebius, Hist. hb. vi. cap. 33, who remarks, that this heresy became extinct almost as soon as it arose.

St. Epiphanius is very full on the subject of this sect. Her. 19, where he observes, that Elxai was a Jew by birth; and that, not being able to live according to the law of Moses, he invented new opinions, and gained followers. He was a professed enemy to virginity, and obliged all, who followed his doctrine, to marry. He tutored them to hypocrisy in times of persecution; pretending it was lawful to adore idols, provided the heart had no share therein.

Some have doubted whether the Elcesaites should be reckoned among the Christian, or Jewish sects; for though they acknowledged Christ as a great king, it is not certain whether they meant Jesus Christ, or some other pretended Messiah.

ELCESIUM, in *Ancient Geography*, a town of Sicily. Ptolemy.

ELCHE, in *Geography*, a town of Spain, in the province of Valencia, in the midst of plantains and olive-trees. The palm-trees, about the month of May, are loaded with fruit, in pendant clusters, which, forming a complete circle, resemble, when ripe, a crown of gold, with a plume of feathers rising from its centre. Each cluster, says Mr. Townsend, (*Travels*, vol. iii.) would, to appearance, nearly fill a bushel, and is said to weigh from six to ten arrobas. Elche is divided into three parishes, and contains 17,400 persons. The great church is a beautiful building, with a majestic dome, and is elegantly fitted up. This city, which was the "Ilici" of the Romans, and may not be improperly denominated the "city of dates," from the palms that surround it, belongs to the count of Aldamira. It is governed by his corregidor, four regidores, as many deputies from the commons, two alcaldes, and one alguazil mayor. The ducal palace is situated on the brink of a deep ravine, and bears the marks of the most remote antiquity. It was recovered from the Moors by Peter, surnamed the Cruel, A. D. 1363. Elche is distant four or five leagues S.W. from Alicante. Its environs abound in wine and fruit.

ELCHINGEN, originally *Aichingen*, formerly a rich imperial abbey of Germany, on a high mountain close by the Danube, surrounded on all sides by the territory of Ulm. At the peace of Luneville it was secularized and given as an indemnity to the king of Bavaria. It is from this place that the French marshal Ney takes his new title of duke.

ELCOSIS, or HELCOSIS, from *ἔλκος*, an ulcer, sometimes also *elecoma*, or *helcoma*, terms synonymous with *exulceratio*. Sauvages uses the word *Elcosis* as the generic title; and the ulcerations which occur in small-pox, syphilis, scrofula, &c. constitute the species. See Nosol. M. th. class X. gen. 27.

ELDA, in *Geography*, a town of Spain, in the province of Valencia; 20 miles W N.W. of Alicante.

ELDAGSEN, or ELDAGSHAUSEN, a town of Germany, in the circle of Lower Saxony, and principality of Calenberg; 16 miles N.E. of Hameln.

ELDANA, in *Ancient Geography*, a town of India, on the other side of the Ganges.—Also, a town of Spain, in the Tarragonese territory, in the country of the Vacczans. Ptolemy.

ELDEN HOLE, in *Geology*, a natural cavern in Der-

byshire, about three miles from Castleton, and four from Buxton, is justly considered one of the wonders in the peak. And a writer, who gives a description of it from an actual survey, near a century ago, properly observes, "would former writers have been content with one wonder instead of seven, it would have done more honour to the peak, than the adding the six imaginary miracles to it, that had nothing in them; and which really depreciated the whole." Indeed, the character anciently given of three will all apply to this;

"Mira alto pecco tria fant, barathrum, specus, antrum."

And it may be added, if a modern traveller, who has given an account of this geological curiosity, had not been imposed upon by the description of those fond of the marvellous, his work would not have been the less valued by those who have too much good sense to become the dupes of credulity. Elden Hole is a large, deep, perpendicular chasm in the limestone strata of a hill, which forms part of the elevation termed the peak; and from the difficulty which has attended the attempts to ascertain its real depth, and the variation in the accounts, it has been reckoned unfathomable, or, what is vulgarly termed, without a bottom. From the bushes, brambles, and projecting masses of stone which encumber the margin of the aperture, it is not easy to obtain a proper station to plumb it with accuracy. More than a century ago, Mr. Cotton affirmed, that, after letting down 884 yards, he was unable to reach the bottom; the plummet still drew, and the line, when drawn up, appeared to have passed through deep water. According to this statement, it must have been near half a mile in depth. Another gentleman let down a line 933 yards, without discovering a bottom. From a probable supposition, that in all these instances the plummet might have been uselessly used, recourse was had to another mode of discovering its depth. Stones were severally let fall into the cavern, and the time, as accurately observed from the delivery out of the hand, till the reverberated sound from the bottom of the abyss reached the ear, was 9' 11" 10". Allowing, therefore, with Dr. Halley, that ponderous bodies fall sixteen feet and a half in one minute, and the velocity of sound to be 1142 feet per second, it will follow, from the compound equation of the descending body, and the ascending sound, that the depth of the cavern is 1266 feet, or 422 yards. Dr. Snort again tried to ascertain the truth of this result, by plumbing from seven different stations, from six of which he could only sink the plummet 192 yards; but from the seventh, after repeated trials, it sunk 295 yards, forty of which the line appeared to have passed through water. Thus, has the depth been diminishing by the repetition of investigation, as the marvellous part of it has been abating, by the extension of science. An account of a personal descent, by Mr. Lloyd, into this fissure is given in the sixty-first volume of the Philosophical Transactions: which, as it appears to be a plain unexaggerated description of this celebrated place, may be acceptable to such as might not choose to gratify their curiosity, or inform their judgment, by a personal survey of this subterranean cavern, "this terrific profound abyss of space and horror." The entrance into Elden Hole consists of a fissure in length from north to south about thirty yards, and nine wide. The descent was for twenty yards in an oblique direction, when the aperture of the fissure contracted, and the passage became narrower, and more difficult from lateral projecting crags. Ten yards beneath this the rope, by which Mr. Lloyd was suspended, reflected fell six yards from the perpendicular, and at this depth the length of the opening

opening appeared about six, and the breadth three yards. The sides were very irregular, covered with various mosses, and dripping continually with water. When he had descended forty-eight yards, the rock opened on the eastern side; and at sixty-two yards he swung to the floor of the cave. The light he describes as sufficient to see to read the smallest print; and by means of which he was enabled to explore the interior of the cavern. This consists of two parts; the one cavity being like a large oven, and the other similar to the dome of a glass-house, with a vaulted communication between them. The largest is about fifty yards in diameter, and the height too great for ascertaining with facility. At the entrance is a grand stalactitical column, ninety feet in height. To the south of the second cavity is a third smaller hole twelve feet long, and six feet wide, beautifully ceiled with gold-coloured stalactites: to the north is another small hole, and a large fragment of rock spangled with a similar substance. From the margin of the second cavern projects a large mass of rock covered with stalactites, and shaped like a buttress. The cavern, sixty feet in height, is internally craggy, and lined with stalactitical concretions; some of which hang from the roof, like pendent drops and icicles, from four to five feet long, and two in diameter. In different directions are several columns with incrustations, covering the lime-stone like a party coloured varnish; the first a deep yellow, the second a stone colour, and the third a rough efflorescence in the shape and colour of roses. Such are the particulars of this extraordinary cavern, as delivered by Mr. Lloyd, and the account as to the depth of it is confirmed by several miners, who have since descended for the purpose of ascertaining it. What was the cause of such a cavernous space, or by what convulsive throes of earth such fissures as this have been made in the most solid parts of the strata, has exercised the ingenuity of the most able philosophers. Some have contended that they are visible demonstrations of the universality of the deluge, and of the globe having been in a state of solution and mixture. And an advocate for this theory in its fullest extent, Mr. Catecott, considers them as *foveolet holes*, by which the waters, which for the purpose of drowning the world had been brought from the great abyss at the centre of the earth, again retreated at its reformation. But one question does not appear to have been answered by the advocates of this system. For if, as they state, the power of gravity were removed, so that the whole substance of the globe was in a state of solution and intermixture; how came these fissures to remain? or be again formed in the solid rocks, when the power of gravity had been restored? Another, but equally improbable account, has been given as a satisfactory one. "This cavern seems to have been occasioned by some *shaks*, as it is here provincially termed, or depression of the earth, effected by the force of water. When the subterraneous passage, which carries off the circulating water from these invisible caverns, is plugged up, so that its vent is stopped, being an incompressible body; and the impinging weight of several columns of the same fluid are added to the prodigious pressure, they will force a new vent in some direction, and having lifted up the superincumbent earth and once got vent, leave the earth to subside wherever it may." The language of this account is philosophical, but the reasoning is unsatisfactory. For as these shaks, or caverns, are observed to exist in the driest parts of the earth, in indurated rocks; and almost invariably in lime-stone strata, a substance of easy solubility in water; a simple mode of accounting for such fissures instantly presents itself, only admitting that at some period or other these parts of the globe were once submerged, or that "the waters once prevailed over the earth." Nature

is simple in her energies, and though she exhibits infinite variety, yet a constant analogy prevails the whole of her operations. These fissures evidently appear to have been formed at the departure of the waters, in the time of some deluge, by the sudden absorption of moisture, and condensation of the dissolved matters; the substances of such rocks in which they are found exhibiting, by the marine exuvia imbedded in them and other extraneous matters, that they have once been in a state of solution. This is clearly evinced by a fact, which often takes place in modelling, to the great annoyance of the artist; when the substances under his plastic hand, by a too sudden evaporation of the aqueous particles, crack in various directions: or as is more visibly exemplified in lands composed of argillaceous soils, where the ground, after great or sudden drought, is seen to crack, and exhibit clefts or crannies of considerable length, breadth, and depth. This simple and easy solution of the phenomenon accords with any theory, in which the earth is supposed to have been once covered with water. But respecting Elden Hole it appears, whether naturally or artificially made, to have been once a mine. For in the floor of the largest cavern is a shaft now covered, which once reached to the water; and is by some supposed to be a continuation of the subterraneous river, which runs out of the cave at Castleton, and there discharges a kind of grit only found in Elden Hole.

ELDER, a word used in some parts of the kingdom for fuel. Dict. Rust.

ELDER Tree, in Botany. See SAMBUCUS.

The common elder will grow on any soil, or in any situation; the trees are frequently seen growing out of old walls, or close to ditches, in very moist places, or from the hollow of another tree; for wherever the seeds are scattered, the plants will come up. The leaves and stalks are so bitter and nauseous, that few animals will browse upon them.

The young shoots of this tree are very full of pith; but as the trees grow old, the wood becomes very hard, and will polish almost as well as the box tree; and is often used for the same purpose.

The bark, leaves, flowers, and berries of this tree, are used in medicine. The inner bark is esteemed good for dropsies. Sydenham directs three handfuls of the inner bark to be boiled in a quart of milk and water, till only a pint remains, of which one half is to be taken in the morning, and the other at night; and this repeated every day. Boerhaave recommends the expressed juice of the middle bark, given from a dram to half an ounce, as the best of hydragogues, when the viscera are found. The leaves, which are said to be purgative and emetic, are outwardly used for the piles and inflammations. The flowers are inwardly used to expel wind; infusions made from them while fresh are gently laxative and aperient; when dry, they are said to promote the cuticular excretion, and to be particularly serviceable in erysipelatous and eruptive disorders; and the berries are esteemed cordial, and useful in hysteric disorders; and are frequently put into gargarisms for sore mouths and throats. Miller and Lewis.

Official preparations of the elder, are the aqua forum sambuci, the bleum sambucinum, the unguentum sambucinum, made of the leaves and inner bark, and also of the flowers, and the syrupus sambuci. See SAMBUCUS.

On the trunk of this tree frequently grows a fungus excrescence, wrinkled, and turned up like an ear, whitish on the outside, and black within, with several little veins. These are called Jew's ears, *auricula Judæorum*; they are accounted good for inflammations and swellings of the tonsils, sore throats, and quinzies.

ELDER, *Marjole*, or *Water*. See VIBURNUM.

ELDERS, SENIORS, in the *Jewish History*, were the most considerable persons, for age, experience, and virtue, among that ancient people; probably the heads of tribes, or rather of the great families of Israel, who, before the settlement of the Hebrew commonwealth, exercised government and authority over their families, and the people. Moses, we read, assembled the elders of the people together, and acquainted them with what the Lord had commanded. (Exod. xii. 16. 21. iv. 29, &c.) Moses and Aaron treat the elders of Israel as representatives of the Jewish nation. The number of these elders was 70; but we may suppose, that as there were 12 tribes, there were 72 elders, 6 of each, and that 70 is set down instead of 72; or rather Moses and Aaron made the 71st and 72d, and exclusively of them, there were but 4 elders of the tribe of Levi. This establishment of 70 elders by Moses seems to have continued, not only during his life, but under Joshua likewise, and under the Judges.

Long afterwards, those who held the first rank in the synagogues were usually called זְבֵנִים, *zekenim*, elders, in imitation of the seventy elders, whom Moses established for the judges of the sanhedrim. Numbers xi. 16, 17. 24, 25. Exod. xxiv. 1. 9. 14. See SANHEDRIM.

The president, or chief, had, in a particular manner, the appellation of elder; being, as it were, the *decanus seniorum*, dean of the elders.

In the assemblies of the primitive Christians, those who held the first place or rank assumed the denomination of presbyters, or elders; for the word *presbyters*, which occurs so frequently in the Old Testament, and which includes alike both bishops and priests, does properly signify elders. See M. Simon's observation thereon, in his Supplement aux Ceremonies des Juifs.

The president, or bishop, as being the chief of the elders, did likewise assume the denomination of elder; whence it is, that in the New Testament the name bishop is frequently confounded with that of presbyter. See BISHOP, and PRESBYTER.

For the like reason, the council of the first churches was called *presbyterium*, or council of the elders, where the bishop presided in quality of first elder, being seated in the middle of the other elders. The priests, or elders, who sat by him, had each his judge's chair; for which reason they are called, by the fathers, *assessores episcoporum*. Nothing of any importance was done till it had first been examined, and resolved, in this assembly, where the bishop only made one body with the other elders, or priests; the jurisdiction which we now call episcopal, not being then dependent on the bishop alone, but on all the elders, over whom he was only the president.

ELDERS is also a denomination still retained in the presbyterian discipline.

The elders are officers, who, in conjunction with the pastors, or ministers, and deacons, compose the consistories, or kirk-sessions, meeting to consider, inspect, and regulate matters of religion and discipline. They are chosen from among the people, and are received publicly with some degree of ceremony. In Scotland, there is an indefinite number of elders in each parish; generally about twelve. See KIRK-SESSIONS, and PRESBYTERY.

EL DORADO, or MANOA, a fabulous region and city, supposed to exist in the Spanish dominions of America, abounding with gold, and distinguished by a community of Amazons. The late discussions of Depons concerning this city are of little moment; as it is now known that Manoa only signifies a lake or a river; and the name originally belonged to a river, which runs into the Ucaia. See MANOA.

ELDPACH, in *Geography*, a town of Germany, in the archduchy of Austria; 6 miles S. of Ips.

ELEA, or ELÆE, in *Ancient Geography*, a river of Italy, in Lucania, on this side of the Apennine, which gave name to the gulf, called by the ancients "Eleates Portus" and "Eleates Sams." It is at present *Pisivota*.

ELEANOR of Guienne, in *Biography* queen of France and England, was married in 1137, at the age of fifteen, to Louis VII. king of France, to whose dominions her estates, as heirs of William, last duke of Guienne, made a very considerable addition. She had two daughters by Louis, whom she accompanied to Palestine. Her own conduct and intrigues with the prince of Antioch, and with a young handsome Turk named Saladin, led to a divorce, which took place in 1152. In the following year she married Henry duke of Normandy, who succeeded to the throne of England, in 1154, under the title of Henry II. Henry, by the possessions of his wife, became a formidable rival to the French king, who had reason ever afterwards to regret the separation for which he had pressed. From her own indiscretions Eleanor had been divorced from her first husband, yet she could not overlook similar failings in Henry, and by her jealousy of fair Rosamond, caused much uneasiness to the king. (See ROSAMOND.) Her jealousy has been called in by historians to account for the rebellion of her sons against the king, whose unnatural conduct has been imputed wholly to her instigation. She was at length seized, and imprisoned just as she was attempting to escape to France. In confinement she remained several years, but on the accession of Richard I. in 1189, she was set at liberty, and was, when he went upon his crusade, made regent of the kingdom. The zeal which she manifested for this prince led her to considerable exertions on his behalf: she went to Navarre to procure him, for a wife, Berengaria, daughter of the king of the country; and when Richard, on his return from Palestine, was imprisoned in Germany, she proceeded thither with a ransom accompanied by the chief judiciary in 1194. After his death she supported the succession of John her son, in prejudice of her grandson Arthur. She died in 1202; though, according to some writers, she took the veil this year, at the abbey of Fontevault, and there finished her busy and chequered life in the year 1204. Moreri. Hume's Hist. vol. i.

ELEATIC PHILOSOPHY, among the *Ancients*, a name given to that of the Eleatic sect, so called because three of its most celebrated preceptors, Parmenides, Zeno, and Leucippus were natives of Elea, in Latin Velia, a town in Magna Grecia, built by a colony of Phœceans in the time of Cyrus.

The founder of this philosophy, or of the Eleatic sect, is supposed to have been Xenophanes, who lived about the fifty-sixth Olympiad, or between five and six hundred years before Christ. (See XENOPHANES.) This sect was divided into two parties, which may be denominated metaphysical and physical; the one rejecting, and the other approving, the appeal to fact and experiment. Of the former kind were Xenophanes, Parmenides, Melissus, and Zeno, of Elea. To the latter class belonged Leucippus, Democritus, Protagoras, Diogenes, and Anaxarchus. For the peculiar and distinguishing tenets of each of these philosophers, see their respective articles. Of the writings of the Eleatic school, nothing remains except a few fragments collected by Henry Stephens; and therefore we chiefly depend for information concerning this sect upon the authority of Plato and Aristotle. We may here observe in general that the philosophers of the first class are supposed to have maintained principles not very unlike those of Spinoza; they held the eternity and immutability of the world; that whatever existed was only

one being; that there was neither any generation nor corruption; that this one being was immovable and immutable, and was the true God; and whatever changes seemed to happen in the universe, they considered as mere appearances and illusions of sense. However, some learned men have supposed, that Xenophanes and his followers, speaking metaphysically, understood by the universe, or the one being, not the material world, but the originating principle of all things, or the true God, whom they expressly affirm to be incorporeal. Thus, Simplicius represents them as merely metaphysical writers, who distinguished between things natural and supernatural; and who made the former to be compounded of different principles. Accordingly, Xenophanes maintained, that the earth consisted of air and fire, that all things were produced out of the earth, and the sun and stars out of clouds, and that there were four elements. Parmenides also distinguished between the doctrine concerning metaphysical objects, called truth, and that concerning physical or corporeal things, called opinion; with respect to the former, there was one immovable principle, but in the latter two that were moveable. *viz.* fire and earth, or heat and cold; in which particulars Zeno agreed with him. The other branch of the Eleatic sect were the Atomic philosophers, who formed their system from their attention to the phenomena of nature. See *ATOMIC philosophy*, *EPICUREANS*, and *STOICS*. See a farther account of the opinions of these ancient philosophers in Cudworth's *Intellectual System*, and Brucker's *Hist. of Philos.* by Enfield, vol. i.

ELECAMPANE, in *Botany*. See *INULA*.

The root of the *inula*, or elecampane, has been long famous in all disorders of the breast and lungs. It is also recommended as a sudorific and alexipharmic, and, as such, has a place in most of the compositions of that intention. Taken freely, it is said to gently loosen the belly, and increase the urinary discharge. The dose of the dry root in substance is from a scruple to a dram, or two. An ointment made of the fresh roots and leaves with lard, is also much recommended in the itch, and other cutaneous foulnesses. The roots yield in distillation an essential oil, which concretes into white flakes, resembling camphor in many of its properties, and soluble in spirit of wine. An extract may also be obtained from the dry root, both by water and spirit; an ounce yielding by water 6½ drams, and by spirit 2½.

ELECAMPANE, *Barbard*. See *HELENIA*.

ELECAMPANE Wine. See *WINE*.

ELECT, from *eligo*, I chuse, chosen, in the *Scriptures*, is applied to the primitive Christians. In which sense, the elect are those chosen and admitted to the favour and blessing of Christianity.

ELECT, in some systems of *Theology*, is a term appropriated to the saints, or the predestinated. In which sense the elect are those persons who are said to be predestinated to glory as the end, and to sanctification as the means.

Dr. Taylor, in his excellent *Paraphrase*, &c. on the Epistle to the Romans (p. 96.) observes, that some of the expressions, whereby the antecedent blessings are signified, (that is, those benefits, which were granted to mankind by the mere grace of God, antecedently to their obedience, and without respect to it, but so that they were intended to be motives to obedience), such as *elect*, *justified*, *sanctified*, &c. may be used in a double sense; namely, either as they are applied to all Christians in general, in relation to their being translated into the kingdom of God, and made his peculiar people, enjoying the privileges of the gospel, or as they signify the effects of those privileges, *viz.* either that excellent disposition and character, which they are intended to produce, or that final state of happiness, which is the reward of it. Wherever any

blessing is assigned to all Christians, without exception; wherever it is said, not to be of works; wherever Christians are exhorted to make a due improvement of it, and threatened with the loss of God's blessing, and of eternal life, if they do not, in this case the expressions, which signify that blessing, are to be understood in a general sense, as denoting a gospel privilege, profession, or obligation. And in this general sense, *saved*, *elect*, *chosen*, *justified*, *sanctified*, are sometimes used, and *calling*, *called*, *election* are, as this writer conceives, always used, in the New Testament. But when any blessing connotes real holiness, as actually existing in the subject, then it may be understood in the special and eminent sense, and always must be understood in this sense, when it implies the actual possession of eternal life: and in this sense *saved*, *elect*, *chosen*, *justified*, *sanctified*, *born of God*, are sometimes used. (Matt. xx. 16. xxiv. 31. xii. 36, 37. 1 Thess. v. 24. 1 John. ii. 29. iv. 7.) See **ELECTION** and **PREDESTINATION**, **ARMINIANS**, **CALVINISTS**, &c.

ELECT is likewise applied to archbishops, bishops, and other officers, who are chosen. but not yet consecrated, or actually invested with their office, or jurisdiction.

The emperor is said to be elect, before he is inaugurated and crowned; a lord mayor is elect before his predecessor's mayoralty is expired, or the sword is put in his hands.

ELECTARY, in *Pharmacy*. See **ELECTUARY**.

ELECTI, in *Church History*, a sect of heretics, who neither used flesh nor married. See **AUDITORS**.

ELECTION, a choice made of any thing, or person, whereby it is preferred to some other.

There seems this difference, however, between *choice* and *election*, that election has usually regard to a company or community, which makes the choice; whereas choice is seldom used, but when a single person makes it.

We say, the election of a bishop, a member of parliament, &c. See **BISHOP**, **BURGESS**, **PARLIAMENT**, *Scots* **PEERS**, **SHERIFF**, &c.

The most solemn election is that of a pope; which is performed by the cardinals in four different ways. The first by the Holy Spirit, as they call it: when the first cardinal who speaks, having given his vote for any person, proceeds to the adoration, and proclaims him pope, as by a sudden inspiration of the Holy Ghost. In which case he is deemed duly elected, if all, or at least two-thirds of the assembly, be consenting thereto.

The second, by compromise, when the whole college pitches on three cardinals, to whom they give a power of nominating the pope; which power expires upon the burning out of a candle lighted on that occasion.

The third by way of poll or scrutiny, which last is the most usual; the cardinals throwing sealed tickets, on which their votes are written, into a chalice, or cup, placed on the altar. Two-thirds of the votes are required to determine an election by scrutiny.

The fourth is by way of acclamation; when the votes being too much divided to elect any body, some of the cardinals desist from their first suffrage, and accede, that is, give their voices to him, who has already the majority by scrutiny.

The way of accession, however, is always added to the scrutiny; it being the constant practice for all the cardinals to give their voices, after the last scrutiny, to him whom they find to have the plurality already. So that all elections of popes are with the unanimous consent of all the cardinals. See **CARDINALS**, **CONCLAVE**, and **POPE**.

ELECTION of numbers, or quantities, in *Arithmetic* and *Algebra*, denotes the different methods of taking any numbers or quantities given, either separately, or in pairs, &c. or it is the sum of all the combinations that can be made

with a different number of quantities, in each set of combinations, out of any number of quantities proposed. Thus, the election of three quantities *a, b, c*, is 7: *a, b, c, ab, ac, bc, abc*; of four quantities 15; and if *N* represent the number of quantities given, $2^N - 1$ is equal to the number of elections required; but as the single quantities are equal in number to the given quantities, the number of proper elections will be $2^N - N - 1$. See COMBINATION.

ELECTION of a clerk of statutes merchant, in *Lexic*, a writ that lies for the choice of a clerk assigned to take bonds called statutes merchant. It is granted out of chancery, on suggestion that the clerk, formerly assigned, is gone to dwell at some other place, or is under an impediment to attend the duty of his office, or that he has not land sufficient to answer his transgressions, if he should act amiss. *Law-Herb. N. Brev* 164.

ELECTION of ecclesiastical persons. Elections for the dignities of the church ought to be free, according to the stat. 9 Ed. II. cap. 14. If any persons, that have a voice in elections, take any reward for an election in any church, college, school, &c. the election shall be void. And if any persons of such societies resign their places to others for reward, they incur a forfeiture of double the sum; and both the parties are rendered incapable of the place. Stat. 31 Eliz. cap. 6.

ELECTION of a vendor of the forest (*electio venditorum foreste*), a writ that lies for the choice of a vendor, where any of the vendors of the forest are dead, or removed from their offices. This writ is directed to the sheriff, and the vendor is to be elected by the freeholders of the county, in the same manner as coroners. *New Nat. Brev* 366.

ELECTION, in *Metaphysics*, is also the state of a person who is left to his own free will, to take or do either one thing or another, which he pleases. See LIBERTY.

ELECTION, in *Theology*, signifies the choice which God, of his good pleasure, makes of angels or men, for the objects of mercy and grace.

The election of the Jews was the choice God made of that people to be more immediately attached to his worship and service, and for the Messiah to be born of them.

This grand and gracious design of Providence commenced with the selection of one family of the earth, to be a repository of true knowledge, and the pattern of obedience and reward among the nations. To this family God particularly revealed himself, visited them with several public and signal dispensations of providence, and at last formed them into a nation, under his special protection, governed them by laws delivered from himself, and placed them in the open view of the world; first in Egypt, and afterwards in the land of Canaan. The head or root of this family was Abraham, who, though he had been an idolater, was selected for this important and beneficial purpose. Accordingly God established a covenant with Abraham, and his seed, or posterity after him, and appointed circumcision as a token of the certainty and perpetuity of this covenant. For about 215 years, from the time when God ordered Abraham to leave his native country, he and his son Isaac, and grandson Jacob, sojourned in the land of Canaan, under the special protection of heaven, till infinite wisdom thought fit to send the family into Egypt, which was then, as it were, the headquarters of idolatry, that they might there increase and become a great nation. At length God delivered them from the servitude of Egypt by dreadful displays of his almighty power, by which he demonstrated himself to be the one true God, in a signal and complete triumph over

idols, even in their metropolis, and in a country celebrated among all surrounding nations. Thus freed from the most humiliating and oppressive bondage, he formed them into a kingdom, of which he himself was the sovereign; gave them a revelation of his nature and will, instituted sturdy ordinances of worship, taught them the way of truth and of life, and set before them various motives to duty; promising singular blessings to their obedience and fidelity, and threatening apostasy and disobedience, or revolt from his government, with very awful judgments. Having settled their constitution, he led them through the wilderness, where he disciplined them for 40 years, carried them to triumph over every kind of opposition, and at last brought them to the promised land. It is here to be observed, that God did not choose the Israelites from any partial regard to that nation, nor because they were better than other people, (Deut. ix. 4, 5) and would always observe his laws. Indeed, he knew the contrary (Deut. xxxii. 29. xxxiii. 5, 6, 15.) It was, indeed, with great propriety, that, among other advantages, he gave them also that of being descended from progenitors illustrious for piety and virtue; and that he granted the extraordinary favours they enjoyed upon Abraham's faith and obedience (Gen. xxii. 16, 17, 18.) But it was not on account of the moral character of the Jewish nation that God made choice of these people; any other nation would have served as well in this respect; but as he thought fit to select one nation of the world, to answer the purposes of his all-wise and benevolent providence in the moral administration of the world, he selected the Israelites, from respect to the virtue and piety of their ancestors. (Exod. iii. 15. vi. 3, 4, 5. Deut. iv. 37.) It should also be observed, that God selected the Israelitish nation, and manifested himself to them by various displays of his power and goodness, not principally for their own sakes, to make them a happy and flourishing people; but to be subservient to his own great and kind designs with regard to all mankind. The selection of this nation, and the divine dispensations respecting it, would serve as a public voucher of the being and providence of God, and of the truth of the revelation delivered to them in all ages, and in all parts of the world. Accordingly the divine scheme, in relation to the Jewish polity, had reference to other people, and even to us at this day, as well as to the Jews themselves. In proof of which we may add, that the situation of this nation, lying upon the borders of Asia, Europe, and Africa, was very convenient for such a general purpose. This scheme was also wisely calculated to answer great ends under all events. If this nation continued obedient, their visible prosperity, under the guardianship of an extraordinary providence, would afford very extensive and useful instruction to the nations of the earth. If these people were disobedient, their calamities and dispersions would answer a similar purpose, by spreading the knowledge of the true God, and of revelation, in the countries where before they were not known. So wisely was this scheme laid at first, with regard to the laws of the nation, both civil and religious, and so carefully has it all along been conducted by the divine Providence, that at this day, more than 3600 years from the time when it first took place, it is of great importance and of public use, for confirming the truth of revelation: not only because the Christian profession, diffused over a great part of the world, has grown out of this scheme, but as the Jews themselves, in virtue of it, after a dispersion of about 1800 years, over the whole face of the earth, every where in a state of ignominy and contempt, have, notwithstanding, subsisted in great numbers, distinct and separate from all other nations. This small nation, generally despised

ELECTION.

and hated, harassed and persecuted, has subsisted in a body, distinct and separate from all other people, even in a state of dispersion and of general contempt and oppression, for nearly 1800 years, agreeably to the prediction. (If. xlv. 28.) Hence we derive a demonstration, that the wisdom, which so formed them into a peculiar body, and the providence, which has so preserved them, that they have, almost ever since the deluge, subsisted in a state divided from the rest of mankind, and are still likely so to remain for a longer period, is not human, but divine. For no human wisdom or power, could form, or, however, could execute, such a vast, extensive design.

As God, in his infinite wisdom and goodness, was pleased to prefer the Israelites before any other people, and to single them out for the purposes of revelation, and for preserving the knowledge, worship, and obedience of the true God, he is said to *choose* them, and they are represented as his *chosen*, or *elect* people. (Deut. iv. 37. vii. 6. x. 15. 1 Kings, iii. 8. 1 Chron. xvi. 13. Ps. xxxiii. 12. cv. 6. 43. cvi. 5. cxxxv. 4. If. xli. 8. o. xliii. 20. xlv. 1, 2. xlv. 4. Ezek. xx. 5. If. xvi. 1. Zech. i. 17. ii. 12.) The first step that was taken by the almighty sovereign, in execution of his purpose of election, was to rescue them from their state of bondage and idolatry in Egypt, with a view to which they are said to be *delivered, saved, bought, or purchased, and redeemed*. Moreover, as they were not only rescued from Egypt, but invited by the Almighty to the honour and happiness of his people, and by many express declarations and acts of mercy engaged to adhere to him as their God. he is said to *call* them, and they were his *called*; and many other expressions occur, which describe not only their deliverance from an oppressed condition, but their establishment in a more happy, and their investiture with many privileges and honours. All the blessings, to which we have already referred, and others of a similar kind which might have been enumerated, were conferred on the Israelites, as the elect people of God by his mere grace or free-favour; they were antecedent to their obedience, and had no respect to it; nevertheless, they were intended to be motives to obedience. It they produced this effect, their election and redemption were confirmed; and they were entitled to all the blessings promised in the covenant subsisting between God and them; which blessings, contrasted against the former, or considered in reference to them, may be called *consequent*: because they were given only in consequence of their obedience.

All the honours and privileges pertaining to the Jews as a people elected by God, and assigned to the whole body of them, do not import an absolute, final state of happiness and favour of any kind; but they are to be considered as displays and instances of God's love and goodness to them, which were to operate as means of holiness and motives to obedience. We may further observe, that this selection of the Jewish nation, and their introduction into a peculiar relation to God, was a scheme for promoting true religion and virtue in all its principles and branches, upon motives adapted to the rational nature of mankind, which principles and branches of true religion are particularly specified in their law. Nor was this constitution in favour of the Jews in any respect prejudicial to the rest of mankind; so far otherwise, it was erected and maintained for the good of the whole world, and the Jews themselves were instructed and commanded to exercise kindness and hospitality towards those who might be considered, with regard to them, as aliens and strangers. However, though the Jews were directed and required to exercise benevolence towards persons of other nations, yet about the time when

the gospel was promulgated, they were unduly elevated on account of their distinguishing privileges, looked upon themselves as the peculiar favourites of heaven, and regarded the rest of mankind with a sovereign contempt. Their constitution, they were ready to imagine, was permanent and immutable; and those who did not submit to their law, were in their estimation unworthy of a place in the church, and unfit for the kingdom of heaven. But the Jewish dispensation, as they ought to have considered, which lasted, if we reckon from the call of Abraham, 430 years before the law was given on mount Sinai, to the coming of Christ, about 1921 years, was introductory to another more perfect and more permanent, to be introduced and established by the promised Messiah. Accordingly, Abraham, the head, or root, of the Jewish nation, is represented as the "father of us all," (Rom. iv. 16, 17.) Gentiles as well as Jews; and the believing Gentiles are said to partake of all the spiritual privileges which the Jews enjoyed, and from which the unbelieving Jews fell; and to be taken into that kingdom and church of God out of which they were cast. Hence, the state, privileges, and honours, &c. of professed Christians, particularly of the believing Gentiles, are expressed by the same phrases with those of the ancient Jewish church. Thus, as God *chose* or *elect*d his ancient people the Jews, and they were his *chosen* and *elect*; so now the whole body of Christians, Gentiles as well as Jews, are admitted to the same honour; as they are selected from the rest of the world, and taken into the kingdom of God, for the knowledge, worship, and obedience of God, in hopes of eternal life. (Rom. viii. 33. Eph. i. 4. Col. iii. 12. 2 Thess. ii. 13. Tit. i. 1. 2 Tim. ii. 10. 1 Pet. i. 1. 2. ii. 9. v. 13.) The same and similar expressions are applied to Christians under the dispensation of the gospel, which were applied to the Jews under their dispensation, and which described the outward privileges and benefits with which they were invested; and in the same manner particular nations are *elect*d to the participation of the outward blessings of Christianity. The advocates of this opinion maintain, that the election, which the apostle Paul states and defends in the 9th chapter of the Epistle to the Romans, and in some other places, is not an election by the absolute decree and purpose of God, to eternal life, but only election to the present privileges and external advantages of the kingdom of God in this world; and that reprobation, or rejection, is not that by an absolute decree to eternal misery, but that it signifies the not being favoured with the forementioned privileges and advantages. To the same purpose we shall here subjoin the following passage from Mr. Pyle's preface to the Epistle to the Romans, cited by Dr. Tomline, the present bishop of Lincoln, in his "Elements of Christian Theology," (vol. ii. p. 304.)

"The errors and vain disputes," says Mr. Pyle, "that have arisen in the latter ages of Christianity concerning faith and works, justification and sanctification, election and reprobation, that have distracted the minds of many Christians, have proceeded from applying particular phrases or passages in the Epistles to particular persons, which originally referred to the state and condition not of particular persons, but of whole churches in their collective capacity. Thus the body of heathens, while in their heathen state, are called aliens, strangers, enemies to God, &c. but such of them as were converted (the churches to whom the apostles wrote) are styled no longer strangers, but of the household of God, a chosen or elected generation, a royal priesthood, justified, sanctified, saints, &c. So the major part of the Jewish nation, who obstinately rejected the gospel of Christ, instead of being any longer the holy nation, the people of God, are called the vessels of wrath, fitted (by their

their own obstinacy) for destruction, reprobate; while the believing Jews became vessels of mercy, fore-ordained, predestinated, to be called into the kingdom or covenant of the gospel, chosen to eternal life; which expressions mean no more than their having been offered the means and opportunities of attaining to the future happiness of heaven, by their knowledge and practice of Christ's religion. Their actual enjoyment of future happiness depended entirely on their virtuous obedience to the gospel; on their diligence to make their calling and election sure, that is, effectual to their salvation. No private persons are ever mentioned in these writings as elected to eternal life by any absolute decree of God. Paul was a chosen vessel; but he was chosen as a proper minister of Christ's gospel, to bear his name to the Gentiles; his being chosen to the crown of life hereafter, was the fruit of his earnest endeavours to keep the faith, (his fidelity) to finish his course, and of his labouring abundantly. To take these expressions otherwise, is to pervert the design of these writings. It is this mistake that has diverted the minds of many good men from attending to the more excellent parts of these writings, the moral and weighty exhortations given to Christians; and by puzzling them about former controversies that do very little, if at all, concern us now, have turned off their thoughts from the great matters of the Christian law, which are most easy to be understood, and requisite to be put in practice." For a farther illustration of these observations, in their peculiar reference to the state of Christians, the reader may consult Dr. Taylor's Key to the Epistle to the Romans, *passim*. Locke on the Epistles. See the next article.

ELECTION also, in the language of some divines, signifies a predestination to grace and glory, and sometimes to glory only. And it has been enjoined as an article of faith, that predestination to grace is gratuitous, merely and simply so; *gratia, quia gratis data*. But the divines are much divided as to the point, whether election to glory be gratuitous, or whether it supposes obedience and good works, *i. e.* whether it be before, or after, the prevision of our obedience. For an account of the different opinions that have been maintained on this subject, see GRACE, PREDESTINATION, and REPROBATION.

ELECTION is also used for a part of *Pharmacy*, being that which teaches how to chuse the medicinal simples, drugs, &c. and to distinguish the good from the bad.

Some distinguish a general election, which gives the rules and marks for all medicines in general; and a particular one for each medicine in particular. Pomet, in his History of Drugs, gives very good rules for this election.

ELECTIVE, something that is done, or passes, by election. See ELECTOR.

ELECTIVE *Attraction*, in *Chemistry*. See AFFINITY.

ELECTOR, formed of the Latin *eligere*, to chuse, any person who has a right to chuse or elect another to an office of honour or trust. But the term elector used to be applied more particularly, and by way of eminence, to those few princes of the German empire, in whom was vested the right of electing or choosing the head of the empire. They were all sovereign princes, and the principal members of the Germanic body. The German name is *Churfürst*, *Kurfürst*, or *Wahlfürst*.

The origin of the electoral dignity, and of the right inherent in the same, is not exactly ascertained. Some place it in the year 966, and attribute the institution to an edict of Otho III. confirmed by pope Gregory V. But this opinion is contradicted by history. It appears, that from the earliest period in the history of Germany, the person who was to reign over all was elected by the suffrage of all,

Thus, Conrad I. was elected either by all the princes and chief men, or by the whole nation. In 1204, posterior to the supposed regulations of Otho III., Conrad II. was elected by all the chief men, and his election was approved of and confirmed by the people; and at the election of Lotharius II., in 1225, 60,000 persons of all ranks were present, and he was named by the chief men, whose nomination was approved by the people.

Others refer the origin of the electoral dignity and exclusive function to Frederick II. who died in 1250; and the first author who mentions the seven electors is Martinus Polonus, who flourished in this reign. It appears, after all, that this restrictive privilege was obtained by degrees. The princes of greater authority were first allowed to name the person whom they wished to be chosen emperor, and the nation retained the right of approving or disapproving the nomination. When they had thus secured the right of voting first, it became needless for the inferior ecclesiastics or barons to attend merely to confirm their choice, more especially as their attendance would be troublesome and expensive. And as the electors were sovereign princes, possessed of most extensive territories, they were strongly supported by their numerous attendants and allies, and considered as the representatives of all the higher classes of German nobility. See Robertson's Charles V., vol. i. chap. 5.

The institution of electors has also been ascribed to Rudolph of Habsburgh, the founder of the house of Austria, in 1280. Their number, however, was unsettled till the fourteenth century; it was Charles IV. who, by his golden bull of the year 1356, limited the same to seven, three ecclesiastical, *viz.* the archbishops of Mayence or Mentz, Treves, and Cologne; and four secular, *viz.* the king of Bohemia, the count Palatine, the duke of Saxony, and the margrave of Brandenburg. In 1648, the duke of Bavaria was put in the place of the count Palatine, who was outlawed by the emperor for having accepted the crown of Bohemia; but as he was at length restored to his rank, and a new electoral dignity was created for the duke of Bavaria, which increased the number of electors to eight. In 1692 a ninth electorate was added by the emperor Leopold, in favour of the duke of Hanover, of the house of Brunswick Luneburg. From that period to the year 1777, the electoral college consisted of the three ecclesiastical electors, Mentz, Treves, and Cologne, and the six secular, Bohemia, the palatinate of the Rhine, Saxony, Brandenburg, Bavaria, and Hanover.

The dominions of the last elector palatine of the Rhine, having devolved, in December 1777, to the elector of Bavaria, the electoral college was again reduced to eight members, until the peace of Luneville; when the three ecclesiastical electorates were secularized, the archbishop of Ratibon introduced as a new elector arch-chancellor, and the duke of Wirtemberg, the landgrave of Hesse Cassel, the margrave of Baden, and the grand duke of Tofcany, as duke of Salzburg, raised to the electoral dignity. This increased the number of electors to ten, *viz.* the elector arch-chancellor, Bohemia, Bavaria, Saxony, Brandenburg, Hanover, Wirtemberg, Hesse Cassel, Baden, and Salzburg.

But this arrangement was not of long duration. In the year 1806 the German empire was dissolved. Bavaria and Wirtemberg, on joining the Confederation of the Rhine, under the protection of the French empire, assumed the royal dignity; Hanover was in possession of the French; Baden and Salzburg took the titles of grand dukes; the elector arch-chancellor that of the prince primate of the Confederacy of the Rhine; and the year following Saxony likewise

likewise assumed the royal dignity; Hesse Cassel was annexed to the new kingdom of Westphalia; Bohemia as part of the dominions of Austria, and Brandenburg as part of those of Prussia, reverted to these two houses as independent monarchical states. Thus the electoral college was not only dissolved with the dissolution of the German empire: but the title of elector, a title which for so long a series of years conferred a rank equal to that of the old kings of Europe, became altogether extinct.

Besides the power of electing an emperor, the electors had a right to capitulate with the new head of the empire, to dictate the conditions on which he was to reign, and to depose him if he broke those conditions. They actually deposed Adolphus of Nassau in 1298, and Wencellaus in 1401. They were sovereign and independent princes in their respective dominions, had the "privilegium de non appellando illimitatum," that of making war, coining, and exercising every act of sovereignty. They formed a separate college in the diet of the empire, and had among themselves a particular covenant, or league, called the "Kurverein." They had precedence of all the other princes of the empire, even of cardinals, and ranked with kings. There was, however, a difference between the secular and ecclesiastical electors; none of the latter could be chosen emperor, and they were to be thirty years of age before they could attain the electoral dignity, whilst the majority of the secular electors was fixed at eighteen years of age, and any of them might be placed at the head of the empire; indeed they might even vote in their own favour.

The several functions of the electors were exercised by deputies. The elector of Mentz was arch-chancellor in Germany; Treves, in Gaul and the kingdom of Arles; Cologne, in Italy; Bohemia was arch-cupbearer; Bavaria, arch-secular, or officer who serves out the seals; Saxony, arch-marshal; Brandenburg, arch-chamberlain; Hanover, arch-treasurer. During the vacancy of the imperial throne, the elector of Saxony used to be vicar of the empire in the north, and the elector of Bavaria ruled as vicar over the southern circles.

The last electors of the German empire were; 1. Charles Theodore, baron Dahlberg, elector of Ratisbon and arch-chancellor, now prince primate. 2. Frederick William III. king of Prussia, elector of Brandenburg. 3. George III. king of Great Britain, elector of Hanover. 4. Ferdinand Joseph, elector of Saltzburg, now duke of Saltzburg. 5. Frederick II. elector, now king of Wirtemberg. 6. Charles Frederick, elector, now grand duke of Baden. 7. William IX. elector of Hesse Cassel, driven from his dominions by the French. 8. Maximilian Joseph, elector, at present king of Bavaria. 9. Frederick Augustus IV. elector, at present king of Saxony; and, 10. Francis II. elector of Bohemia, at present emperor of Austria.

ELECTOR of *Bavaria, the late*, son of the emperor Charles VII., was not only a very fine performer on the viol da gamba, but a good composer. And it is but justice to the memory of that prince to say, that upon an examination of the score of an entire mass for four voices, with instrumental accompaniments, which is now before us, we find the design and composition much superior to the generality of dilettanti productions.

ELECTORAL CROWN, or *Coronet*. See CROWN.

ELECTORATE, a term used formerly to denote the dignity of an elector of the German empire, *die Churfürstliche Würde*, or the territories belonging to an elector of Germany, *ein Churfürstenthum*. See ELECTOR.

ELECTRA, in *Ancient Geography*, a small town of the

Peloponnesus, in Messenia, upon the route from Andania to Cyparissæ, according to Pausanias. It was watered by two rivers, one of the same name, and another called *Cœus*.

ELECTRAS, a river placed by Ptolemy in the southern part of the Isle of Crete.

ELECTRESS DOWAGER of Saxony, the late, daughter of the emperor Charles VII. and sister of the late elector of Bavaria, was not only an illustrious dilettanti in music, but a princess of great knowledge and talents in the art. After the decease of her consort, when her time was no longer occupied by cares of state, applying herself wholly to the study of the fine arts, and travelling into Italy, she not only wrote two serious dramas in the Italian language, "Talestri," and "Il Trionfo della Fedeltà," but set them to music, and performed the principal part: both were printed in score at Leipzig, and much admired all over Germany, where they have frequently been performed. This princess had learnt to sing at an early period of her life of Porpora, and been taught the principles of composition by Haffé, and both sung and wrote in such a manner as did honour to those great masters, as well as her own genius and application.

This princess was celebrated all over Europe for her talents, and the progress she had made in the arts, of which she was a constant protectress. Her electoral highness was a poetess, a paintress, and so able a musician, that she played, sung, and composed, in a manner at which dilettanti seldom arrive.

ELECTRIA, in *Ancient Geography*, one of the ancient names of the Isle of Samos.

ELECTRIC, or ELECTRICAL, *adj.* (from the Latin *electrum*, amber, or from *ἤλεκτρον*, the Greek name of the same natural substance,) belonging to that branch of natural philosophy which has been denominated *electricity*. Thus we hear of the electric fluid, electric attraction and repulsion, electrical machine, electrical apparatus, &c.

ELECTRIC, *subst.* denotes a body capable of being excited (either by means of friction or otherwise) so as to exhibit the phenomena of electricity; and which body is at the same time impervious to that power. Some of the phenomena of electricity are said to have been first observed in amber, hence the word electric was derived from the Latin or Greek name of that substance.

All the bodies which come under our notice are more or less capable of being excited so as to exhibit electrical phenomena; and are more or less pervious to that power. And it is to be remarked, that those bodies, which are less pervious, are more capable of being excited: whilst, on the other hand, those which are more pervious, are less capable of being excited. Those bodies, in which the capability of being excited is more conspicuous than their permeability, are called *electrics*, or *non-conductors*, and those in which the capability of being pervaded is more conspicuous than that of being excited, are called *conductors*, or *non-electrics*.

Both these classes of bodies contain a vast gradation from the most perfect to the most imperfect of each kind; the most perfect conductors, or non-electrics, being those through which the passage of the electric power meets with the least resistance; and the most perfect electrics, or non-conductors, being those which oppose the greatest resistance to the passage of that power. There may also be more powerfully excited. But it must be observed, 1st, that, strictly speaking, there is no substance known, which may be considered as a perfect electric, or a perfect conductor; for the electric power finds some resistance in going through the best conductors, and it will, in some measure, pass through, or, at least, over the surface of, the best electrics; and, 2dly, that the limits of the above-mentioned two classes of bodies come

to near to each other, that several bodies may, by the least alteration of temperature, or of some other circumstance, be rendered either more of the nature of an electric, or more of the nature of a conductor. See CONDUCTORS of electricity. We shall now arrange the electric, or (as they are sometimes called) the *electric per se*, in the following list, and in the order of their perfection, commencing with the best; as far as such arrangement is practicable; we shall then add several necessary remarks respecting some of these bodies.

Electric.

Glass, and all vitrifications, even those of metallic substances.

All precious stones, the most transparent of which are generally the best; such as diamonds, rubies, emeralds, topazes, sapphires, garnets, &c.

Amber,

Sulphur,

Shell-lac, and all resins, or resinous compounds,

All bituminous substances,

Silk,

Wax,

Cotton,

All dry animal substances, as feathers, wool, hair, &c.

Paper, *

White sugar, and sugar-candy,

Air, and gasses,

The vapour of quicksilver, according to Dr. Priestley,

A perfect Torricellian vacuum,

Ice of distilled water at the temperature of 13° below 0 of Fahrenheit's thermometer.

Oils,

Metallic oxyds,

The ashes of animal and vegetable substances,

All dry vegetable substances,

All hard stones, the hardest of which are the best.

It has been said above, that, in general, the electric are such as will not conduct the electric power, and are at the same time capable of being excited. This last property, however, must not be considered as belonging to them all, or rather, that they may all be subjected to the trial, for several of them, though impervious to the electric power, are not capable of being excited on account of their peculiar constitution, and such are air, oils, the Torricellian vacuum, &c.

Most of the above-mentioned substances, and probably all those which are capable of being subject to experiments, when rendered very hot, lose their electric property, and become quite, though not equally, good conductors. The degree of heat at which this change of property takes place is various in various bodies. Thus, red-hot glass, melted resin, baked wood made very hot, ice in a temperature above 0 of Fahrenheit's thermometer, and water, &c. are conductors of the electric power. It is rather surprising that the focus of a burning glass is not a conductor. It has been observed, that glass, especially the hardest and best vitrified, often is a very imperfect electric, or even a pretty good conductor. The ab *è* Nollet and others have endeavoured to investigate the cause of this occurrence in glass by means of experiments; but they have not been able to ascertain it. Glass vessels, made for electrical purposes, are often rendered very good electric by use and time, though they were bad electric when new. And, on the other hand, some glass vessels, which had been long used for excitation, have sometimes lost nearly all their power.

With respect to the non-conducting property of a va-

cuum, the following observations deserve the attention of the scientific reader. It is well known that the vacuum produced by means of an air-pump, even of the most perfect construction, is a conductor of the electric power: or that the more the air is rarefied within a given vessel, the more easily will the electric power pass through that vessel. But Mr. Walsh, assisted by Mr. De Lur, boiled the quicksilver in a double barometer. *viz.* in an arched glass tube, the legs of which formed two barometers, connected at top by the curved part, in which the vacuum or absence of air was as perfect as could be effected; and they found that the electric power would not pass through this vacuum (Priestley's Observations on Air, &c. vol. i.) Mr. Morgan, some time after, made several experiments of the like sort, which confirmed the above-mentioned discovery; (Phil. Trans. vol. 73.) so that the fact seems to be fully ascertained, though one cannot comprehend why it should be so; for if the electric power can pass easier and easier through a given space, in proportion as the air in it is more and more rarefied, why does it not pass in the easiest manner possible when the air has been entirely removed? And this fact appears still more surprising, if it be admitted that the electric phenomena are produced by a fluid highly elastic.

The various transitions of water from the state of a conductor to that of a non-conductor, or an electric, are also deserving of notice. Ice, as we have already mentioned, is an electric below a certain temperature, and so much so, that Mr. Achard, who discovered this property of it in the year 1776, whirled a spheroid of ice in a proper machine with a rubber, &c. like the glass cylinders of a common electrical machine, and by this means he electrified the prime conductor, so as to attract, repel, give sparks, &c. Above that degree of temperature, the ice begins to conduct, and this conducting property increases as the temperature is raised, so that the water, when pretty hot or near boiling, is a most excellent conductor; but as soon as it is converted into vapour, the conducting property diminishes, and when the vapour is mixed with the air, so as to become invisible, its conducting power ceases altogether; as is indicated by the high electric state of the atmosphere in dry weather, when it is known that a great deal of aqueous vapour is mixed with the air.

After the preceding discrimination of substances, with respect to their electric, or their non-conducting property, the reader may naturally ask, how is it to be ascertained whether a body is or is not an electric? The answer is, that there are various methods of determining these properties in bodies, and which can not all be applied indiscriminately in all cases. For common purposes, when an electrical machine, (furnished with a prime conductor, to which an electrometer is affixed,) is in action, in which case, the electrometer is diverging, if you touch the prime conductor with any given substance, you will easily perceive whether that substance is an electric, or a conductor; for, in the first case, the electrometer will continue in a state of divergency; whereas in the latter it will collapse. For this purpose, the substance in question must have a certain extension; and whilst one extremity is presented to the prime conductor, the other extremity of it must communicate with the ground, either through the body of the person that holds it, or otherwise; for, if it be too short, though an electric, the electricity from the prime conductor will pass over its surface to the hand that holds it, and the electrometer will of course collapse. The experiment may be performed nearly as well without an electrometer; *viz.* by drawing sparks from the prime conductor with one hand,

or with a knobbed wire, and presenting the substance in question with the other hand; for if that substance is a conductor, the sparks will cease: and if an electric, the sparks will continue. Thus, the electric nature of any substance may be determined in a gross manner; but when an accurate determination is required, then recourse must be had to other means, which must be diversified according to the substance in question. Thus, if it be an elastic fluid, a glass vessel may be filled with it, and an electrified electrometer may be admitted to it. If it be a liquid, a glass tube may be filled with it; putting a cork at each end, and passing a pin through each cork, so as to touch the liquid; with this tube, then, you must repeatedly touch the electrified prime conductor of an electrical machine, and mark the effects produced upon the electrometer; you must also try how it will convey the shock of a charged jar, *viz.* whether silently, or with a report, &c. The best way of determining the electric property of solids is, by rubbing them against the hand, or a piece of silk, or woollen cloth, and the like. But in conducting these experiments, the operator may be easily deceived by the moisture which several substances absorb with great readiness; and in consequence of which, these bodies will appear as pretty good conductors. Thus, white paper, and especially the thick brown paper, in its common state, will be found to be a conductor, and, of course, incapable of being excited; but when well dried before a fire, and whilst it remains in a hot state, it is quite a non-conductor, and it may be powerfully excited by friction. Even baked wood, if not well varnished, (which ought to be done immediately after its being taken out of the oven,) will easily absorb moisture, and in consequence of which it will lose its non-conducting property. The various methods of exciting electrics are described under the article EXCITATION.

A natural transition from the effect to the cause will induce the human mind to inquire why are certain bodies electrics, whilst others are conductors of the electric power? But though innumerable experiments have been instituted expressly for that purpose, and various conjectures have been offered, yet, it must be acknowledged, that no satisfactory information has been obtained; for no peculiar property has been discovered to belong exclusively to either of the above-mentioned classes of bodies. When the catalogue of electrics and conductors was very short and imperfect, it was supposed that the two conducting principles were metals and water; so that whatever contained a certain quantity of either of these substances, or of both, was a conductor; otherwise it was an electric. But in a more advanced state of the subject, the fallacy of the above-mentioned supposition was readily manifested; nor, in truth, has any thing else been substituted which might furnish a satisfactory explanation of the question.

The word *electric* is often used to denote that part of the electrical machine which furnishes the electric power, when rubbed, &c. *viz.* an electric body of a particular configuration, being moved against a rubber by the mechanism which is annexed to it, is thereby excited, and communicates the electric power to the prime conductor. (See *ELECTRICAL MACHINES*.) For this purpose, various substances and various forms have been tried and often used; such as glass, sulphur, resin, sealing-wax, varnished pasteboard, varnished silk, and baked wood: and these have been formed into globes, spheroids, cylinders, plates, &c. When the two electricities were first discovered, and it was found that glass, or vitrifications in general, produced one kind of electricity, which was thereby called the *virgineous electricity*; whilst sulphur and resinous bodies produced the

other kind, called the *resinous electricity*; then electrical machines were mounted with electrics of one of these materials, or of the other, according as one or the other of those kinds of electricities was required. But when it was found that a machine, mounted with a single electric of any kind, would produce both electricities at the same time; for if the prime conductor acquires the virgineous electricity, the insulated rubber would acquire the resinous, and *vice versa*; then the necessity of using two different electrics was removed, and the only thing which was attended to was the choice of an electric that might be very durable, and at the same time capable of a powerful excitation. After an innumerable variety of experiments made with the above-mentioned, and various other substances, glass has been found to be the material fittest for the purpose, and altogether preferable to all others. Its shape has also been often varied; but the forms which are at present principally used, as having been found more advantageous, are cylinders, globes, and flat circular plates, especially the first and last; for now one hardly ever finds a machine mounted with a globe. Amongst the various kinds of glass which have been tried for this purpose, the preference has been given to the best flint glass; and, accordingly, of this material the cylinders, or the plates, for electrical machines, are at present mostly made. The abbé Nollet observes, that the hardest, most compact, and best vitrified kind of French glass, is the most difficult to be excited. But Dr. Priestley says, "I have some reason to think that common bottle metal is fittest for the purpose of excitation; at least, the best globe I have yet seen is one that I have of that metal. Its virtue is certainly exceeding great, and I attribute it in part to the great hardness of the metal, and in part to its exquisite polish."

Though a glass vessel exhausted of air does not shew any signs of electricity on its external surface, yet it has been found, that the electric power of a glass globe, or cylinder, is strongest, when the air within it is a little rarefied.

It has long been questioned, whether a coating of some electric substance, as resin, turpentine, &c. on the inside surface of the glass, had any effect towards increasing its electric power; and, after a great many trials, it seems, that if it does not increase the power of a good glass globe, or cylinder, it does at least improve a bad one. The most approved composition for this purpose consists of four parts of Venice turpentine, one part of resin, and one part of bees' wax. This composition must be boiled gently over a fire, stirring it continually for about an hour; afterwards it is left to cool, and reserved for use. When a globe, or a cylinder, is to be lined with it, some small pieces of it are introduced into the glass; then, by holding the glass near the fire, the mixture is melted, and is equally spread over its internal surface to about the thickness of a six-pence. In this operation, care must be taken that the glass be heated gradually, and be continually turned, so as to heat it pretty equally in all its parts, otherwise it is apt to break.

At present, however, this resinous lining is hardly ever applied; for, with a pretty good cylinder, or globe, and the zinc amalgam upon the rubber, the modern electrical machines furnish as much electricity as can reasonably be expected.

ELECTRIC CHARGE. See CHARGE and LEYDEN PHIAL.

ELECTRICAL-AIR-THERMOMETER, is an instrument contrived by Mr. Kinnerley of Philadelphia, for the purpose of observing the effects of electrization upon air, and with this instrument Mr. K. made several experiments, which he describes in a letter to Dr. Franklin, dated March the 12th, 1761. *Fig. 26. of Plate IV. Electricity*, represents

this instrument; the body of which consists of a glass tube A B, about eleven or twelve inches long, and about two inches in diameter. It is closed air-tight at top and bottom by two brass caps, the lower one of which is fastened to the wooden stand D. Through a hole in the upper cap, a small glass tube H O, open at both ends, is introduced, and its lower aperture is immersed in a small quantity of water at the bottom of the large tube. Two wires F G, I E, proceed through the brass caps within the tube A B, and their extremities G, I, are furnished with brass balls, which may be situated nearer or farther from each other, by sliding F G up or down through the hole in the upper brass cap. The external part of the wire F G is also furnished with a ball F, that of the wire I E terminates in a hook. The holes through which the tube H O, and the wires F G, I E, pass, must be sealed, so as to prevent the passage of any air. It will be easily comprehended, that when the air within the tube A B is rarefied, it will press upon the water at the bottom B of the tube, and will force it to rise in the cavity of the small tube H O; then, according as the water rises more or less in the small tube, so it shews the greater or less rarefaction of the air within the tube A B.

If the water, when this instrument is to be used, is all at the bottom of the large tube, and none of it has risen within the small tube, it will be proper to blow into the small tube, by applying the mouth at H; after which, on removing the mouth, the water will be found to rise a little within the small tube; and a mark may be fixed on the outside against the surface of the water that has thus risen within the small tube. The experiments which Mr. Kinnerley made with this instrument are as follows:

He fastened this thermometer on an electric stand, and connected the wire F with the prime conductor of an electrical machine in action. Thus he kept it well electrified for a considerable time, but it produced no remarkable effect; from whence he inferred that the electric virtue, when in a state of rest, had no more heat than the air, and other matter wherein it resides.

When the two wires within the tube A B were in contact, a large charge of electricity, from above thirty square feet of coated glass, produced no rarefaction in the air; which shewed, that the wires were not heated by the electric power passing through them.

When the wires were about two inches asunder, the charge of a three pint bottle, darting from one to the other, rarefied the air very evidently; which shewed, that the electric fire produced heat in itself, as Mr. Kinnerley says, as well as in the air, by its rapid motion.

The charge of a jar, which contained about five gallons and a half, darting from wire to wire, would cause a prodigious expansion of the air; and the charge of his battery of thirty square feet of coated glass would raise the water in the small tube quite to the top. Upon the subsiding of the air, the column of water, by its gravity, instantly subsided, till it was in equilibrium with the rarefied air. It then gradually descended, as the air cooled, and settled where it stood before. By carefully observing at what height the descending water first stopped, the degree of rarefaction, he says, might be discovered, which, in great explosions, was very considerable. Mr. Kinnerley obviously remarks, that the first sudden rise of the water, upon an explosion being made in the vessel A B, is not to be ascribed to the rarefaction of the air by heat, but to the quantity of air actually displaced by the electrical flash. It is only when that first sudden rise has subsided, that the degree of its rarefaction by the heat can be estimated, viz. by the height at which the water then stands above the common level.

If the experiments be performed in a room, wherein the temperature is variable, then an allowance must be made for this circumstance in estimating the effect of the electrification; for the electrical air-thermometer is affected by heat or cold in general, as well as by that which is occasioned by an electrical explosion.

Since this instrument was first made known to the scientific world, the philosophical instrument makers have often varied its form; but this variation of shape has not been accompanied with any real improvement.

ELECTRICAL APPARATUS, is an assortment of all the electrical instruments that have been invented for the purpose of performing any experiments that belong to the science of electricity; comprehending even the materials necessary for constructing these and other instruments that may be occasionally suggested in the course of any experimental inquiry. For the sake of distinction, the articles of an electrical apparatus may be arranged under the following divisions.

1. Instruments and materials necessary for producing electricity.
2. Instruments necessary for ascertaining its quality, and for measuring its quantity.
3. Instruments necessary for the accumulation, retention, and employment of electricity.
4. Instruments necessary for the experimental demonstration of the laws that have been ascertained in the science of electricity.
5. Instruments useful in the performance of entertaining experiments.
6. Instruments necessary for atmospheric electricity.
7. Instruments belonging to that branch which has been denominated *Galvanic electricity*, or *Galvanism*.
8. Instruments peculiarly useful in medical electricity.
9. Materials and tools principally useful to a practical electrician.

As most of these instruments have obtained, and are known by particular names, their descriptions will be found under those names; therefore, the present article needs not contain more than an enumeration of them, accompanied with general remarks, and some explanation of such instruments, materials, &c. which are not commonly known under any particular appellations.

1. The principal instrument for the production of electricity is the electrical machine, viz. a machine containing an electric, and a mechanism, by means of which that electric may be whirled or moved against a rubber, so as to excite and to communicate the electricity, which is thereby produced, to an insulated conductor, called the *prime conductor*. The size and form of these machines have been continually varied, according as experience, and new discoveries, have pointed out any old defects, or some new advantages; and likewise according to the fancy, the wants, and the opulence of the proprietor. The description of the principal electrical machines, together with the instructions necessary for the proper use and management of the same, will be found under the article *ELECTRICAL MACHINE*.

Next to the electrical machine, properly so called, comes the electrophorus, which, when its size is upwards of six inches in diameter, and it is properly managed, will furnish electricity sufficient for a variety of experiments, for it will give pretty long sparks, it will charge a Leyden phial, &c. See the article *ELECTROPHORUS*.

But a great variety of experiments, especially of the theoretical kind, (viz. such as tend to explain the principles of the science,) may be performed with instruments much simpler

ELECTRICAL.

simpler than the electrical machine or the electrophorus; and these are a few glass tubes, and a stick of sealing wax. In order to obtain a great deal of electricity, these tubes should be made as long as a person can wield through his hand at one stroke, (which is about three feet,) and about two inches in diameter. The thickness of the metal is not material, but if it be equal to that of common window glass, it may be reckoned sufficient both for strength and for excitation. These tubes should be closed at one end; and it will be useful to have a brass cap with a stop-cock fitted to the other extremity of at least one of these tubes; for in this case, the air within the tube may be rarefied or condensed by means of an air-pump, or a condensing syringe; and experiments may then be tried with it in those different states. One or two other tubes ought to have the polish taken off from their external surface, (which may be accomplished by means of emery, or a grinding-stone,) for the purpose of producing negative electricity. This, however, may also be obtained by rubbing a stick of sealing wax, or even a stick of baked wood, as long as this is preserved free from moisture.

The glass tubes for excitation must be kept perfectly clean, and dry both within and without. They act best when they are a little warmer than the ambient air. If the operator hold one of these tubes with one hand by one extremity, and draw his other hand (provided this be clean and dry) gently over the tube from one extremity to the other, a few times repeatedly; the tube will soon shew signs of excitation, by attracting light bodies, giving sparks, affecting an electrometer, &c. The application of a proper rubber is better than the human hand, and will occasion a more powerful excitation. The best rubber for a smooth glass tube is the rough side of black oiled silk, especially when a little amalgam of mercury and tin, or rather of mercury and zinc, is spread upon it. The best rubber for a rough glass tube, for a stick of sealing-wax, or of sulphur, or of baked wood, is soft new flannel, or rather skins, such as hare skins, cat skins, &c. tanned with the hair on.

2. The instruments necessary for ascertaining the quality, and the quantity of electricity, are called *Electrometers*, which see.

3. The instruments proper for accumulating, retaining, and employing the electric power, are very numerous, but they may be comprehended under the following general appellations, viz. insulated conductors, and insulating stands; coated electrics, or the Leyden phial in its various shapes; discharging rods, and the universal discharger. See *INSULATION*, *LEYDEN PHIAL*, *ELECTRICAL BATTERY*, and *DISCHARGER of Electricity*.

4. Under the appellation of instruments necessary for the illustration of the laws of electricity, in a general sense, one should comprehend all those which are enumerated in the other sections of the present article; since the experiments that are made with them do all tend to illustrate the laws of electricity; excepting, however, a few, which are mere variations of others.

5. The instruments useful for the performance of entertaining experiments are likewise very numerous; but they will be found described under the article *ELECTRICAL Experiments*.

6. The instruments necessary for exploring the electricity of the atmosphere, are described under the article *ELECTRICITY, Atmospherical*.

7. The apparatus peculiar to that branch of electricity, which has been called *Galvanism*, will be found described under that name.

8. The application of electricity to medical purposes re-

quires very few particular instruments, besides those which are commonly in use for other experiments. They consist of a few directors, a discharging electrometer, a few wooden points, and some other trifling appendages, for which see *Medical Electricity*.

9. The extensive and fertile science of electricity perhaps furnishes more opportunities for signaling the genius of the operator, than any other branch of natural philosophy. There is hardly an electrician whose mind does not suggest some alteration, or some contrivance, entirely new, in the course of his experiments. His ideas may sometimes be ill founded, and may at other times be proper and useful. In either case a prompt and ready construction is desirable;—the aid of regular workmen is dilatory and expensive; and, though in an imperfect state, the workmanship of the electrician himself may, in most cases, expeditiously put his ideas to the test of actual trial. Therefore, for the accomplishment of this object, he ought to furnish himself with several articles or materials ready to be worked upon, and some tools to work with. The articles most useful are, glass tubes, and glass sticks of various sizes, glass plates, and slips of flat glass, and glass phials of different sizes; (some of those used by apothecaries will frequently be found very useful;) sealing wax, rosin, sulphur, shell-lac, and Venice turpentine; tin-foil; brass and iron wire, some brass balls of different diameters. Each of these balls ought to have a hole, in order to fix it, or screw it upon a wire. Also some electrical cement, and some electrical varnish, the first of which is described under the article *CEMENT*, and the second under the article *COATING of Electrics*. To these there may be also added silk threads, small pitch-balls, and cork-balls, gold and silver leaf, gilt paper, &c. But, besides all these, a variety of other materials may be suggested by new discoveries, or new ideas, which cannot be foreseen. With respect to tools, it is not possible to state the precise number and kind that may be wanted; but for most purposes, those which are usually put in the middle sized tool chests, that are sold by ironmongers, will be found fully sufficient.

Electrical Atmosphere. See *ATMOSPHERE*, in *Electricity*.

Electrical Attraction and Repulsion. This kind of attraction takes place between bodies that are electrified, and all other kinds of bodies, in certain circumstances; or, more properly speaking, it takes place between bodies possessed of different electricities; that is, between bodies possessed of the positive or vitreous electricity, and bodies possessed of the negative or resinous electricity. The repulsion takes place only between bodies possessed of the same kind of electricity. The various peculiar phenomena, which attend both this attraction and this repulsion, are highly deserving of attentive consideration, for upon them the subject of electricity principally depends. But though their effects are evident and striking, though they have been exhibited under an endless variety of forms and combinations, though innumerable experiments have been made, and many hypotheses have been offered for their explanation; yet the true cause upon which they depend is by no means understood. In order to proceed with that regularity, which seems more likely to be attended with perspicuity, we shall, in the first place, briefly endeavour to point out the difference between this and all other kinds of attraction and repulsion; we shall, in the next place, describe the phenomena of this kind of attraction and repulsion, to which we shall annex the explanation according to the most approved hypothesis, viz. that of a single electric fluid, which goes under the name of the Franklinian hypothesis; and we shall, lastly, examine

examine some of the other hypotheses that have been advanced in explanation of those phenomena.

Five kinds of attraction have been observed amongst natural bodies; *viz.* 1st, the attraction of gravitation, which forces all bodies, when not hindered, to fall towards the centre of the earth. This attraction is mutual between all bodies; but unless one body be vastly larger than the other, this attraction between them cannot be discerned; 2dly, the attraction of cohesion, by which the particles of bodies adhere to each other, and form the different forms of bodies, or lumps of matter. This kind of attraction vanishes at a distance vastly small; so that though a body be very hard, yet if once broken, and the parts be adapted to each other, the cohesion cannot thereby be restored; 3dly, the chemical attraction, or affinity, which takes place between certain heterogeneous substances when they come in contact with each other; 4thly, the magnetic attraction, which takes place principally between the opposite poles of magnets, or between a magnet and iron, including such compound bodies as contain iron. We have said *principally* between those substances, because a few other bodies, which are said not to contain any iron, are slightly attracted by the magnet. The magnetic repulsion takes place between the homologous poles of magnets only; 5thly, the electric attraction, which takes place between bodies of every kind, provided they are possessed of different electricities; for though in common experiments an electrified body attracts another body which appears to be in a natural, or unelectrified, state; yet, on a closer examination, it will be found, that the latter body does actually acquire the electricity contrary to that of the former, before any attraction takes place, as will be shewn in the sequel. From the above-mentioned properties peculiar to each kind of attraction, that of electricity may be easily distinguished from the rest. We shall now proceed to describe the phenomena.

If light bodies of any kind, such as pieces of paper, of straw, of thread, of metallic leaves, feathers, &c. be thrown upon a table, and an excited glass tube be held horizontally over them at the distance of four or five inches, as in fig. 27, the small bodies will instantly fly towards the tube, and after having touched the surface of it, several of them will be instantly repelled by it; whilst others will adhere to it a considerable time before they are repelled; and some of them will continue to adhere to it without their being ever repelled. Those bodies which have been repelled, as soon as they come in contact with the table, or with some other conducting body, at no great distance from the excited tube, will soon after be attracted again by the tube, then they will be repelled a second time, and so on repeatedly for a considerable number of times, or until the electric power of the tube is in great measure exhausted. The same thing takes place, if, instead of the excited glass tube, an electrified and insulated conductor, such as the prime conductor of an electrical machine, be presented to the light bodies; or if an excited electric of any other kind be used.

The general explanation of these apparently strange and contradictory phenomena, upon the Franklinian theory of a single electric fluid, is as follows. The positive, or *plus*, electricity of the excited glass tube, forces the light bodies, which come within its sphere of action, to deposit their natural share of electric fluid upon the table, in consequence of which they become electrified negatively, or *minus*, and in that state they are attracted by the tube; which explains the assertion, that electric attraction takes place only between bodies possessed of different electricities. When the bodies, on being attracted, come in contact with the tube, they acquire the electricity of the tube, *viz.* become positive, and

in that state they are repelled, which explains the other assertion, namely, that repulsion takes place between bodies possessed of the same kind of electricity. If the bodies thus repelled come in contact with the table, or with any conductor, they deposit their positive electricity upon it, become electrified negatively for the reason already alleged, and in that state are again attracted by the tube. The reason why some bodies adhere to the tube longer than others, is, that their being bad conductors prevents their acquiring the electricity of the tube so soon as other bodies that are better conductors. A few bodies remain adhering to the tube without any tendency to fly off, when, in consequence of their having some sharp corners or projection a little removed from the surface of the tube, they throw out the electric fluid into the ambient air as fast as they receive it from the excited tube; hence they cannot actually become possessed of the same kind of electricity as the tube, and, of course, cannot be repelled. If, instead of the excited glass tube, which, in the usual way of rubbing it, is possessed of the positive electricity, you use an excited rick of sealing wax, which is negatively electrified, the light bodies will be attracted and repelled exactly in the same manner, and the explanation is the same, excepting that the acquisition and deposition of the electric fluid must be reversed; *viz.* the rick of sealing wax being negative will oblige the small bodies to acquire some electric fluid from the table, which renders them positively electrified, and, of course, capable of being attracted by the sealing wax; then on their touching the sealing wax, they deposit their electric fluid upon it, become negative, and are repelled, and so forth. This experiment exhibits all the phenomena of electric attraction and repulsion; but in order to prove the various assertions that have been made with respect to the acquisition and deposition of electricity, &c. every one of the various phenomena must be shewn apart, by a particular experiment: and these experiments now follow.

Experiment 1.—Fasten a small body, as, for instance, a small piece of cork, to a silk thread of about eight or ten inches in length; and holding the thread by its extremity, let the small body hang at the distance of about seven or eight inches from the prime conductor, when this is moderately electrified. This small body will not, in this case, be attracted, because, being insulated, it cannot, by depositing its fluid upon, or by receiving it from, some other body (when the prime conductor is electrified negatively,) become possessed of the contrary electricity. But if a finger or any conducting substance be presented to that side of the small body which is farthest from the prime conductor, then the small body will be immediately attracted; for it has now deposited its own fluid upon, or has acquired some (if the prime conductor be negative) from the body that has been presented to it. And when this suspended body has touched the prime conductor, it will instantly fly from it, on account of the repulsion which takes place between bodies possessed of the same kind of electricity. It must, however, be observed, that if the insulated small body be brought too near to the prime conductor, or the latter be too powerfully electrified, then the small insulated body will be attracted, though no conducting body has been presented to it. But in this case its natural quantity of electric fluid will be either propelled into the contiguous air, or will be crowded on that part of the body which is farthest from the conductor, when the prime conductor is electrified *positively*; but if it be electrified *negatively*, then the additional quantity of fluid, which is required to render the small body positive, will be acquired from the air; or the natural quantity of fluid belonging to that body will be all crowded on that

ELECTRICAL.

sides of it, which is nearest to the prime conductor. If, instead of the silk thread, this small body be suspended by a linen thread, then the attraction will take place at a much greater distance, as in this case the electric fluid will be easily conducted by the linen thread, &c.

Experiment 2.—Put a small light body upon a pane of glass, and, holding the glass by one corner, place it under an electrified conductor, or an excited electric, at a moderate distance from it; which must be proportionate to the intensity of the electricity. The small body thus situated will not be attracted; but if in this state you apply a finger to the lower surface of the glass plate, just against the place where the body stands, then the attraction will take place immediately; because the lower surface of the glass will give its electric fluid to the finger, in consequence of which its upper surface is enabled to receive the electric fluid from the small body, and then that body is attracted by the conductor, or by the excited electric. In fact, if the pane of glass be examined by means of an electrometer, that part of its surface, which has been contiguous to the small body, will be found electrified positively, and its opposite surface will be found negative. In this disposition of the apparatus, the small body, though acted upon by the electricity of the conductor, could not divest itself of its own electric fluid, because the glass being an electric could not receive that fluid on one surface, unless its opposite surface could deposit its own fluid upon some other conductor. (See *LEYDEN PHIAL*.) It must be observed, however, that when the electricity of the conductor, or of the excited electric, is too powerful, and is brought too near, the small body will be attracted though the finger be not applied to the lower surface of the pane of glass. But in this case the electric fluid of the lower part of the glass will be forced into the air.

Experiment 3.—A B and B C, (fig. 28.) are two pieces of thick iron or brass wire, insulated upon two sticks of sealing wax, which are stuck fast upon two pieces of wood, so as to form two insulating stands. Each of the wires has a cork-ball electrometer affixed to one end. Place these two wires in contact with each other at B, and in one direction, as shewn in the figure, with the electrometers at their farther extremities A, C. Bring an excited glass tube D within seven or eight inches of the electrometer C, and it will be found that both the electrometers at A and C will diverge; with this difference, that the electrometer at C diverges with negative, and the electrometer at A with positive electricity, which may be proved by presenting an excited stick of sealing wax to each electrometer, as will be shewn in experiment 6. These electricities arise from the action of the excited tube D, which, being positive, drives the electric fluid from the electrometer C, and the wire B C, to the electrometer A, and wire A B; thence the former becomes undercharged or negative, and the latter overcharged or positive. If the tube D be removed, both the electrometers will collapse; for the electric fluid will return from A B to B C, and both the wires, &c. will remain in the same state as they were before. But if whilst the tube D remains near the end C, as in the figure, and the electrometers are diverging, the two wires with their stands be separated, then, on withdrawing the glass tube, the electrometers will continue to diverge C with negative, and A with positive electricity; because now the contact of the wires at B being interrupted, the electric fluid cannot return from the wire A B to the wire B C; and this plainly shews the effect which an electrified body produces upon other bodies that are brought within its sphere of action. If in the above described experiment an excited stick of sealing-wax be used instead of the glass tube, the same appearances will take

place; excepting that the electrometer C will be positive, and A negative.

Experiment 4.—This experiment shews, that a body, once repelled by an electrified body, will not be again attracted by it, unless it first deposits its electricity upon some other body.

Take a glass tube (whether smooth or rough is not material), and after having excited it by rubbing, let a small light feather be let out of your fingers at the distance of about eight or ten inches from it. This feather will be immediately attracted by the tube, and will stick very close to its surface, for a few seconds, and sometimes longer; after which time it will be repelled, and if the tube be kept under it, the feather will continue to float in the air at a considerable distance from the tube, without ever coming near it, excepting when it comes in contact with some conducting body, upon which it may deposit its electricity; for after that it will be readily attracted again. If the excited tube be managed dextrously, the feather may be driven at pleasure through the air of a room from one part of it to another. The reason why, when the feather is first attracted by the glass tube, it remains adhering to it for a considerable time, and sometimes will not fly from it without shaking the tube, is, that being an electric, it will not easily acquire the electricity from the tube.

This experiment is attended with a remarkable circumstance, which is, that when the feather is kept floating in the air at a distance from the excited tube, by the force of electric repulsion, it always presents the same part towards the tube; somewhat like the moon, which always presents the same part of its surface towards the earth. You may move the excited tube swiftly about the feather, and yet the same side of the feather will be constantly turned towards it. The reason of this phenomenon is, that the equilibrium of the electric fluid in the various parts of the feather, being once disturbed, cannot be easily restored, because the feather is an electric, or, at least, a very imperfect conductor. When the feather has acquired a certain quantity of electricity from the tube, it is plain that the action of the excited tube will drive that super-induced electricity to that side of the feather which happens to be farthest; hence, that part will always be repelled the farthest.

Experiment 5.—Hold a common linen thread by one end, and present it to an excited electric, or to an electrified conductor, such as the prime conductor of an electrical machine, the thread will be attracted by it, and will remain adhering to it as long as the electric or the conductor continues electrified. The reason why in this experiment the thread, after having been attracted, is not repelled by the electrified body, is, that it cannot become possessed of the same kind of electricity with the electrified body, on account of its being held by the hand of the operator; for whatever kind of electricity is communicated to it, will be conveyed to the hand of the operator, and from it to the ground, &c. In this experiment care must be had that the thread be not very dry; for, in that case, the passage of the electricity through it, being partially interrupted, the lower extremity of the thread may, for a short time, acquire the same electricity as the electrified body possesses, and may of course be repelled.

Experiment 6.—Place an electrometer, consisting of two cork balls suspended by threads, upon an insulating stand, as in fig. 29, and the threads of the electrometer will hang down parallel to each other. If then you bring an electrified body near it, the cork balls will be instantly attracted, and having acquired some electricity from it, will soon after be repelled, and will afterwards, when the electrified body has been removed, continue diverging, which is the state exhibited

bited in the figure. If now you bring any electrified body near them, they will either fly from it, as in fig. 30; when that body is possessed of the same kind of electricity, or they will fly to it, as in fig. 31, when that body is possessed of the other kind of electricity. And this is the method by which it may be determined, whether an electrified body is positive or negative. It must, however, be observed, that if the body in question be powerfully electrified, and be brought too near to the cork-balls, the latter will at last be attracted by it; for in this case, the action of the electricity in that body is sufficient to drive the natural fluid of the electrometer, together with that which occasioned its divergency, to the remotest part of it; or is capable of attracting the fluid when negatively electrified, &c.

That the repulsion amongst bodies possessed of the same kind of electricity is more conspicuous when the electricity is stronger, and *vice versa*, nobody will doubt; but it may be enquired, whether the angle of divergency of an electrometer bears any assignable proportion to the intensity of the electricity which actuates it. The determination of this question was attempted by the ingenious Fr. Beccaria, of Turin, and his experiments were performed in the following manner.

Experiment 7.—In the middle of a large room he insulated a cylinder of tin, which measured about four feet in length, and about three inches in diameter; and to it he affixed a very delicate electrometer: another tin cylinder, exactly equal and similar to the former, and having a long insulating handle, was held by an assistant. Things being thus prepared, this philosopher communicated some electricity to the former cylinder, in consequence of which the electrometer, which had been adjusted to it, diverged; in this state, by means of sights placed upon a ruler at a distance, he measured the angle of divergency, and noted it. He then desired the assistant to touch the first cylinder, which was electrified, with the second, which was not; and immediately to withdraw. By this means it is evident, that the electricity of the first cylinder must have been divided into two equal parts, and that this cylinder must now retain only the half of what it contained before. In this state Fr. Beccaria measured the angle of divergency of the electrometer in the same manner as he had done before, and also noted it. The whole of this experiment he repeated several times both in the same, and in different days, and from the concurrence of the results, he found that the chord of half the angle of divergency was proportionate to the quantity of electricity in the cylinder; *viz.* the chord of half the large angle was double the chord of half the small angle; answering to the quantities of electricity in the cylinder. See Beccaria's *Elettricismo Artificiale*, chap. vi. p. 1. art. 1.

M. De Sauffure attempted the determination of the same question in the following manner. He took two electrometers as equal and similar as could be made; and electrified one of them, so that the balls were separated by about six lines. He then touched the top of the electrified electrometer with the top of that which was not electrified; by which means the electricity was equally divided between the two electrometers; and in this state each pair of balls diverged four lines; consequently a diminution of half the density of electricity had lessened the separation of the balls by one-third. One of these electrometers was then deprived of its electricity, and was afterwards brought in contact with the other as before, in consequence of which the electricity was divided, and the divergency of the balls was diminished likewise by one-third, &c. This experiment being repeated several times, either with positive or negative electricity, was constantly attended with the same result.

Upon the Franklinian hypothesis of a single electric fluid, the attraction of bodies differently electrified is easily explained, for, according to that hypothesis, the electric fluid is elastic, *viz.* repulsive of its own particles; but attractive of all other kinds of matter; therefore it is easy to conceive that the electric fluid, super-induced upon a body electrified positively, attracts the undercharged matter of a body electrified negatively. The attraction between a body positively, and another negatively electrified, is so obvious as to require no farther illustration.

The repulsion of bodies electrified positively is also easily explained; but the repulsion of bodies electrified negatively requires much more attentive consideration. The first explanation which occurred to those who adopted the above-mentioned hypothesis is, that when bodies are electrified positively, that excess of electric fluid which resides upon their surfaces forms two atmospheres repulsive of each other, and the bodies remaining in the centres of their respective atmospheres must necessarily recede from each other. If the bodies are electrified negatively (*viz.* are in part exhausted of their natural fluid of electric fluid,) then they are attracted by the denser fluid existing either in the atmosphere contiguous to them, or to other neighbouring bodies, which occasions them still to recede from one another. Other patrons of the same hypothesis observed, that as the denser electric fluid surrounding two bodies negatively electrified, acts equally on all sides of those bodies, it cannot occasion their repulsion. Is not the repulsion, they say, owing rather to an accumulation of electric fluid on the surfaces of the two bodies; which accumulation is produced by the attraction of the bodies, and the difficulty the fluid finds in entering them. This difficulty in entering was supposed to be owing chiefly to the air on the surface of bodies, which is probably a little condensed there.

Lord Mahon, in his Principles of Electricity, explains the electrical attraction and repulsion in a very ingenious manner. He placed an electrified electrometer under the receiver of an air-pump; then began to exhaust the receiver, in consequence of which the divergency of the electrometer decreased. He then let the air return into the receiver, and this circumstance alone caused the electrometer to increase its angle of divergency. "From these experiments, he says, it appears, that when bodies are charged with electricity, it is the *particles of circumambient air being electrified*, that constitutes the electrical atmosphere which exists around those bodies.

"Now since an electrical atmosphere, (whether negative or positive,) consists of electrified air; it evidently follows that the density of the electricity of that air must be in some inverse ratio of the distance from the charged body, which causes that electrical atmosphere.

"From these simple considerations, it is easy to reduce all the different phenomena of electrical attraction and repulsion to one plain and convenient principle, derived from the very nature of a disturbed electrical equilibrium; namely, to the elastic tendency of the electrical fluid, to impel every body, charged either in *plus* or in *minus*, towards that part of its electrical atmosphere where its natural electrical equilibrium would be the most easily restored.

"From this simple principle, it is evident, that bodies, which are charged with contrary electricities, must tend to approach each other, whenever the skirts of their oppositely electrified atmospheres interfere.

"From the same simple principle, it is also easy to understand, why bodies, that are charged with the same kind of electricity, tend to diverge from each other. Every body that is electrified, (whether in *plus* or in *minus*), has a constant tendency to return to its natural state; and this causes it to
electrify,

electrify, in a certain degree, other bodies in contact with it, and the air in its vicinity, in a manner similar to that explained above.

"If two bodies (for example) be both positive; neither body will be able to deposit its superabundant electricity upon the other body, which is also similarly electrified *in plus*. It is, therefore, evident, from the simple principle mentioned above, that if these bodies be brought near each other, each body will be impelled towards the particles of air on its other side, which are electrified *in plus* only in a small degree. That is to say, that each body will tend to diverge from the other.

"If the bodies, on the contrary, be both negative; neither body will be able to have its deficient electricity supplied from the other body, which is also similarly electrified *in minus*. It is therefore evident, from the simple principle mentioned above, that if these bodies be brought near each other, each body will be impelled towards the particles of air on its other side, which are electrified *in minus* only in a small degree. That is to say, that each body will tend to diverge from the other. So that bodies, which are charged with the same kind of electricity, (whether positive or negative,) must necessarily tend to diverge from each other."

Mr. Cavallo explains the repulsion of bodies negatively electrified in the following manner. (Treatise on Electr. vol. iii. p. 193. of the 4th edit.)

"PROPOSITION I.—No electricity can appear on the surface of a body, or no body can be electrified either positively or negatively, unless the contrary electricity can take place on other bodies contiguous to it.

"This proposition may be proved by a great many experiments and observations, such as may be seen in vol. i. and ii. of this my work.

"PROP. II.—There is something on the surface of bodies which prevents the sudden incorporation of the two electricities; viz. of that possessed by the electrified body, with the contrary electricity possessed by the contiguous air, or other surrounding bodies.

"Without examining the nature, the extent, and the laws of this property in bodies, it will be sufficient, for the present purpose, to observe, that the fact is certainly so; for otherwise a body could not possibly be electrified, or it would not remain electrified for a single moment.

"PROP. III.—Supposing that every particle of a fluid has an attraction towards every particle of a solid; if the solid be left at liberty in a certain quantity of that fluid, it will be attracted towards the common centre of attraction of all the particles of the fluid.

"Let the body be extremely small, and it is evident that it must be drawn towards the common centre of attraction; for if it be placed on one side of the said centre, the attractive particles on the opposite side, being more numerous, will naturally draw it that way. If the body be large, the same reasoning shews that the effect must be the same; for the attractive force of all its particles being concentrated in a point or centre, will draw that centre towards the centre of attraction of all the particles of the fluid. Thus, if the fluid be of a spherical form, and the solid body be likewise spherical, the centre of the latter will coincide with that of the former.

"Corollary 1.—The same thing must happen, when the quantity of fluid is smaller than the bulk of the body; in which case the former must be within the latter.

"Cor. 2.—If the attraction of the particles of the fluid be exerted only towards the surface of the solid, and not towards its internal parts; the effect will be the same; when the body is of a regular shape, as spherical, cubical, &c. but

with very irregular shapes, the difference will be very trifling, and not deserving of notice in this place.

"The application of the foregoing propositions in explanation of the repulsion which takes place between bodies possessed of the same kind of electricity is very easy, and, in my opinion, conclusive. According to the Franklinian hypothesis, the electric fluid is elastic, or repulsive of its own particles, and attractive of the particles of other matter. Let then A and B. (fig. 32.) be two spheres of metal, suspended in the open air, contiguous to each other, and capable of being easily moved. Let some electricity be communicated to them, and by Prop. I. it will appear, that whilst the bodies touch each other, as shewn in fig. 32, the electricity which is communicated cannot be dispersed equally all over their surfaces, but it must be thicker, or more condensed, on the parts that are remote from the mutual point of contact, because there the air is at liberty to acquire a contrary electricity; whereas, near the point of contact the electricity cannot be manifested, because in that place there is no air or other body that can acquire the contrary electricity. Therefore the atmospheres of contrary electricity cannot be concentric with the spheres A and B; but must be situated as in fig. 32. It follows, therefore, by Prop. III. that the spherical bodies, being attracted towards the centre of these atmospheres, appear to repel each other, as shewn in fig. 33; so that when the bodies are electrified positively, in which case, according to the hypothesis, they have acquired an additional quantity of electric fluid, negative atmospheres will be formed round them, and the additional or superfluous electric fluid of the bodies will attract, and be attracted by, those negative atmospheres. And when the bodies are electrified negatively, in which case, according to the hypothesis, they have lost part of their usual quantity of electric fluid, positive atmospheres will be formed round them, which will attract the under-charged bodies."

Experiment 8.—This experiment shews the attraction and repulsion by means of the electric light.

Fix a pointed wire upon the prime conductor of an electrical machine, having the point outward, and fix another pointed wire in the like manner upon the insulated rubber of the same machine; then let the machine be put in action, and the points of both wires will appear illumined; viz. the former with a pencil, and the latter with a star. In this situation, bring an excited glass tube sideway of the point which proceeds from the prime conductor, and it will be found that the luminous pencil issuing from that point is turned sideway; viz. is repelled by the atmosphere of the tube. If the excited tube be held just opposite to the point, the luminous pencil will vanish entirely, because both the tube and the point are electrified positively. If the excited tube be brought near the point of the wire which proceeds from the rubber, the star upon it will turn itself towards the tube; for this wire is electrified negatively, and the tube positively. If instead of the tube, a stick of sealing wax, or any other electric possessed of the negative electricity, be used; then the pencil of light will be attracted by it, and the star will be repelled, or it may be entirely suppressed if the stick of sealing wax be placed directly before it.

Hitherto we have treated of experiments performed in the ambient air; but it is now necessary to add a brief account of the manner in which electric attraction and repulsion are affected in rarefied air.

Towards the end of the 17th century, Mr. Boyle observed, that excited electricities would attract in the vacuum of his air-pump; whence he concluded, that the presence, or absence of air, did not interfere with electric attraction. Not long after, Mr. Grey repeated Boyle's experiments with the

air-pump, and obtained a similar effect; but at that time the air pumps were very imperfect; their exhaustion was very moderate; and, of course, the conclusions from the experiments that were made within their receivers could not furnish much useful instruction. It seems that F. Beccaria was the first person who asserted, that in a perfect vacuum there would be no electric attraction. Lord Mahon suspended a cork-ball electrometer within the receiver of an air-pump, and electrified it. "I then (he says) began to exhaust the receiver; upon doing which, the balls soon began to divaricate gradually *less and less*. And as soon as the short barometer gauge was got down to about one quarter of an inch (the barometer being that day at the height of $29\frac{1}{2}$ inches), the divarication of the balls from each other became reduced to less than one quarter of an inch.

"So that by $\frac{1}{11\frac{1}{2}}$ parts of the natural quantity of air contained in the receiver being exhausted, the divarication of the electrometrical balls was diminished to less than one-tenth part. For the chord of the angle of divarication was decreased from above $2\frac{1}{2}$ inches to less than one quarter of an inch. That is to say, that the versed sine of the angle of divarication was decreased considerably more than an hundred times; because the versed sines are always as the squares of the chords.

"I should be inclined to imagine, if this experiment were made with great accuracy, and with a proper electrometer, that the versed sine of the angle of divarication would always be in the same ratio as the density of the air in the receiver, provided that proper means were taken to keep the apparatus sufficiently free from moisture during the experiments." Principles of Electricity, p. 10.

Mr. Cavallo describes a series of experiments which he made with an excellent air-pump, (Phil. Trans. vol. lxxiii.) from which he deduced the following conclusion. "It seems (he says) deducible from those experiments, that electric attraction and repulsion take place in every degree of rarefaction, from the lowest to about one thousand, but that the effect diminishes in proportion as the air is more rarefied; and by following this law, we may, perhaps, conclude with Beccaria, that there is no electric attraction, nor repulsion in a perfect vacuum; though this will, perhaps, be impossible to be verified experimentally, because, when in an exhausted receiver, no attraction, or repulsion, is observed between bodies to which electricity is communicated, it will be only suspected that those bodies are not sufficiently small and light. But, from reasoning, it seems likely that electric attraction and repulsion cannot take place in a perfect vacuum, by which I only mean a perfect absence of air. For either this vacuum is a conductor, or a non-conductor of electricity. If a conductor, and as much nearer to perfection as it becomes more free from air, it must be a perfect conductor at the same time that it becomes a perfect vacuum; in which case, electric attraction, or repulsion, cannot take place amongst bodies inclosed in it; for, according to every notion we have of electricity, those motions indicate, or are the consequence of the intervening space, in some measure, obstructing the free passage of the electric fluid. And if the perfect vacuum be a perfect non-conductor, then neither electric attraction nor repulsion can take place in it."

Such are the facts which have been observed respecting electric attraction and repulsion, either in the ambient, or in rarefied air. The only thing which now remains to be added, is a short account of the various explanations of these phenomena, which have been advanced, besides the explanation upon the Franklinian hypothesis, which has been already annexed to them.

When the knowledge of electricity was in its infancy, electricians supposed that certain *uniform effluvia* were emitted by excited electrics, and that these effluvia would adhere to all light bodies which happened to be in their way, and would carry them back to the electric. We need not lose time in endeavouring to manifest the absurdity of this hypothesis.

When Mr. Du Fay discovered the two opposite electricities, which he called the *vitreous* and the *resinous electricities*, the idea of two distinct electric fluids was naturally adopted. Each of these fluids was supposed to be elastic, *viz.* repulsive, with respect to its own particles, but attractive of the other fluid. These two fluids were supposed to be equally attracted by all bodies, and while they continue in their union to exhibit no mark of their existence. It was then imagined, that by the excitation of an electric, these two fluids were separated from each other, and one body became furcharged with one, while another body became furcharged with the other electric fluid. The two electric fluids being thus separated, would shew their respective powers, and their eagerness to rush into re-union with one another. When bodies are charged with either of these fluids, they are disposed to repel each other in consequence of the elastic nature of the fluid, be it the vitreous, or the resinous. But they are attracted by all other bodies, *viz.* they are attracted by bodies which have a lesser share of that particular fluid with which they are charged, and they are much more powerfully attracted by those bodies which are overcharged with the opposite fluid.

The theory of Æpinus is a modification of the Franklinian hypothesis. For he admits a single elastic electric fluid; but he thinks that all the particles of matter, when divested of their natural share of that electric fluid, must repel one another; for that otherwise (since all substances have in them a certain quantity of the electric fluid, the particles of which repel one another, and are attracted by all other matter), it could happen that bodies, in their natural state, with respect to electricity, should neither retract nor repel one another. According to this author, then, the repulsion of bodies negatively electrified, is in consequence of the repulsion existing between the particles of matter, which manifests itself when those particles are deprived of their natural share of electric fluid; for the mutual repulsive property of the particles of the electric fluid, and the mutual repulsive property of the particles of matter, seem to neutralize each other when combined, and to act when separated. ELECTRICAL Experiments. The history of the sciences clearly shews that the human species has obtained a much greater share of knowledge respecting the works of nature, within the last two hundred years, than during the twenty or more centuries preceding them. If it be inquired how came this great scientific advancement to be made in a period so very short, it will be found that this is entirely owing to

the happy substitution of experiments to opinions; or of matter of fact to the wanderings of the imagination. When the learner was accustomed implicitly to believe, and to repeat, the fanciful explanations of the teacher, errors and absurdities were propagated without the possibility of correction or of improvement. But when the student of nature adopted the motto of "Nullius in verba," and listened only to the results of experiments, or to the unerring mathematical deductions from those results, then the temple of science was raised with rapidity and triumph, by the accumulation of facts upon facts, which were firmly cemented by the strictest reasoning.

The science of electricity is a striking instance of the above-mentioned observation; for whatever is known of it has been acquired by means of a laborious experimental inquiry: and it is to be remarked, that the results of experiments have generally turned out different from any pre-conceived hypothesis. The general and comprehensive deductions which have been pointed out by the concurrence of many experiments are called the Laws of Electricity, and in mentioning these laws under their various denominations, we shall describe the experiments which are necessary for their demonstration; but there are several other experiments, which, though not absolutely necessary for the demonstration of these laws, are, nevertheless, either entertaining or useful in some other point of view; and these will be described in the present article.

Experiments relating to Electrics and Conductors.

The principal method of discriminating these two kinds of bodies from each other is described under the article

ELECTRICAL Attraction and Repulsion; but the following experiments will shew how to determine these and other analogous properties in particular cases, where the above-mentioned general method cannot be applied.

Experiment 1.—Mr. Henley's method of shewing the slight conducting power of smoke, and of the vapour of water.

Suspend a cork ball electrometer from the ceiling of a room, so as to stand about four or five feet above the conductor of an electrical machine; then put the machine in action very gently, so that the balls of the electrometer may not be affected by it. Stick a short piece of wax taper, just blown out, upon the prime conductor, and under the electrometer, so that the smoke may ascend to the latter. In this situation, if the machine be put in action as gently as before, the electrometer will open with the same kind of electricity with which the prime conductor is charged, which shews that the smoke is a conductor in a small degree. If, instead of the wax taper, a metallic vessel full of hot water be placed upon the conductor, and the machine be put in action as before, the electrometer will also be caused to diverge, shewing that the vapour of the water is a partial conductor.

Experiment 2.—To prove that certain electrics become conductors when they are made very hot.

Take a glass tube of about one-twentieth of an inch in diameter, and above a foot in length; let it be hermetically closed at one end, and introduce a wire in it, so as to be extended through its whole length. Let two or three inches of this wire project above the open end of the tube, and there fasten it with a cork. Above the closed end of the tube another wire, which will be separated from the wire within the tube by the thickness of the glass tube. In these circumstances, if you endeavour to lend a shock through the two wires, (*viz.* the wire within the glass tube, and that which is twisted on the outside of it,) by connecting one of them with the outside, and the other with the knob of a charged Leyden phial, you will find that the discharge can-

not be made unless the tube be broken, because the circuit is interrupted by the thickness of the glass at the end of the tube, which is interposed between the two wires. But put that end of the tube to which the external wire is fastened into the fire, heating it gradually until it becomes barely red hot; then endeavour to discharge the jar again through the wires, and you will find that the charge is easily transmitted from wire to wire, through the substance of the glass, which, by being made red-hot, is become a conductor.

When the conducting power of hot resinous substances, oils, &c. is to be examined, bend a glass tube in the form of an arch C E F D, *fig. 34.*, and fasten a silk string G C D to it, which serves to hold it by when it is to be set near the fire. Fill the middle part of this tube with the substance in question, be it rosin, sealing-wax, &c.; then introduce two wires A E, B F, through the apertures, so that they may touch the rosin, &c. or penetrate a little way into it. This done, let a person hold the tube, by the silk string G, over a clear fire, so as to melt the rosin, or other substance, in it; and at the same time, by connecting one of the wires, A or B, with the outside of a charged Leyden phial, and touching the other wire with the knob of the phial, endeavour to make the discharge through the rosin, and it will be found, that while the rosin is cold no charge can be transmitted through it. As the rosin melts, the conducting power will begin to be manifested, and when the rosin is quite melted, the shocks will pass freely through it.

Experiment 3.—To try the conducting or non-conducting property of hot air.

The conducting property of air has by no means been fully determined, but the reader may form what judgment he thinks proper upon the following facts.

Electrify an insulated cork ball electrometer, or electrify the prime conductor of an electrical machine, when the quadrant electrometer is set upon it; then bring a red-hot iron within less than an inch distance from the electrometer, or prime conductor, and either of them will soon lose its electricity, which is conducted by the hot air contiguous to the iron; for if the experiment be repeated with the same iron when cold, the electricity will not be conducted away. It has been observed, that a battery may be discharged by introducing a red-hot iron between two knobs communicating with the inside and outside coating of the battery, and standing at some distance from each other. But if, instead of iron, there be introduced a piece of red-hot glass between the two knobs, (the distance between them remaining as at first,) then the battery cannot be discharged; whence we may infer, that either hot air is not so good a conductor as has been generally believed, or that air heated by iron (perhaps in consequence of its containing ignited iron particles) is a better conductor than when heated by red-hot glass.

Mr. Read endeavours to prove that hot air is not a conductor, and his experiments we shall now subjoin in his own words.

"It has been also commonly said that hot air conducts electricity. With a view to ascertain this matter, the following experiments were made: To one end of a long piece of wood (which served as a handle) was fixed a glass rod fifteen inches long; to the remote end of the glass was fixed a pith-ball electrometer. Having electrified the balls, I held them by the wooden handle, and projected them into a large oven, immediately after the fire was drawn out of it; the consequence was, that when I performed the operation slowly, the balls lost their electricity; but that when done quick, with as little delay as possible, their electric charge was not diminished. The electricity, in the first case, was found to have escaped along the glass into the wooden handle,

dle, and so to the earth owing to the great heat the glass rod had acquired, by which it became a conductor of the fluid, for until it had cooled a little, the balls could not be charged again.

"I shall lay before the reader one circumstance more, because it may tend to throw light on what degree of heat the oven was in at the time the observations were made. The baker having pointed out to me the hottest part of the oven, with a quick motion in and out, I plunged the electrified balls into that part of it, by which one thread and ball was burned off, but the remaining ball shewed that it still retained its electric charge, because it was strongly attracted on the approach of my finger." *Read's Summary View of Spontaneous Electricity*, p. 8.

Experiment 4.—To shew that metallic substances conduct the electric power through their substance.

Take a wire of any kind of metal, and cover part of it with some electric substance, as rosin, sealing-wax, &c.; then discharge a Leyden phial through it, and it will be found that the wire conducts as well with as without that electric coating.

Experiment 5.—To shew that the fluids of the human body are better conductors of electricity than water.

Take a glass tube, about one-fourth of an inch in diameter, and about six inches long, or rather take two such tubes, exactly equal in length and diameter, and holding one of them with one extremity in water, let it be filled with that fluid. The water will soon fill the tube, in virtue of the capillary attraction, especially if the tube be held inclined to the surface of the water. After the same manner let the other tube be filled with blood, or some other fluid of the human body. Now let an electric jar be charged, and let the circuit through which the jar is to be discharged be formed by the interposition of one of those tubes, (to the extremities of which slender wires may be fitted, so as just to touch the fluid contained in it,) and likewise by the interposition of a person who may be desirous of trying the experiment. In this manner, if the discharge of the jar be made several times, alternately changing the glass tube, *viz.* using once that which is filled with water, then the other which is filled with blood, &c., it will be found that the shock is felt more sensibly when the glass tube filled with the animal fluid forms part of the circuit, than when the tube filled with water is used.

The person who tries this experiment needs not be afraid of the shocks, because their force is much weakened by passing through that small quantity of fluid which is contained in the glass tube. Besides, the strength of the shocks should not be greater than may be just felt. It is only necessary to charge the Leyden phial always equally high, which is easily done by using Mr. Lane's discharging electrometer. See *DISCHARGER of electricity*.

After the same manner the degree of conducting power of various substances may be ascertained. Thus it may be observed, that sea-water conducts better than fresh water, and that common fresh water conducts better than distilled water. The conducting powers of certain powders may also be tried in this manner.

Experiment 6. To determine the different conducting powers of metallic substances.

Connect with the hook, which communicates with the outside coating of a battery, containing at least thirty square feet of coated surface, a wire of about one-fiftieth part of an inch in diameter, and about two feet long. The other end of the wire must be fastened to one end of the discharging rod; this done, charge the battery, and then, by bringing the discharging rod near its wires, send the explosion

through the small wire, which by this means will be made red-hot, and melted, so as to fall upon the floor in different glowing pieces. When a wire is melted in this manner, sparks are frequently seen at a considerable distance from it, which are red-hot particles of the metal, that by the violence of the explosion are scattered in all directions. If the force of the battery be very great, the wire will be entirely dispersed by the explosion, so that none of it can afterwards be found.

By repeating this experiment with wires of different metals, and using the same force of explosion, it will be found that some metals are fused more readily than others, whilst some are not sensibly affected; which shews the difference of their conducting powers. But in conducting such experiments, the power of the battery must be adjusted to the size of the wires, which must be of equal diameters and lengths. It is also to be remarked, that when every thing is properly adjusted, and the battery is charged always equally high; some wires are melted through their whole length, whilst others are barely melted at their extremities, or are only rendered red-hot.

No person seems to have succeeded so well as Mr. Van Marum in the determination of the conducting powers of metallic substances; for which purpose he employed the famous electrical machine belonging to the museum of Teyler, and an electrical battery, which contained 225 square feet of coated surface. Mr. Van Marum had wires of different metals drawn of the same diameter, which was equal to one-thirty second part of an inch; and, by exposing equal lengths of them successively to the above-mentioned battery, which was charged equally high in every experiment; he found, that of the leaden wire 120 inches were melted, of tin wire the like quantity, of iron wire five inches were fused, of gold wire three inches and a half, and of silver wire, or brass, or copper, a quarter of an inch only was melted, which shews a pretty good estimate of their fusibility by the action of electricity, whence the conducting power may be inferred, by considering this to be in the inverse ratio of their fusibility.

In order to compare this electrical fusibility of the metallic substances with their fusibility by the common fire, we shall now add the latter; which, according to the academicians of Dijon, is as follows.

Tin melts at 170° of Reaumur's thermometer.

Lead	-	230
Silver	-	450
Gold	-	563
Copper	-	630
Iron	-	696

According to Mr. Wedgwood's experiments,

Brass melts at 3807° of Fahrenheit's thermometer.

Swedish copper 4587

Fine silver - 4717

Fine gold - 5237

Cast iron - 17,977. *Phil. Trans.* vol. 72.

From the above-mentioned and other electrical experiments, made with the same electrical machine and battery, Mr. Van Marum deduces the following conclusions, *viz.* that lead is the worst, and upon the whole, copper is the most eligible metal for the construction of a conductor of lightning.—That he could not possibly determine the proportion between the lengths and diameters of metallic wires, that could be melted by the power of the Teylerian machine.—That iron, tin, and copper, were melted into globules; but this was not the case with the other metals.—That the metallic globules were sometimes thrown to the distance of thirty feet and upwards.—That the globules of tin remained red-hot

red-hot for about eight or ten seconds; and that when the wires were very long, the fusion was but partial.

Mr. Van Marum had the curiosity of trying whether the metallic wires could be fused and calcined in water; *viz.* by sending the charge of the battery through them whilst standing under water; and he succeeded whenever he used the eighth part of that length of wire, which would have been calcined if the experiment had been performed in air.

The facility with which iron and steel are fused by means of electricity, and the violence with which small particles of them burn, renders them peculiarly useful in entertaining experiments. The filaments produced in turning articles of steel are so very readily ignited by an electric shock, that some of the finest of them may be burned by the discharge of a six ounce coated phial, or even a smaller one. They may be also burned by a single spark from a large prime-conductor.

Experiment 7. To show that the focus of a burning glass is not a conductor of electricity.

Let a wire, that proceeds from the outside of a charged Leyden phial, come within an inch of the knob of that phial, or, in short, to as to be very little farther from it than the striking distance. Let then the focus of the solar rays, that are collected by a lens or mirror, fall midway between the knob of the phial and the wire which proceeds from its outside, and it will be found that the charge of the phial is by no means dissipated; whereas if the flame of a candle, or any other conductor, be interposed between the knob and the wire, the discharge will take place immediately. This experiment seems to corroborate the supposition, that the rays of the sun, or of light in general, have no heat in themselves, but that they only extricate the caloric from such bodies as they happen to fall upon, provided those bodies obstruct their course and are not transparent.

Experiments relating to electric Attraction and Repulsion.

The laws of electric attraction and repulsion are as follow. Bodies possessed of the same kind of electricity (whether positive or negative) repel each other; but bodies possessed of different kinds of electricity attract each other. See the article *ELECTRIC Attraction and Repulsion.*

Experiment 1. The dancing images.

Fig. 35. represents two flat circular plates, either of brass or copper, about six inches in diameter. The plate A is suspended horizontally from the prime conductor by means of a chain, or wire. The lower plate B, which is generally made a little larger in diameter, is situated parallel to the former at the distance of about three inches. This lower plate is fixed to the stand C, so that it may be raised higher or lower, which is accomplished by the following simple construction. A smooth and straight wire is rivetted in the centre of the plate B, and moves in a hole made through the axis of the stand C, which, by being slit along an inch or two from the top, is rendered springy, so as to hold the above-mentioned wire pretty tight in any situation. The stand C rests upon the table, &c.

Place any kind of light bodies upon the lower plate B, such as bran, bits of paper, pieces of gold-leaf, &c. then work the electrical machine which stands contiguous to the other end of the prime conductor, and the light bodies will soon move between the two plates, leaping alternately from the one to the other with considerable velocity. If instead of bran, or irregular pieces of other matter, small figures of men and other things cut in paper, and painted, be put upon the lower plate, these will generally move in an erect position, but will sometimes leap one upon another, or will

exhibit different postures, affording a pleasing entertainment to an observing company. In this experiment both the attraction and the repulsion are observed at the same time; and the reason of these phenomena is explained in the article *ELECTRIC Attraction and Repulsion.*

Experiment 2. The electric well.—Place upon an insulating stand a metal quart mug, or some other conducting body nearly of the same form and dimensions. Fasten a short cork-ball electrometer to the extremity of a silk thread that proceeds from the ceiling of the room, or from some convenient stand, so that the electrometer may be suspended within the mug, and no part of it may be above the aperture thereof. This done, electrify the mug, by giving it a spark with an excited electric or other wire; and you will find that the electrometer, whilst it remains in that insulated situation, even if it be made to touch the sides of the mug, is not attracted by it, nor does it acquire any electricity; but if, whilst it hangs suspended within the mug, a conductor, standing out of the mug, be made to communicate with the electrometer, or is only presented to it, then the electrometer acquires an electricity contrary to that of the mug, and is of course immediately attracted by it.

The reason why, in this experiment, the electrometer contracts no electricity, whilst it remains suspended entirely within the cavity of the mug, is that the electricity of the mug acts upon the electrometer on all sides, hence the electrometer has no opportunity of paring with its electric fluid, when the mug is electrified positively; nor of receiving any, when the mug is electrified negatively. But as soon as any conductor communicates with it, the electrometer becomes immediately possessed of the electricity contrary to that of the mug, &c. If, by raising the silk thread a little way, part of the electrometer, *viz.* of its linen threads, be lifted just above the mouth of the mug, the balls will be immediately attracted; for in this case the action of the electricity of the mug will enable the electrometer to receive from, or to impart to, the contiguous air, some electric fluid; or else the electric fluid of the balls may be crowded upon that part of the linen threads which project above the aperture of the mug, &c. hence the balls will acquire an electricity contrary to that of the mug, and will of course be attracted by it.

The electricity which is communicated to the mug resides entirely upon its external surface, for the air contiguous to it can easily acquire the contrary electricity; but no electricity can be manifested on the internal surface of the mug, because the air within that cavity, being entirely surrounded by the electrified mug, cannot acquire the contrary electricity, excepting towards the aperture of the mug, where in fact a little electricity is to be observed.

Experiment 3. The electrified capillary stream.—Let a small metallic bucket, nearly full of water, be suspended to the prime conductor, and let the water proceed from it. drop after drop, either by means of a glass capillary syphon, as represented in *fig. 36*, or by means of a hole in the bottom, as represented in *fig. 37*. In this disposition, if the electrical machine be put in action, the water, which, when not electrified, only dropt from the aperture, will now run in a full stream, which will even be subdivided into other smaller streams; and, if the experiment be made in the dark, it will appear beautifully illumined. The abbé Nollet, who made a vast number of experiments respecting this electrified stream, as well as on the action of electricity in evaporations, obtained the following results.

The electrified stream, though it divides, and carries the liquid a great way, is neither sensibly accelerated nor retarded, when the pipe through which it issues is not less than a French line in diameter.

Under this diameter, if the tube is wide enough to let the liquid run in a continued stream, electricity accelerates it a little, but less than a person would imagine, if he judged by the number of jets which are formed, and by the distance to which they go.

If the tube be a capillary one, from which the water only drops naturally, the electrified jet not only becomes a continued stream, and even divided into several streams, but is also considerably accelerated; and the smaller the capillary tube is, the greater, in proportion, is the acceleration.

So great is the effect of the electric virtue, that it drives the water in a constant stream out of a very small capillary tube, out of which it had not before been able even to drop.

Electricity augments the natural evaporation of fluids, for, excepting mercury and oil, all the others that were tried suffered a diminution, which could not be ascribed to any other cause than electricity.

If it be communicated to insulated fruits, fluids, and, in general, to bodies of every kind, which are actually in a state of evaporation; it increases that evaporation in a greater or lesser degree, according as those bodies are naturally more or less evaporable, according as the vessels which contain them are conductors or electric, and as they expose a greater or lesser surface to the open air. But from some very accurate experiments made by M. De Saussure with his hair hygrometer, it appears that the electricity promotes the evaporation of those bodies which are supersaturated with water, but not of those which do not contain a superabundant quantity of it.

Experiment 4. The electrified bells.—A short description of this experiment is contained in the article BELL, but inadvertently, without referring to the figure; we shall therefore supply the defect in this place, and shall add some other varieties of this entertaining apparatus. *Fig. 38. Plate V.* represents the bell apparatus in its simple and original state. *A B* is a piece of brass to which the three brass bells *C, E, G*, and the two brass balls, or clappers, *D, F*, are fastened; the two bells *C* and *G* being suspended by brass chains; and the middle bell with the two clappers being suspended by silk threads. A chain likewise proceeds from the inside of the middle bell *E*, and falls upon the table. This machinery is suspended at the end of the prime conductor by passing the knobbed wire, which is usually affixed thereto, through the hole *H*.

Fig. 39. is another mode of mounting the bells. The pillar *A* is of glass; the horizontal wires at the top of it are of brass, and are fastened to the brass ball *a*. The four bells *o, o, o, o*, are suspended to the extremities of the horizontal wires by means of wires or chains; the four clappers are suspended by silk threads; and the middle bell *c* is fixed to the stand which is a conductor. When this apparatus is to be used, it must be placed upon a table with the knob *a* in contact with the prime conductor. In that situation, if the electrical machine be put in action, the four bells *o, o, o, o*, becoming electrified, attract the clappers; these become electrified and are repelled by those four bells, and strike against the middle bell *c*, upon which they deposit their electricity, and are then again attracted by the four bells, &c. so that the ringing continues as long as the electrical machine is kept in action.

Fig. 40. represents another set of bells, in which the bells are differently tuned, and they are struck successively by the same clapper. These bells are fixed all round the bottom board *b i k*, from the middle of which a glass pillar rises, to the top of which a pointed wire is fastened, and upon this wire the flyer *b c d* rests, like the magnetic needle of a com-

pass. (The nature of this flyer will be shewn in the sequel of this article.) From one arm of the flyer a wire proceeds, which nearly reaches the bottom board, and a clapper, suspended by a silk string, is fastened to the same arm of the flyer between the wire *g* and the apex *d*. To use this apparatus, the prime conductor must be removed from the electrical machine, and the bell apparatus is placed so, that the flyer *b c d* may come very near the cylinder of the machine. In this situation, if the machine be worked, the electricity of the cylinder will cause the flyer to turn in a direction contrary to the pointed extremities of its arms, and at the same time the clapper will successively strike each of the bells and the vertical wire *g*, the reason of which may be easily derived from what has been said above respecting the other bells.

Experiment 5. The artificial spider seemingly animated by electricity.—*Fig. 41.* represents a Leyden phial, to the outside of which the brass hoop and arm *a b c* is fixed. The ball *e* of this brass arm rises to the same level as the ball *d*, which communicates with the inside coating of the phial; *e* is an artificial spider made of cork, with a few short threads run through, to represent its legs. This spider is suspended by a silk thread, which proceeds from the ceiling of the room, or from any other convenient support, so that the spider may hang mid-way between the two balls *d* and *e*, when the Leyden phial is not charged. Let the place of the phial upon the table be marked; then charge this phial by putting its ball *d* in contact with the prime conductor, &c. and replace it in the above-mentioned situation. The spider will now begin to move from one ball to the other, and back again, and will continue this motion for a considerable time; sometimes for several hours.

The inside of the Leyden phial being charged positively, the spider is attracted by the ball *d*, which communicates to it a small quantity of electricity; the spider then becoming possessed of the same kind of electricity as the ball *d*, is repelled by it and is attracted by the ball *e*, whereupon it deposits its electricity, and is afterwards attracted again by *d*, and so on. In this manner the phial is gradually discharged.

Experiment 6. To spin sealing-wax by means of electricity. Stick a small piece of sealing-wax on the extremity of a wire, and warm it so as to render it ready to drop; and at the same time let the electrical machine be worked; then stop the motion of the machine, and instantly bring the hot sealing-wax within four or five inches of the prime conductor, moving it about in a winding circuit, and you will find that the sealing-wax throws several exceedingly fine threads to the prime conductor, which appear like red wool. This experiment answers best when the conductor is covered with varnish.

Mr. Adams describes this experiment in the following manner. "Stick," he says, "a piece of sealing-wax on the conductor, in such a manner as it may be easily set on fire by a taper. While it is flaming, turn the cylinder, the wax will become pointed and shoot out an almost invisible thread into the air, to the length of a yard and more. If the filaments that are thrown out by the wax are received on a sheet of paper, the paper will be covered with them in a very curious manner, and the particles of the wax will be so far sub-divided as to resemble fine cotton. To fasten the piece of wax conveniently to the conductor, stick it first on a small piece of paper, then twist the end of the paper so as to fit one of the holes which are made in the prime conductor; when it is thus placed, it may be easily fired by a taper."

ELECTRICAL.

Experiment 7. The dancing balls.—Fix a pointed wire upon the prime conductor, with the point outwards; then take a glass tumbler, grasp it with your hands, and present its inside surface to the point of the wire upon the prime conductor, while the electrical machine is in motion. By this means the glass tumbler will soon become charged; for its inside surface acquires the electricity from the point, and its outside loses its natural quantity of electric fluid through the hands, which serve as a temporary coating. This done, put a few pith-balls upon the table, and cover them with the charged glass tumbler. The balls will immediately begin to leap up along the sides of the glass, as represented in *fig. 42*; and will continue that motion for a considerable time.

In this experiment the pith-balls are attracted and repelled by the electrified inside surface of the glass, the electricity of which they gradually conduct to the table, or other conducting body, upon which the glass is set; at the same time that the contrary electricity of the external surface of the glass is communicated to the surrounding air.

Experiment 8. The electrified head of hair.—If a person, having pretty long hair, not tied up, upon his head, be placed upon an insulating stand, and by means of a wire, or chain, or by touching it with his extended hand, be connected with the prime conductor, and the electrical machine be put in action, the hairs on his head, by repelling each other, will stretch out in a surprising manner. Instead of a human being, a small wooden head, covered with hair, is placed upon the prime conductor, and, on working the machine, the hair will be all stretched out, like the rays diverging from a centre. The same thing will take place if a downy feather, or a bundle of threads, tied up at one end, like a tassel, be fixed to the prime conductor.

Experiment 9. The metallic leaf suspended in the air.—Cut a piece of gold, or silver, or brass leaf, in the form of a square, or of a lozenge, like *A*, *fig. 43*; place it upon a broad metallic plate *B*, and hold the plate under the ball of the wire, which is usually fixed to the end of the prime conductor. On working the machine, the metallic leaf will rise from the plate *B*, and will remain suspended between that plate and the ball *C*, with one point, or angle, towards the one, and the opposite towards the other, without touching either. This effect is owing to the action of the points of the leaf; for the point enables the leaf to absorb the electric fluid from the prime conductor, without actually touching it, and the opposite point discharges that fluid upon the plate *B* also without actual contact. If the plate *B* be moved round the ball *C*, as represented at *D*, the leaf will also move round without touching either ball or plate.

Experiments relating to electric Light.

The two electricities produce peculiar luminous appearances, which are particularly described under the article **ELECTRIC LIGHT**; but it is necessary in this place barely to mention, that a pointed conductor, proceeding from a body positively electrified, is, in the dark, illuminated with a pencil of light; but, if the body be electrified negatively, the point will be illumined with a star, or globe of light, provided the electrified body is electrified powerfully enough. If a pointed conductor be presented to an electrified body, the above luminous appearances are reversed; viz. a pencil of light will appear upon the point when the body is electrified negatively, and a star when the body is electrified positively.

Experiment 1. The spiral tube.—*Fig. 44.* represents an instrument composed of two glass tubes *C*, *D*, one within the other, and closed with two knobbed brass caps *A* and

B. The innermost of these tubes has a spiral row of small round pieces of tin-foil, stuck upon its outside surface, and lying at about one-thirtieth of an inch from each other. If this instrument be held by one of its extremities, and its other extremity be presented to the prime conductor, every spark that it receives from the prime conductor will cause small sparks to appear between all the round pieces of tin-foil that are stuck upon the inner tube, which, in a dark room, affords a pleasing spectacle; the instrument appearing encompassed by a spiral line of fire.

The small pieces of tin-foil are also stuck upon a flat plate of glass, so as to represent curve lines, flowers, letters, &c. and they are illumined after the same manner as the spiral tube. But the best way of exhibiting a luminous word is to stick a long slip of tin-foil, in a zig-zag manner, upon a flat plate of glass, one end of this slip communicating with a brass knob on one of the glass plates, and the other extremity communicating with a hook, or another brass ball on the opposite side of the glass. The letters are formed by cutting small interstices in the parallel slips of tin-foil. A plate of this sort is represented in *fig. 45*, where *b* is the hook to which a chain is suspended, and *C* is the brass ball which, being presented to the prime conductor, receives the sparks, &c.

If the surface of the glass plate, opposite to that upon which the tin foil is stuck, is pointed with different transparent colours, the sparks will appear tinged of the colours through which they are seen.

Experiment 2. The artificial Bolonian stone, and other phosphorescent substances, illumined by the electric light.

The penetrability of the electric light is shewn in a very striking manner, either with the real, or with the artificial Bolonian stone, which was invented by Mr. Canton, and is prepared in the following manner. "Calcine some common oyster-shells, (if they be old, and half calcined by time, as are commonly found upon the sea-shore, they are much better for this purpose,) by keeping them in a good coal-fire for half an hour. Let the purest part of the calx be pulverized and sifted; mix three parts of this powder with one part of flowers of sulphur; let this mixture be rammed into a crucible of about an inch and a half in depth, till it be almost full; and let it be placed in the middle of the fire, where it must be kept red hot for one hour, at least, and then set it by to cool: when cold, turn it out of the crucible, and cutting, or breaking it to pieces, scrape off, upon a trial, the brightest parts, which, if good phosphorus, will be a white powder, and may be preserved by keeping it in a dry phial well stopp'd."

If this phosphorus, whether in or out of the phial, be kept in the dark, it will not give any light; but if it be exposed to the light either of the day, or of any luminous object, and be afterwards brought into a dark place, it will then appear lucid for a considerable time. When good, about a quarter of an ounce of this phosphorus, in a two-ounce phial, will, after having been exposed to the light, and then brought into a dark place, afford light sufficient for reading the hour upon a watch. For farther particulars respecting this phosphorus, see the 58th vol. of the Phil. Trans. See **BOLONIAN STONE** and **PHOSPHORUS**.

If the phial containing some of the above described phosphorus be held near the prime conductor, when a few strong sparks are drawn from it, within three or four inches of the phial, in a dark room; the phosphorus will be illumined by them, and will afterwards continue to shine for about three or four minutes, the light, however, gradually decreasing. This is the simplest way of exhibiting this phosphorus; but, with very little trouble, various curious preparations

preparations may be made with it, which we shall now proceed to describe, observing, once for all, that though strong sparks will illuminate this phosphorus sufficiently well, when taken near it; yet the light which is afforded by the discharge of a Leyden phial will produce the effect in a superior manner.

This phosphoric powder may be stuck upon a board by means of the white of an egg, so as to represent figures of the planets, letters, or any thing else at pleasure; and these representations may be illumined in the above-mentioned manner.

A beautiful method of expressing geometrical figures with the above-mentioned phosphorus is as follows. Bend small glass tubes, of about the tenth part of an inch in diameter, in the shape of the intended figures, and then fill them with the phosphoric powder. These tubes, so filled, may be illumined in the manner already described, and they are not nearly so subject to be spoiled as the figures represented upon a board.

When this phosphorus is stuck uniformly upon a card, place a small key upon it, and discharge a Leyden jar very near it, in a dark room. This done, lay hold of the card by one corner, and throw off the key. The phosphorus will appear illumined all over the card, excepting where the key stood, and the representation of the key will be so exact, that a spectator will hardly believe that the key has been removed.

When oyster-shells are thrown carelessly into the fire, and are kept therein different lengths of time, they acquire different degrees of phosphoric power, and some of them, when afterwards illumined by the electric light, will exhibit the prismatic colours in a beautiful manner. But besides the oyster-shells, almost all calcareous substances, when dry and hot, and especially when burned to lime, have the property of being illumined by the discharge of a Leyden phial passed over their surfaces; and of continuing to shine for about a few seconds, or a minute, or even longer. Paper, or a card, made very dry and hot, has the same property. When a jar is discharged through a piece of loaf-sugar, the sugar is generally broken, and every piece is beautifully illumined.

Experiment 3. The aurora borealis, and Leyden vacuum.—Take a phial nearly of the shape and size of a Florence flask; fix a stop-cock to its neck, and exhaust the air out of it by means of the air-pump. If this phial be rubbed in the common manner, such as is used for exciting electrics, it will appear luminous within, being full of a flashing light, which much resembles the aurora borealis, or northern lights. This phial may also be rendered luminous, by holding it by either end, and bringing the other end to the prime conductor, when the electrical machine is in action. In this case, all the cavity of the phial will instantly appear full of a flashing light, which remains in it for a considerable time after it has been removed from the prime conductor. And it is to be remarked, that if the phial, after it has been removed from the prime conductor, (and even several hours after its flashing light has ceased to appear,) be grasped with the hand, strong flashes of light will immediately appear within it, which often reach from one of its extremities to the other.

There are two causes upon which this experiment depends. The first is the conducting nature of the vacuum, and the second is the charging and discharging of the glass; for when the outside of the glass phial is put in contact with the prime conductor, the electric fluid, which is communicated to the outside of that part of the phial, causes the natural fluid belonging to the inside surface to depart from its place, and to go to the opposite side of the phial; and

this fluid, by passing through the partial vacuum, causes the light within the phial, which light is more or less subdivided, according as the vacuum is more or less perfect. Now, that part of the phial which has touched the prime conductor is actually charged; for its outside surface has acquired an additional quantity of electric fluid, and the inside surface has lost part of its own; but since the outside of the phial has no coating, therefore, when it is removed from the prime conductor, and is not grasped with the hand, or other conductor, the charged part of the glass can only be discharged gradually; that is, whilst its outside surface is communicating its superfluous fluid to the contiguous air, the inside surface acquires that fluid from the other end of the phial, and the passage of this fluid through the vacuum causes the flashing. When the phial is grasped with the hand then its discharge is accelerated.

When a phial of this sort is coated with tin-foil on its outside for about three or four inches, it is then called the Leyden vacuum, it being, in fact, an exhausted Leyden phial. The *figs.* 46. and 47. represent this phial in its best construction. A brass ferrule, having a hole with a valve, is cemented to the neck of this phial, and a round brass cap is screwed over it. A wire, terminating in a point, though not a very sharp one, proceeds from the ferrule a short way within the phial. The inside of this phial requires no coating, on account of the conducting nature of the vacuum.

This phial clearly exhibits the direction of the electric fluid, both in charging and discharging; for if it be held by its coated lower part, and its brass knob be presented to the prime conductor positively electrified, a pencil of light will be seen to proceed from the point of the wire, as in *fig.* 46; and when it is discharged, a star or globe of light will appear in the place of the pencil, as in *fig.* 47. If the phial be held by its brass cap, and its coated part be presented to the prime conductor; then the point of the wire in its inside will appear illumined with a star when charging, and with a pencil when discharging. If it be presented to a conductor negatively electrified, these appearances will be reversed.

Experiment 4. The luminous conductor.—*Fig.* 48. represents a prime conductor invented by the late Mr. Henley, for the purpose of showing the direction of the electric fluid by the appearances of its light. The middle part E F of this conductor consists of a glass tube about eighteen inches long, and three or four inches in diameter. To both ends of this tube brass pieces F D, B E, are cemented air-tight, one of which has a pointed wire C, which serves as a collector to receive the electric fluid from the machine, when the instrument is set near it, and the other has a knobbed wire G, from which a strong spark may be drawn; and from each of the pieces F D, B E, a knobbed wire proceeds within the cavity of the glass tube. One of the brass pieces, *viz.* either F D or B E, is composed of two parts; that is, a cap F, which is cemented to the glass tube, and has a hole with a valve by which the cavity of the glass tube may be exhausted of air; and the ball D, which is screwed upon the cap F. The supporters of this instrument are two glass pillars fixed into the bottom board H, and screwed to the brass caps, or having at their upper extremities two semi-circular hollows, upon which the conductor is barely laid. When the glass tube of this conductor has been exhausted by means of an air-pump, and the brass ball is screwed on, as represented in the figure, then it is fit for use, and may serve for a prime conductor to an electrical machine.

If the point C of this conductor is set before the excited glass cylinder of the machine, it will appear illumined with a star; at the same time the glass tube will appear throughout illumined with a weak light; but from the knobbed wire,

wire, that proceeds from the piece FD, within the glass tube, a brighter lucid pencil issues, and the opposite knob appears illumined with a star or round body of light, which, as well as the pencil of rays, is very clear, and discernible amidst the other light, which occupies almost the whole cavity of the glass tube. If the point C, instead of being presented to the excited cylinder, be connected with the rubber of the machine, the appearances of the light within the tube EF will be reversed; the knob which communicates with the brass piece FD appearing illumined with a star, and the opposite one with a pencil of rays; because in this case the direction of the electric fluid is just the contrary of what it was before, it then going from D to B, and now coming from B and going to D. If the wires within the tube EF, instead of being furnished with balls, (which, however, need not be large,) be pointed, the appearances of the light will be the same, but not quite so strong in this as in the former case.

Experiment 5. The visible electric atmosphere.—The following curious experiment is described by the celebrated Beccaria; but it seems that few persons have been able to repeat it with success; probably owing to the great delicacy and caution with which it must be conducted.

G I, in fig. 49, represents the receiver with the brass plate of an air-pump. In the middle of the plate FI a short metallic rod is fixed, bearing a metallic ball B, nicely polished, and about two inches in diameter. From the top of the receiver another rod AD proceeds, which is furnished with a like ball A, and is cemented air-tight into the neck C of the glass receiver. The distance between the two balls A and B is about four inches, or rather more. When the receiver is exhausted of air, if the ball A be electrified positively, by touching the top D of the rod AD with the prime conductor, or with an excited glass tube, a lucid atmosphere will appear about it, which, though it consists of a feeble light, is, however, very conspicuous, and very well defined; at the same time that the ball B has not the least light about its surface. The atmosphere does not exist all round the ball A; but it reaches from about the middle of the ball, to a small distance beyond that side of its surface which faces the opposite ball. If the rod with the ball A be electrified negatively, then a lucid atmosphere, like that which has been described above, will appear upon the ball B, reaching from its middle to a small distance beyond that side of it which faces the ball A; and at the same time the ball A, which is electrified negatively, remains destitute of light.

In this experiment the operator must take care not to electrify the ball A too much, for in that case the electricity will pass in the form of a spark from one ball to the other, and the experiment will not have the desired effect.

Experiments to be performed with the Leyden Phial and the electrical Battery.

The properties of the Leyden phial are enumerated and explained under the article of that name, which see.

Experiment 1. To pierce a card, and other substances by the discharge of a Leyden phial, or charged jar.—Take a card, a quire of paper, or the cover of a book, hold it close to the outside coating of a charged jar; put one knob of the discharging rod upon the card, or quire of paper, &c. so that between the knob and the coating of the jar the thickness of that card, or quire of paper only, may be interposed; then by bringing the other knob of the discharging rod near the knob of the jar, make the discharge; and the electric matter rushing through the circuit, from the positive to the negative surface of the jar, will pierce a hole,

and often more than one hole, quite through the card or quire of paper. This hole, or holes, are larger or smaller, according as the card, &c. is more damp or more dry. It is to be remarked, that if the nozzles be presented immediately to it, they will be affected with a smell somewhat like sulphur or phosphorus, and like that which is produced, though not so strongly, by an excited electric. This hole has a burr raised on each side, excepting when the card has been pressed too hard between the discharging rod and the jar, which shews, that the hole is made not in the direction of the electric fluid, but in every direction from the centre of the resisting body.

If this experiment be performed with two cards instead of one, which two cards, however, must be kept very little distant from each other, (which may be easily effected by bending a little one of the cards;) each of the cards, after the discharge, will be found pierced with one or more holes, and each hole will be found to have burrs on both surfaces of each card.

If instead of paper, a very thin plate of glass, rosin, sealing-wax, or the like, be interposed between the knob of the discharging rod, and the outside coating of the jar; on making the discharge, this will be broken in pieces. Small insects may be killed in this manner. They may be held between the outside coating of the jar and the knob of the discharging rod, like the above-mentioned card; and a shock from a common Leyden phial, sent through one of them, will instantly deprive it of life, if the insect be very small; but if larger, it will be stunned for a time, but it will afterwards revive. This, however, depends on the quantity of the charge and size of the jar, as well as the size of the insect. In this experiment if the insect, discharging rod, &c. be not managed properly, the charge of the jar will pass through, but over the insect, in which case it will not produce the desired effect.

Experiment 2. To stain paper, or mark glass by the discharge of the Leyden phial.—Lay a chain, that forms part of the circuit between the two coated sides of a charged jar, upon a sheet of white paper, and after having made the discharge, the paper will be found tinged with a blackish tinge at the places which corresponded to the junctures of the links. If the charge be very great, the paper, instead of being stained with spots, will be found burned quite through. If the chain be laid upon a pane of glass, this will, after the discharge, be found marked with indelible spots, but not so strongly as the paper.

When this experiment is performed in the dark, a spark is seen at every juncture of the links of the chain, and each spark is attended with a kind of radiation, as if particles of the metal in an ignited state were thrown off. When the links are small, and the charge of the jar is pretty high, the chain, on making the discharge, appears like a continued luminous line; which evidently shews that the electric fluid meets with some resistance, or obstruction, in passing from one link of the chain to another.

Experiment 3. To burst small glass tubes by means of a Leyden phial.—Take a narrow glass tube, viz. less than a tenth of an inch in diameter, fill it with water, and insert a wire at each opening of the tube, so that part of the wire may project out of the tube at each end, and the other extremities may come within a small distance of each other within the tube. If this preparation be made part of the circuit between the inside and outside coating of the charged Leyden phial, on making the discharge, the glass tube will be broken with violence. But in this experiment the size of the phial, height of the charge, &c. must be proportioned to the size of the glass tube; otherwise the tube will not be broken.

broken. In short, if the discharge forms a visible spark in the water within the tube, the latter will be broken; but if the wires are too far apart, and no spark takes place, then the tube will not be broken. This experiment evidently shews that water is a very bad conductor of electricity.

Experiment 4. To fire gunpowder.—Make a small cartridge of paper, and fill it with gunpowder, or else fill the tube of a quill with it; insert two wires, one at each extremity, so that their ends within the quill, or cartridge, may be about one-fifth of an inch from one another. This done, send the charge of a phial through the wires, and the spark which takes place between the extremities of the wires within the cartridge or quill, will set fire to the powder. If the gunpowder be mixed with steel filings, it will take fire more readily, and by a very small shock.

Experiment 5. To light a candle by the discharge of a jar.—Take a wire of the size of a common knitting needle, and, by means of a slender flexible wire or chain, let one end of it communicate with the outside coating of a Leyden jar, that contains about ten inches of coated surface. Twist, but very loosely, some cotton round the other extremity of the above mentioned thick wire, and so as entirely to conceal that extremity of the wire. This head of cotton must be rolled in powder of *lycopodium*, or in powder of resin, which, indeed, answers better than the *lycopodium*, though it is not so clean. By this means, a good deal of the powder will adhere to the cotton. This done, the jar is charged, and then the head of cotton is brought hastily towards the knob of the jar, so as to cause the charge to pass through the head of cotton; on doing which the cotton will instantly be set on fire, and will continue to burn long enough to light a candle with it. This experiment was contrived by Dr. Ingenhousz.

Experiment 6. To strike metals into glass.—Take two slips of common window glass, about three inches in length, and half an inch broad; put a small slip of gold, silver, or brass leaf between them, and tie them together, or press them between the boards of the press which belongs to the universal discharger (see DISCHARGER), leaving a little of the metallic leaf out at the two opposite ends of the glasses; then send a shock through the metallic leaf, and the force of the explosion will drive part of the metal into so close a contact with the glass, that it cannot be wiped off, or even be affected by the usual menstrua which would otherwise dissolve it. In this experiment the glasses are generally shattered to pieces; but whether they are broken or not, the indelible metallic tinge will always be found in several places, and sometimes all along the surface of the glasses.

Experiment 7. To melt wires.—We have, in a preceding part of this article, described the melting of wires by means of an electrical battery, for the purpose of determining their various conducting powers. We shall now, however, describe some other peculiar phenomena with which the melting of wires is attended. In melting wires of a considerable length, it is often to be observed, that when the force of the battery is just sufficient to render the wire red-hot, the redness begins at one end of it; namely, at that which communicates with the positive side of the battery, and from thence it gradually proceeds to the other end; which affords an ocular demonstration of the theory of a single electric fluid. Indeed the wire is not rendered red-hot in one place before the other, in consequence of the electric fluid passing first through the former, and then through the latter; for that difference of time is by no means appreciable; but because the electric fluid loses some of its impetus, or of its velocity, in going through the wire, in consequence of which, that part of the wire which the electric fluid enters suffers the

greatest effect of the shock, and therefore becomes red sooner, and in a greater degree.

If a wire be stretched by appending weights to it, and such a battery be then discharged through it, as will render it barely red hot, the wire will be found to be considerably lengthened by it. But if the wire be left loose, then, after a similar explosion, it will be found shortened. (See Nairne's paper in the 70th vol. of the Phil. Transf.)

If a wire be thus melted upon a piece of glass, the glass, after the explosion, will be found marked with all the prismatic colours. But the most beautiful impressions are made upon paper. For this purpose, a battery must be used of such a size as entirely to disperse the wire, which must be laid upon a piece of white paper. The explosion will generally fix part of the metal in its metallic state into the paper, and will mark the paper on both sides of this metallic track with a smoky broad band of colour, which differs according to the metal that has been exploded; the gold, for instance, makes a purplish stain; the silver, a grey, or inclining to yellow, and so on.

Experiment 8. To shew that the electric fluid prefers a short passage through the air to a long one through the best conductors.—Take a wire of about five feet in length, or more, and bend it in the form represented in *fig. 50, viz.* so that the parts A, B, may come within half an inch of each other; then connect the extremities of it with the hook of a battery, and with the discharging rod; that is, one with the former, and the other with the latter, so as to send the charge through the wire. On making the discharge, a spark will be seen between A and B, which shews that the electric fluid prefers a short passage through the air between A and B, to a long one through the wire. The charge, however, does not pass entirely through the air at A B; but part of it also goes through the wire A D B, which may be proved by interposing a short and very fine wire between A and B; for, on making the discharge, this fine wire will hardly be made red hot; whereas, if the large wire A D B be cut at D, so as to interrupt the circuit A D B, the small wire will be melted, and dissipated by a discharge similar to the former.

Experiment 9. To produce globules of metal.—Take a slender wire, and insert it in a glass tube of about a quarter of an inch in diameter; then send the charge of a battery through it, and the wire will be melted and reduced into globules of different sizes, which will be found adhering to the inside surface of the glass tube, and may be easily separated from it. These globules, on examination with a microscope, will be found to be mostly hollow, and, in truth, they are little more than a mere scoria of the metal.

Experiment 10. The Fairy circles.—Fix upon each of the knobs of the universal discharger (see DISCHARGER of Electricity), or upon the wires which support those knobs, a flatish and smooth piece of metal, (watch cases are very proper for this purpose,) so that the surfaces of those pieces of metal may be near to each other sufficiently for the charge of a battery to pass from one to the other; then connect one wire of the discharger with the outside coating of the battery, and the other wire, by the help of the discharging rod, with the inside coating of it, so as to make the discharge. This discharge will mark a beautiful spot upon the surfaces of the metal. It consists of one central spot and some concentric circles, which are more or less numerous, and more or less distinct, according as the metal upon which they are marked is more or less fusible, and according likewise to the power of the battery. The central spot as well as the circles lie at a little distance from one another, and they consist of dots and cavities, indicating a true fusion.

The most beautiful of these rings are produced by a number of discharges repeatedly taken from a large battery, every part of the apparatus remaining exactly in the same situation. If the pieces of metal receive the explosion in vacuo, the spots which are formed upon them are very irregular and confused. This is an experiment of Dr. Priestley.

These spots have been called *Fairy circles*, on account of their bearing some resemblance to the spots so called, which are often observed upon the grass in the fields. These, which may be called natural Fairy circles in the fields, have been attributed to the action of lightning, on account of their bearing some resemblance to the above-mentioned effects of electricity; the supposition, however, is not well founded; for the Fairy circles in the fields have no central spot, no concentric circles, nor, in general, are they of a circular form. The present prevailing idea respecting the origin of those spots in the fields is, that they are formed by beds of mushrooms. See the article.

Experiment 11. To mark coloured rings upon metals.—Fix a plain piece of metal of any kind upon one of the wires of the universal discharger, (see *DISCHARGER of Electricity*), and upon the other wire fix a sharp-pointed needle, with the point just opposite to the surface of the metal; then connect one wire of the discharger with the outside of a battery, and the other wire with the discharging rod, &c. In this manner, if the discharges be repeatedly sent either from the point of the needle to the piece of metal, or from the latter to the former, these discharges will gradually mark the surface of the piece of metal opposite to the point, with circles consisting of all the prismatic colours; which are evidently occasioned by very thin laminae of the metal, raised by the force of the explosions. These colours appear sooner, and the rings are closer to each other, when the point is situated nearer to the surface of the metal. The number of rings is greater or less according as the point of the needle is more or less sharp; and they are represented equally well upon any of the metals. The point of the needle is also coloured to a considerable distance; the colours upon it returning in circles, though not very distinctly. See Priestley's paper in the 58th vol. of the *Phil. Transf.*

Experiment 12. To shew the effects of the discharge of the Leyden phial upon colours.—If cards or pieces of wood be painted with different colours, and a Leyden phial be discharged successively over each coloured surface, black marks, more or less dense and more or less broad, will be found marked upon them. These experiments are commodiously performed with the universal discharger. The painted card is laid horizontally upon its tablet, and the points of its two wires (for the knobs must be removed) are laid in contact with the painted surface of the card, and at about two inches distance from each other. The other extremities of the wires are connected with the Leyden phial, and thus the charge is passed over the painted surface of the card. A Leyden phial, containing about a foot and a half of coated surface, is sufficient for these experiments.

Mr. Cavallo, who originally made these experiments in a great variety of ways, says, "Vermilion was marked with a strong black track, about one-tenth of an inch broad. The track was generally single, but sometimes it was divided in two towards the middle, and at other times, especially when the wires were set at a considerable distance from each other, the track was interrupted in the middle. It often happened, but not always, that the impression was stronger at the extremity of that wire which was connected with the positive side of the phial; whereas, the spot contiguous to the other wire was neither so strongly marked, nor

did it surround the point of that wire so much as the former.

"Carmine received a faint and slender impression of a purple colour. Verdigris was shaken off from the surface of the card, except when it had been mixed with strong gum-water, in which case it received a very faint impression. White lead was marked with a strong black track, not so broad as that on vermilion. Red lead was marked with a faint track, much like carmine. The other colours I tried were orpiment, gambodge, sap-green, red ink, ultramarine, Prussian blue, and a few others, which were compounds of the above; but they received no impression."

It has been often observed, that when the lightning has struck the masts of ships, it has passed over such parts as were covered with lamp-black and tar, or lamp-black and oil, without the least injury; at the same time that it has shivered the uncoated parts. (See the 48th and 67th vols. of the *Phil. Transf.*) In order to examine this property of black paint, Mr. Cavallo instituted a series of experiments. "I procured," he says, "some pieces of paper painted on both sides with oil colours, and sending the charge of two feet of coated glass over each of them, by making the interruption of the circuit upon their surfaces, I observed that the pieces of paper painted with lamp-black, Prussian blue, vermilion, and purple brown, were torn by the explosion; but white lead, Naples yellow, English ochre, and verdigris, remained unhurt. The same flock, sent over a piece of paper painted very thick with lamp-black and oil, left not the least impression. I also sent the flock over a piece of paper unequally painted with purple brown, and the paper was torn where the paint lay very thin, but it remained unhurt where the paint was evidently thicker. These experiments I repeated several times, and with some little variation, which naturally produced different effects; however, they all seem to point out the following proposition.

"1. A coat of oil paint, over any substance, defends it from the effects of such an electric shock, as would otherwise injure it; but does by no means defend it from any electric shock whatever. 2. No one colour seems preferable to the others, if they are equal in substance, and equally well mixed with oil; but a thick coating does certainly afford a better defence than a thinner one.

"By rubbing the above-mentioned pieces of paper, I found that the paper painted with lamp-black and oil was more easily excited, and acquired a stronger electricity, than the papers painted with the other colours; and perhaps on this account it may be, that lamp-black and oil might resist the shock somewhat better than the other paints.

"It is remarkable, that vermilion receives the black impression when painted with linseed oil, nearly as well as when painted with water. The paper painted with white-lead and oil receives a black mark; but its nature is very singular. The track, when first made, is almost as dark as that marked on white lead painted with water, but it gradually loses its blackness, and in about one hour's time (or longer, if the paint is not fresh) it appears without any darknels; and when the painted paper is laid in a proper light, appears only marked with a colourless track, as if made by a finger nail. I also sent the flock over a piece of board which had been painted with white lead and oil about four years before, and the explosion marked the black track upon this also; this track, however, was not so strong, nor vanished so soon, as that marked upon the painted paper; but in about two days' time it also vanished entirely."

Experiment 13. To magnetize steel by means of electricity—Take a common sewing needle, which upon trial is found not to be magnetic, place it in the circuit between the inside and outside of a battery, containing about eight or ten feet of coated surface; and send the charge of it through the needle. The effects will be as follow: If the needle be struck, lying east and west, that end of it which is entered by the charge, *viz.* that end which communicates with the positive side of the battery, or jar, will afterwards point north; but if the needle be struck, lying north and south, that end of it which lay towards the north will in any case point north; and the needle will acquire a stronger virtue in this than in the former case. Lastly, if the needle is set perpendicular to the horizon, and the electric shock is given to either point of it, afterwards the lower extremity of the needle will point north. Franklin's letters, &c. p. 90; and Beccaria's *Artif. Electr.* § 731. to 734.

Mr. Van Marum, using the very large battery of the Teylerian museum, which contained 130 square feet of coated surface, tried to magnetize needles made out of watch-springs, which measured 3 and even 6 inches in length; and likewise steel bars of 9 inches in length, from a quarter to half an inch broad, and about a 12th of an inch thick. It was observed, that, 1st, when the bar or needle was placed horizontally in the magnetic meridian, whichever way the shock entered, the end of the bar that stood towards the north acquired the north polarity, or the power of turning towards the north, when freely suspended, and the opposite end acquired the south polarity. If the bar, before it received the shock, had some polarity, and was placed with its poles contrary to the usual direction, then its natural polarity was always diminished, and often reversed, so that the extremity of it, which, in receiving the shock, looked towards the north, became the north pole, &c.

2. When the bar or needle was struck standing perpendicularly, its lowest end became the north pole in any case, even when the bar was previously possessed of some magnetic virtue, and was placed with the south pole downwards; all other circumstances being alike, the bars seemed to acquire an equal degree of magnetic power, whether they were struck whilst standing horizontally in the magnetic meridian, or perpendicular to the horizon.

3. When a bar or needle was placed in the magnetic equator, whichever way it entered, the shock never gave it any magnetism; but if the shock was passed through its width, then the needle acquired a considerable degree of magnetism, and that end of it which lay towards the west became the north pole, and the other end the south pole.

4. If a needle or bar, already magnetic, or a real magnet, was struck in any direction, its power was always diminished; and this took place with bars of considerable size; one being 7.08 inches long, 0.26 broad, and 0.05 thick.

5. Lastly, when the shock was so strong in proportion to the size of the needle, as to render it hot, then the needle either acquired a very slight magnetic power, or none at all.

Experiment 14. To oxydate and to deoxydate metallic substances by means of electricity.—If the charge of a battery be passed through a metallic oxyd, a partial deoxydation generally ensues; and it has already been observed in various parts of this article, that a strong shock calcines or oxydates a metallic substance. Mr. Van Marum, using the same powerful machine which has been mentioned in the preceding experiment, and the purest metallic oxyds, which were confined between glasses whilst the shock was passed over them; observed, that the oxyds were rendered metallic so far as to exhibit several grains of the metal, large enough to be dis-

cerned by the naked eye, and to be easily separated from the rest. With respect to the oxydation, whenever a spark was employed much greater than that which was barely necessary to fuse the metal, part of the latter was oxydated, and even dispersed into smoke. It is to be remarked, that this oxydation or smoke generally produced several filaments of various lengths and thicknesses, which swam in the air. It was farther observed, that if a conductor was presented to these flying filaments of metallic oxyd, they were soon attracted by it; but after the first contact they were instantly repelled, and were generally broke into fragments.

Experiments producing several curious configurations by means of electricity.

Some years ago, professor Lichtenberg of Gottingen produced several curious configurations by sifting or puffing certain powders upon an excited electrophorus; and since that time, several ways of producing similar effects have been discovered by various persons. The principal method of producing these impressions in general, is to electrify a perfect or an imperfect electric, and then to throw certain powders upon it, which will dispose their particles into various remarkable forms. These powders may be sifted over the electrified body from a common sieve; they may be tied up in linen rags, and shook out of them; they may be projected by means of a brush; (*viz.* by taking a little of the powder between a finger and thumb, and drawing it over the brush, or by rubbing a lump of chalk, whiting, &c. over the brush) also by means of a pair of bellows. But a more commodious method is as follows: Fix a tube of glass, or wood, or metal, to the neck of a small bottle of elastic gum, commonly called India rubber; put the powders, which you want to project, into this bottle, and then tie a double piece of flannel over the aperture of the tube. If this bottle, so prepared, be held in the hand, and be squeezed, by alternately opening and shutting the hand, the powders will be projected in a fine diffused manner. As for the nature of the powders, almost every substance that can be pulverized sufficiently fine will produce some configurations when projected upon an electrified substance. This chalk, sulphur, cinnabar, rosin, dragon's blood, gum arabic, evaporated decoctions of colouring woods, and many others, may be employed for this purpose either single or mixed.

Experiment 15.—Take a pane of glass, clean and dry, hold it suspended by one corner, or lay it flat upon a table, and draw over the surface of it the knob of a Leyden phial, moderately charged with positive electricity in its inside. Then lift up the glass, if laid upon a table, and, holding it suspended, project upon it, by means of the elastic gum bottle, a mixed powder, consisting of dragon's blood and gum arabic in equal parts. The two powders will be separated upon the glass; the red powder of dragon's blood falling on certain places, so as altogether to form an oblong radiated track, consisting of two colours intermixed in a thousand odd ways. The reason of this separation of the powders is, that in the act of projecting them, the powders become actually electrified, and as some of them thereby acquire the positive, whilst others acquire the negative electricity; therefore the former are attracted by those parts of the glass, or other electric, which are electrified negatively, and the latter are attracted by those parts of the electric which are possessed of the positive electricity.

If, instead of drawing the knob of the jar over the surface of the glass, you only touch the surface of it here and there with the knob of the jar, and then project the mixed powders

powders as before; separate star-like figures will be formed about those points. The stars, however, are more defined when a single powder is projected. Their rays or ramifications sometimes are few and strong; at other times they are numerous and slender; and frequently they do not go quite round the points which had been touched with the knob of the jar.

Experiment 2.—Repeat the preceding experiment with this variation only; *viz.* that now the Leyden phial be charged negatively in the inside, and the appearance of the configurations will be much different from the above described, which was produced by positive electricity. In the present, very few rays or branches will be observed: the powders mostly disposing themselves in roundish spots, and generally it will be found, that a central spot of one powder is surrounded by another powder of a different colour.

Instead of dragon's blood and gum arabic, powders of other colours may be projected upon the pane of glass, such as powdered Prussian blue, sulphur, vermilion, rosa, &c. and thus the colours of the configurations may be varied.

These powders adhere to the glass rather slightly; *viz.* so as not to bear being touched; yet, if a piece of paper be gently laid on the painted side of the glass, without rubbing it, and the edge of the paper be passed all round the edge of the glass, the figures may be preserved without injury. But a better method is, to lay another pane of glass of the same size upon the former, and to fasten them by passing a slip of paper all round their edges. If powders of such colours as are used by enamellers be projected upon glass or porcelain, and these be afterwards exposed to a proper degree of heat in an enameller's furnace, the configurations will thereby be rendered indelible.

Experiment 3.—Take a piece of common writing paper, hold it very near the fire, so as to render it quite dry and very hot; lay it flat upon a dry marble slab, or a very dry table, and in that situation draw over it the knob of a charged Leyden phial, then lift up the piece of paper by one corner, and holding it suspended, project upon it the mixed powder of dragon's blood and gum arabic by means of the elastic gum bottle. The configurations in this case are very beautiful, and may be made in various shapes, such as letters, stars, stripes, &c. by moving the knob of the Leyden phial in the desired direction; but they are of one colour; *viz.* red; for the gum arabic being nearly of the colour of the paper, cannot be distinguished upon it. If the paper thus painted be held very near to the fire during a few seconds, the powder of dragon's blood being a resinous substance, will be melted, and will be fastened on the paper; after which the powder of gum arabic may be wiped off with a handkerchief.

Powders of other colours may be projected upon the paper after the same manner; but unless they are of a resinous nature, so as to be easily melted by heat, it is very difficult to fasten them to the paper. In these experiments the Leyden phial must not be charged too high nor too low; for, in the former case, the figure will be too confused and irregular, and in the latter it will be too faint. In order to form a neat and determinate figure, and to leave the rest of the paper clean, the powders must not be projected perpendicularly to the paper, but the stream must be thrown in a direction parallel to the surface of the paper. It is also necessary to perform these experiments in as expeditious a manner as possible; for, if the paper be suffered to cool too much, or the electricity to dissipate, the desired effect cannot be obtained.

Experiment 4.—Instead of the paper, the impressions may be made upon marble, by drawing the knob of the charged

phial over it; the marble being very dry and hot. After the same manner, these configurations may be made upon all sorts of electric, or semi-electric substances, and they may be preserved by covering them with a glass plate, or else by partially melting the substance, &c. when this is of the proper nature. It is also practicable to transpose these impressions from the electric plate to a piece of white paper; but the method is rather tedious. See Bennet's method of performing it, in his work on electricity; or in Cavallo's *Elect.* 4th edit. vol. iii. p. 148.

Experiment 5.—A very regular figure may be formed on the surface of a resinous plate in the following manner. Lay the resinous plate upon a table, insulate one or more pointed wires over the plate, with their points directed towards its surface, and distant about an inch and an half, or two inches. Then, by touching these wires alternately with a positive and a negative Leyden phial, throw the alternate sparks upon the resinous surface, and afterwards, by projecting powders of different colours, you will obtain very regular figures, consisting of concentric zones of different colours, which assume the forms of circles, of ellipses, or of other curves, according as one or more pointed wires are used, and according as those wires are situated nearer to, or further from, each other.

Experiment 6.—Cut a figure of any sort out of the middle of a card, as, for instance, a profile, a flower, &c. Place a piece of white silk (white satin answers very well) upon a table; lay the card upon it, and a gold leaf over the card; in which case it is evident, that the gold leaf will touch the silk only within the limits of the figure that has been cut out of the card. This done, lay another card over the gold leaf, and put a book, or something else, heavy upon it to keep it down. Care, however, must be had to leave two projections of the gold leaf out of the cards at opposite ends. Lastly, if you send the charge of a battery through the gold leaf, by connecting one of its projections with the inside, and the other with the outside of the battery, the gold leaf will be melted, and will be forced into the substance of the silk, so as to stain it with a purple spot of the shape and size of the figure cut in the card. The battery for this experiment must have force sufficient to melt the gold leaf completely. By using different metallic leaves, and different figures, various beautiful ornaments may be marked upon silk.

Experiment 7.—Hold a piece of writing paper near the fire to render it dry and warm, then lay it upon a table, and rub it with a dry hand, which operation will excite it. Now let a piece of sealing-wax be lighted, and after having suffered it to burn for about five or six seconds, lift up the excited paper from the table, and hold it up by one corner; blow out the flame of the sealing-wax, and present the melted end of it to the paper at the distance of about an inch, moving it quickly in various directions. In doing this, the electricity of the paper will attract the sealing wax in the form of exceedingly fine filaments, which may afterwards be melted and fastened to the paper, by holding the paper very near the fire for a short time. A small piece of sealing-wax, stuck upon a wire or a pin, answers better than a common stick of sealing-wax.

Some of the configurations described in the preceding experiments are exhibited in *Plate VI.*

Experiments relating to Knobs and Points.

Sharp or pointed bodies have the property of throwing off or of imbibing electricity incomparably better than flat or blunt bodies; and it is for this reason, that, in the construction of electrical machines and electrical apparatus in general, points and sharp corners, edges, &c. are avoided

as much as possible, excepting where a point or points are particularly required; as, for the example, is the case at that end of the prime conductor which faces the excited electric, where the pointed wires of the collector are required for the purpose of imbibing the electricity. The principle upon which this property of points depends, is explained under the article POINT.

Experiment 1. To draw the electric fluid silently from the prime conductor.—Let a person hold the knob of a brass rod at such a distance from the prime conductor that sparks may easily fly from the latter to the former, when the machine is in action; while these sparks are going off, let the sharp point of a needle be presented to the prime conductor, at about twice the distance from it that the knobbed rod is held, and you will find that no more sparks will go to the rod; remove the needle, or cover its point with a needle, and the sparks will be seen as before: present the needle, and the sparks disappear, which evidently shews, that the point of the needle draws off *silently* almost all the fluid that the cylinder of the machine throws upon the prime conductor. If, whilst the pointed needle stands presented to the prime conductor, you form the finger and thumb of your hand like a ring, and surround the point of the needle, the action of this point will be suppressed, as is manifested by the sparks, that, in this case, will go to the rod; which shews, that a point will act as a point only whilst it remains free and disencumbered; but not when surrounded by other bodies.

If the needle be fixed upon the prime conductor with the point outward, then, on working the machine, no sparks can be drawn from the prime conductor, or, perhaps, an exceedingly small one when a knobbed conductor is brought nearly in contact with it; the pointed needle dissipating the electricity in the surrounding air; and indeed this is an effectual method of electrifying the air of a room.

This experiment answers equally well with negative or with positive electricity. A pointed wire, fixed on the end of a spiral tube, such as has been described in the preceding part of this article, will draw sparks on account of the interruptions.

Experiment 2. To discharge a Leyden phial silently.—When a large jar is fully charged, which would give a violent shock, put one of your hands in contact with its outside coating; with the other hand hold a sharp pointed needle, and keeping the point directed towards the knob of the jar, proceed gradually towards it, until the point of the needle touches the knob. This operation discharges the jar completely, and the operator will either receive no shock at all, or so small a one as can hardly be perceived. The point of the needle, therefore, has silently and gradually drawn all the charge from the inside of the Leyden phial.

If this experiment be performed in the dark, the point of the needle will appear illumined in its way towards the knob of the phial, which is another proof of its drawing off the charge.

Experiment 3. To observe the wind which proceeds from an electrified point.—When a pointed wire (the sharper the better) is fixed at the end of the prime conductor, or indeed in any part of it, with the point outward, let the electrical machine be put in action, and present the face, or the palm of the hand, to the above-mentioned point, at the distance of about three inches, and a wind will be perceived to proceed from it.

Fasten five or six pieces of paper to a cork, like the leaves of a water-wheel in hydraulics; pass a needle, by way of an axis, through the cork, and suspend it by applying the end of the needle to a magnet. Let a pointed wire be fixed

at the end of the prime conductor, and present the paper vanes of the cork suspended, &c. to the current of air which proceeds from that point, when the machine is in action; and the force of that wind will cause the cork to turn round.

This current of air always proceeds from the point, whether the point be electrified positively or negatively; therefore it is not the influx or the efflux of the electric fluid that occasions the wind; but it is owing to the particles of air which, requiring the same electricity as the pointed wire, are repelled from it in virtue of the repulsion which takes place between bodies possessed of the same kind of electricity, be it positive or negative. Other particles of air succeed those which are repelled first, and these being electrified are also repelled, and so on.

When the wire, instead of a pointed termination, is furnished with a ball of about an inch and a quarter in diameter, a curious phenomenon may be observed, by presenting the flame of a candle to it, *viz.* so that the middle of the flame may be even with the middle of the ball. The machine being put in action, it will be found that the flame is blown from the ball, when the latter is electrified positively, *viz.* when connected with the positive conductor; and it will be blown towards it when the ball is electrified negatively, *viz.* when it is connected with the rubber of the machine, or with a negative prime conductor; which seems to shew the real influx and efflux of the electric fluid, according to the Franklinian theory.

Experiment 4. The electric fly, or flyer.—Fig. 51. Plate VII. represents a pointed wire fixed upon the prime conductor, and supporting the brass flyer, which consists of slender brass wires fixed to a brass cap, which is hollow in its under side, and rests in *equilibrium* upon the point of the wire W, like the magnetic needle of a compass. The outer terminations of the wires are pointed, and are bent all the same way. When the electrical machine is put in action, the fly will immediately begin to move round in an horizontal plane, and in the direction of the letters *a, b, c, d, viz.* contrary to the direction of the points of the wires. If the experiment be repeated with a prime conductor negatively electrified, the fly will turn the same way as before, *viz.* in the direction of the letters *a, b, c, d.* The reason of this effect depends upon the repulsion existing between bodies possessed of the same kind of electricity; for whether the fly is electrified positively or negatively, the air opposite to the points of the wires (on account of the points easily transmitting electricity) acquires a strong electricity analogous to that of the points, and therefore the air and the points must repel each other. This explanation is confirmed, by observing that the above-mentioned fly not only does not move in *vacuo*, but even if placed under a clove receiver it will turn for a little while only, and will then stop; for the quantity of air within the receiver will soon acquire its maximum of electricity.

Fig. 52. represents an improved flyer, which was invented by Edward King, esq. and is described by Mr. Ferguson in his Select Mechanical Exercises. We shall transcribe Mr. Ferguson's words.

“The sun and earth go round the common centre of gravity between them in a solar year, and the earth and moon go round the common centre of gravity between them in a lunar month. These motions are represented by an electrical experiment, as follows: The ball S represents the sun, E the earth, and M the moon, connected by bended wires *a c*, and *b d*: *a* is the centre of gravity between the sun and earth, and *b* is the centre of gravity between the earth and moon. These three balls, and their connecting wires,

are hung and supported on the sharp point of a wire A, which is stuck upright in the prime conductor B of the electrical machine; the earth and moon hanging upon the sharp point of the wire *c a e*, in which wire is a pointed short pin, sticking out horizontally at *c*, and there is just such another pin at *d*, sticking out in the same manner, in the wire that connects the earth and moon.

“When the cylinder of the electrical machine is turned, the above-mentioned balls and wires are electrified; and the electrical fire flying off horizontally from the points *c* and *d*, causes S and E to move round their common centre of gravity *a*; and E and M to move round their common centre of gravity *b*. And as E and M are light when compared with S and E, there is much less friction on the point *b* than upon the point *a*; so that E and M will make many more revolutions about the point *b* than S and E make about the point *a*. I have adjusted the weights of the balls so, that E and M go twelve times round *b* in the same time that S and E go only once round *a*. It makes a good amusing experiment in electricity; but it is so far from proving that the motions of the planets in the heavens are owing to a like cause, that it plainly proves they are not. For the real fun and planets are not connected by wires or bars of metal, &c.

Experiment 5. The electrified cotton.—Take a small lock of cotton, extend it in every direction as much as may be practicable, and by means of a linen thread, about five or six inches long, or by a thread drawn out of the same cotton, tie it to the end of the prime conductor; then let the electrical machine be put in action, and the lock of cotton, on being electrified, will immediately swell out, by repelling its filaments from each other, and will stretch itself towards the nearest conductor. In this situation, the machine continuing in action, present the end of a finger, or the knob of a wire, towards the lock of cotton, and this will then immediately move towards the finger, endeavouring to touch it. But take a sharp pointed needle in the other hand, and present its point towards the cotton, a little above the end of the above-mentioned finger, and you will find that the cotton immediately shrinks upwards, and moves towards the prime conductor. Remove the needle, and the cotton will come again towards the finger. Present the needle, and the cotton will shrink again; which clearly shews that the needle, being sharp pointed, draws off the electric fluid from the cotton, and puts it in a state of being attracted by the prime conductor; which effect cannot be produced by a wire having a blunted end, or a round ball for its termination.

Promiscuous Experiments.

Experiment 1. To crystallize a solution of pot-ash.—Take a glass tube, about four inches long, and about one quarter of an inch in diameter, open at both ends. Moisten the inside of it with a strong solution of pot-ash; adapt two corks to the extremities of the tube, and introduce a wire through each cork. The extremities of those wires within the tube should be about three quarters of an inch distant from each other. This done, connect one of the wires with the outside coating of a pretty large electric jar, and connect the other wire with the discharging electrometer (see DISCHARGER of Electricity); then let the discharge be repeatedly passed through the tube, and after a certain number of discharges, the alkaline solution within the tube will give manifest tokens of crystallization.

This experiment, at an early period of the science, was supposed to prove, that the electric fluid is an acid, which, combining with the alkali, neutralized it, and disposed it to crystallize. The fact, however, is, that the explosions,

which take place within the tube, by acting on the common air, produce a certain quantity of carbonic acid, which combines with the alkali, and disposes it to crystallize.

Experiment 2. The inflammable air pistol.—This experiment shews that a very small electric spark is sufficient to inflame hydrogen gas, or, as it was formerly called, inflammable air. The *figs. 53, and 54.* represent a pistol for this purpose, which is made of brass; but it is here represented as transparent, in order to shew its internal parts. It consists of a cavity A B C, to the aperture, A, of which a cork is fitted. To the lower part of it a perforated brass piece is screwed, into which a glass tube D E is cemented, and within this tube a wire G F is likewise cemented. This wire is furnished with a small ball at its external termination, and is bent at its other extremity, so as to come within about a tenth of an inch of the brass piece. *Fig. 54.* shews this brass piece with the glass tube, &c. separate from the rest, and it likewise shews the brass cap I, which, when the pistol is not used, is screwed at H, as is shewn by the dotted line in *fig. 53*, and it serves to defend the glass tube E. It will be easily comprehended, that if a person holds this pistol in one hand, and brings the ball F near the prime conductor of an electrical machine, in action, or presents an excited glass tube or stick of sealing-wax to it, so as to give a spark to the said ball E, a similar spark will take place between the end of the bent wire within the tube, and the brass piece contiguous to it. When the pistol is properly charged with the inflammable gas, and the cork is adapted to the aperture of it, if a person holding it by its middle, communicates a spark in the above described manner to the ball F; the spark which takes place within the pistol will inflame the gas, which produces a loud report, and drives out the cork with great violence.

The inflammable gas for this purpose must be kept in a common bottle well corked, and when the pistol is to be charged, the corks are removed both from the pistol and from the bottle, the pistol is inverted over the bottle, adapting the aperture of the one to that of the other, and after remaining in that situation during about 10 or 15 seconds, the pistol is separated from the bottle, and the corks are instantly replaced in both their apertures. By this operation the common air, which is in the pistol, mixes with the inflammable gas, for this being much lighter will ascend into the pistol, whilst part of the common air of the pistol will descend into the bottle. The pistol is then ready to be fired off. The form of these pistols has been often diversified. They have been rendered capable of being filled with certain determinate quantities of elastic fluids, and that for the purpose of producing the greatest possible effect. They have, in fact, rendered them capable of driving a leaden bullet with considerable force. For the preparation of the inflammable gas, see the article HYDROGEN GAS.

Experiment 3. Mr. Volta's inflammable air lamp.—*Fig. 55.* represents this instrument, which was invented by Mr. Volta. A is a glass globe to contain the hydrogen gas; B is a glass basin or reservoir to hold water; D is a stop-cock which is to form occasionally a communication between the water in the reservoir B and the cavity of the vessel A. The water passes into the latter through the metal pipe *g g*, which is fixed to the upper part of the reservoir A. At S is a small cock, to cut off, or open, a communication with the air in the ball and the jet K. N is a small pipe to hold a piece of wax taper; L is a brass pillar, on the top of which is a brass ball; *a* is a pillar of glass furnished at top with a socket, through which a wire *b* slides, and a ball is screwed to the end of this wire. F is a stop-cock, by which the ball A is filled with the inflammable gas, and which afterwards

erves to confine the gas, and the water that falls from the balloon B into the ball A.

To use this instrument, after having filled the reservoir A with pure hydrogen gas, and the balloon B with water, turn the cocks D and S, and the water which falls from B will force some of the gas out of the jet K into the air. If then an electric spark is made to pass from the brass ball m_1 to the brass ball n , the jet of gas out of the pipe K will be inflamed. And when it is required to put it out, the cock S first, and then the cock D must be stopped, viz. must be turned so as to cut off the communication.

To fill the vessel A with inflammable gas; having previously filled A with water, place the foot R under water, on a board or stool in a large tub of water, then the gas is conveyed by a bent glass tube from the vessel in which that gas is generated, to the aperture under the foot R; whence the gas ascends into the vessel A, and the water comes out of it at the same time. When A is full of the gas, the cock F is shut up, and the vessel is taken out of the water, &c. (See PNEUMATIC tub, and HYDROGEN GAS.) This instrument is useful for lighting a candle, and of late it has been much improved, so that it is now sold in London expressly for that purpose. These improved instruments contain also an electrophorus, and the whole is disposed so, that by turning a single cock, the stream of gas is forced out of the pipe, and is lighted at the same time. A more particular description of these improved instruments belongs to other subjects.

Experiment 4. To inflame spirits of wine by means of electricity.—The power of the electric spark is sufficient to inflame inflammable spirits when it is passed through them, and especially when the spirits are a little warm.

Suspend to the prime conductor a short rod, having a small knob at its end; pour some spirit of wine, a little warmed, into a metal spoon. (The best way of warming the spirits is to hold the spoon over the flame of a candle during a minute at most.) Hold the spoon by the handle, and place it so that the above mentioned small knob may stand at about the distance of one inch above the surface of the spirit. In this disposition, if the electrical machine be put in action, by turning the wheel, a spark will come from the little knob to the spoon, which, by passing through the spirit of wine, will set it on fire. Care, however, must be had, that the spark does not fly from the knob to the edge of the spoon; for in this case the spirit will not be inflamed. On this account it is proper to use a large spoon.

This experiment succeeds equally well whether the conductor be electrified positively or negatively; it being not the direction, but the rapid motion of the electric fluid, that sets the spirit on fire.

This experiment may be varied different ways, and may be rendered very amusing to a company of spectators. A person, for instance, standing upon an insulating stool, and communicating with the prime conductor, may hold the spoon with the spirits in his hand, and another person, standing upon the floor, may set the spirits on fire, by bringing his finger within a small distance of its surface. Instead of using his finger, he may inflame the spirits by presenting a piece of ice, which will render the effect more surprising. If the spoon is held by the person who stands upon the floor, and the insulated person brings some conducting substance over the surface of the spirits, the experiment will succeed equally well.

Mr. Winkler says that oil, pitch, and sealing-wax, might be lighted by electric sparks, provided those substances were first heated to a degree next to kindling. Priestley's Hist. of Elect. period vii.

Experiment 5. To cause the mercury to rise in a thermometer

by means of electricity.—Fix a wooden ball to the wire that proceeds from the extremity of the prime conductor, and place another like wooden ball or a wire, or other conductor, that communicates with the earth, at about half an inch distance from the other ball; in which situation it is clear, that when the machine is in action, a stream of electric fluid will pass from one ball to the other. Now if you place the bulb of a mercurial thermometer in that stream, viz. between the two wooden balls, the mercury will be gradually raised in it by the action of the electric stream. By continuing to work the machine, the mercury may be raised several degrees above its former station.

For this experiment the bulb of the thermometer must be quite detached from the scale, so that the scale may begin at least three inches above the bulb. This experiment, upon the whole, seems to answer best when the balls are of soft wood. Mr. Adams says, "with a cylinder of about seven inches and a half in diameter, the fluid passing from a ball of lignum vitæ to a ball of beech, and thence to the ground, elevated the quicksilver in the thermometer from 68° to 110° , repeatedly to 105° . The thermometer was raised from 68° to 85° , by the fluid passing from a point of box to a point of lignum vitæ; from 67° to 100° , from a point of box to a ball of box; from 66° to 100° , from a ball of box to a brass point; from 69° to 100° , from ball to ball; the bulb of the thermometer covered with flannel." Adams's Ess. on Elect. p. 58.

Experiment 6. The atmosphere of smoke.—Take a brass ball, or any piece of metal that is free from points or edges, of about three or four inches in diameter, and insulate it upon a narrow insulating stand; then give it a spark with the knob of a charged phial, and immediately after present it to a wax taper just blown out and smoking. The smoke, in this case, will be attracted by the electrified body, and, by encompassing that body, will form a kind of atmosphere about it. This atmosphere will remain for a few seconds, and afterwards, beginning from the bottom, will gradually vanish, until at last, entirely departing from the electrified body, it goes off in a slender column, that soon rarefies and diffuses itself into a considerable space.

This experiment will not succeed unless it be performed in very dry weather, and in a room where the air is not agitated. Care must also be taken, that in blowing out the taper, and in presenting it to the electrified body, the air be disturbed as little as possible.

The effect which is produced in this experiment is far from proving the existence of any electrical atmosphere, as some persons have been induced to suppose. The smoke is attracted by the electrified body in the same manner, and for the same reason, that other bodies are attracted by it. The smoke remains suspended about that body, and cannot all come into contact with its surface, on account of its elasticity. It remains so long suspended about the electrified body, and is not immediately repelled, because it is a bad conductor, and acquires the electricity very slowly; but when it has acquired a sufficient quantity of that power, it begins to quit the electrified body, and ascending in the air, expands itself into a large space, in consequence of the repulsion which takes place amongst its own electrified particles.

Experiment 7. The electrified cup and chain.—Insulate a metallic cup, or any other concave piece of metal, and within it place a pretty long metallic chain, having a silk thread tied to one of its extremities. To the handle of the cup, or to a wire proceeding from it, suspend a cork ball electrometer; then electrify the cup by giving it a spark with the knob of a charged phial, in consequence of which the balls of the electrometer will immediately diverge. If in this situation

ELECTRICAL.

situation one end of the chain, held by the silk thread, be gradually raised above the cup, the other end remaining in it, the balls of the electrometer will converge a little, and more or less in proportion to the elevation of the chain above the cup. Lower the chain again, and the divergence of the electrometer will be increased, and so on; which proves that the electricity of the cup and chain together is more dense when these bodies are in a compact, than when they are in a more extended form; or that the density of the electric power is nearly, if not exactly, in the inverse proportion of the surface; so that if equal quantities of electricity be communicated to two bodies differing in the extension of their surfaces, the electric virtue will be denser upon the small than upon the large surface. And two bodies of equal and similar surfaces, but one of them hollow and the other solid, will acquire an equal share of electricity if they are both, at the same time, brought in contact with the prime conductor, or with any other electrified body.

The same property was shewn by T. Ronayne, esq. in the following different manner: He excited a long slip of white flannel, or a silk ribbon, by rubbing it with his fingers; then, by applying his hand to it, took off as many sparks as the excited electric would give; but when the flannel, or silk, had lost the power of giving sparks in this manner, he doubled or rolled it up, in consequence of which the contracted flannel, &c. appeared so strongly electrical as to give sparks even spontaneously.

Experiment 8. To pierce holes through glass by means of electric sparks.—Take a common phial, or let a glass tube of any diameter, and about four or five inches long, be closed either hermetically, or by means of sealing-wax, at one end, and fill about the half of it with olive oil; then stop the aperture with a cork, through which a wire must be passed. This wire must come so far within the tube, as to have its extremity below the surface of the oil, and must be bent so as to touch the surface of the glass. Things being thus prepared, bend the external part of the wire in the form of a ring, and suspend it together with the phial, or tube, to the wire at the extremity of the prime conductor. Now put the electrical machine in action, and bring the knuckle of a finger, or the knob of a wire, near the outside of the tube, just opposite to the extremity of the wire within; the consequence will be, that a spark passes from the wire to the knuckle, which makes a hole, and sometimes more than one hole through the glass. By turning the wire about, or by raising and lowering it, many holes may be successively made in the same phial or tube, after the above-mentioned manner.

It is very remarkable, that so small a force as a simple spark from an ordinary electrical machine should perforate a substance so hard as glass. It has sometimes made a hole through glass that was nearly a quarter of an inch thick. It seems that the oil, being an electric, prevents the electricity of the spark to spread beyond the very narrow place on the surface of the glass which touches the point of the wire, and that the spark becomes so powerful in consequence of its being so confined or concentrated.

Experiment 9. To shew the direction of the electric fluid in the discharge of a Leyden phial by the flame of a wax taper.—Remove the circular tablet from the middle of the universal discharger. (See DISCHARGER.) Fix the two wires of that instrument in the same horizontal direction, and so that their knobs may be about two inches distant from each other. Fix a piece of wax-taper, lighted, so that its flame may stand midway between the two knobs. Having disposed the apparatus in this manner, if you connect, by means of a chain or otherwise, the outside of a charged jar with one of the horizontal wires of the universal discharger, and bring the

knob of the jar to the other wire, you will observe, that on making the discharge, (which must pass from one knob to the other, through the flame of the wax taper,) the flame is always driven in the direction of the electric fluid, that is, it will be blown upon the knob of that wire which communicates with the negative side of the jar.

In this experiment the jar must have an exceedingly small charge, viz. just sufficient to pass from one knob to the other, which experience will presently determine, otherwise the experiment will either not succeed, or it may be rendered equivocal. The reason why this experiment does not succeed with a high charge seems to be, that the high charge, in consequence of its extended sphere of action, disturbs the flame of the wax taper before the actual discharge takes place.

Experiment 10. To render the direction of the electric fluid conspicuous, by the motion of a pith ball.—Bend a card lengthways over a round ruler, so as to form a channel or semi-circular groove; or cut a piece of baked wood in the shape of an oblong channel; for this piece of wood, being painted over with lamp-lack and oil, will answer better than the card. Lay this channel upon the tablet of the universal discharger; place a pith-ball, of about half an inch in diameter, in the middle of the channel; then at equal distances, about half or three-quarters of an inch from the pith-ball, lay the brass knobs of the wires of the universal discharger, viz. one on one side, and the other on the opposite side of the pith ball. The card or piece of wood being dry and rather warm, if you connect, by means of a chain or otherwise, the outside of a charged jar with one of the wires of the universal discharger, and bring the knob of the jar in contact with the other wire, you will observe that on making the discharge, which must pass from one knob to the other, and through the pith-ball, the latter is always driven in the direction of the electric fluid, viz. it is pushed towards that knob which communicates with the negative side of the jar.

This experiment demands great care and attention, and with respect to the charge of the jar the same precautions must be used in this as in the preceding experiment.

Experiment 11. To render the direction of the electric fluid evident by the discharge of a Leyden phial over a card.—Lay a wire upon a table, and place a card over the end of it. Also lay another similar wire upon the card, so that the two wires may be in one direction, and their extremities at about one inch distance from each other. If one of those wires be made to communicate with the outside coating of a charged jar, and the other wire be made to communicate with the knob of the jar, the discharge must evidently pass over the surface of the card from the extremity of one wire to that of the other; but since the extremities of the wires lie on opposite sides of the card, it is also evident, that on making the discharge, a hole must be made by the electric charge in some part of the card. Now it will be found, that the electric fluid runs over that surface of the card which touches the wire that is connected with the positive side of the jar; and in order to pass to the other wire, it breaks a hole exactly over the extremity of that wire which communicates with the negative side of the jar.

This curious experiment, which was invented by Mr. Lullin of Geneva, requires a jar of a moderate size, and moderately charged; for the discharge of a large Leyden phial is apt to pierce several holes, which renders the effect equivocal.

Experiment 12. To shew the penetrability of the electric light.—Let the extremities of two wires, one of which proceeds from the outside of a charged jar, and the other is connected with one branch of the discharging rod, be laid upon a table at about one-tenth of an inch distance from each

each other; then place the thumb exactly over that interruption of the circuit, pressing it flat down. Now bring the discharging rod in contact with the knob of the jar, and on making the discharge, the spark which necessarily takes place under the thumb will illuminate it in such a manner as to flow the bone and the principal blood-vessels. In this experiment the operator needs not be afraid of receiving a shock, for the discharge of the jar passes from wire to wire, and, at most, it only affects the thumb with a sort of tremor, which is far from being painful.

Experiment 13. To illuminate water.—Let every thing be disposed exactly as in the preceding experiment, excepting that instead of the thumb, a large clear glass decanter full of water be laid over the interruption of the circuit. On making the discharge, the water will appear illumined throughout.

After the same manner, viz. by passing the charge of a Leyden phial over the surface of a variety of bodies, or under them, or latly through; these bodies will mostly appear illumined at the time of the discharge, and sometimes for a few seconds after it. Eggs are beautifully illumined by the passage of a charge through their substance. It needs hardly be observed that these experiments must be made in the dark.

Experiment 14. To show that the electric fluid drives small conducting bodies in its way.—Lay some brads dust, or brads filings, upon a metallic plate that communicates with the inside coating of a battery; connect the outside of the battery with the discharging rod by means of a wire; charge the battery, then bring the knob of the discharging rod over the above-mentioned brads dust, and the discharge will be made at a much greater distance (more than double or treble,) than when no brads dust is used, which shews that the electric fluid drives the conducting dust from the plate towards the knob of the discharging rod, and the particles of this dust then serve as steps to facilitate the passage of the fluid. Beccaria was the first who advanced the proposition, that “when the electric fluid is obliged to pass through air, or through any other substance which obstructs its free passage, it throws forward all light conducting substances which happen to be at hand, in order to facilitate its own passage.” Dr. Priestley made a variety of experiments with a view of ascertaining and of elucidating this property of the electric fluid. He formed the circuit between the two sides of the Leyden phial by trains of brads filings, leaving a small interruption in them; he formed heaps of dust at a distance from one another, &c.; but after the account of all those trials he says, “All these experiments shew that light bodies, possessed of a considerable share of electricity, disperse in all directions, carrying the electric matter to places not abounding with it; and that they sometimes promote a sudden discharge of great quantities of that matter from places where it was lodged, to places where there was a defect of it.”

Experiment 15. To take a long spark through an exhausted tube.—This experiment is extracted from a valuable paper of Mr. Morgan, who made numerous electrical experiments in vacuo. “It is,” he says, “surprising to observe, how readily an exhausted tube is charged with electricity. By placing it at ten or twelve inches from the conductor, the light may be seen pervading its inside, and as strong a charge may sometimes be procured as if it were in contact with the conductor; nor does it signify how narrow the bore of the glass may be; for even a thermometer tube, having the minutest perforation possible, will charge with the utmost facility; and in this experiment the phenomena are peculiarly beautiful.

“Let one end of a thermometer tube be sealed hermetically; let the other end be cemented into a brads cap with

a valve, or into a brads cock, so that it may be fitted to the plate of an air pump. When it is exhausted, let the sealed end be applied to the conductor of an electrical machine, while the other end is either held in the hand or connected with the floor. Upon the slightest excitation, the electric fluid will accumulate at the sealed end, and be discharged through the infide in the form of a spark, and this accumulation and discharge may be incessantly repeated till the tube is broken. By this means I have had a spark 42 inches long, and had I been provided with a proper tube, I do not doubt but that I might have had a spark of four times that length. If instead of the sealed end, a bulb be blown at that extremity of the tube, the electric light will fill the whole of that bulb, and then pass through the tube in the form of a brilliant spark, as in the foregoing experiment; but in this case I have seldom been able to repeat the trials above three or four times before the charge has made a small perforation in the bulb.

“If, again, a thermometer filled with mercury, be inverted into a cistern, and the air exhausted so as to form a Torricellian vacuum, the electric light in the bulb, as well as the spark in the tube, will be of a vivid green; but the bulb will not bear a frequent repetition of charges before it is perforated in like manner as when it has been exhausted by an air-pump. It can hardly be necessary to observe, that in these cases the electric fluid assumes the appearance of a spark from the narrowness of the passage through which it forces its way. If a tube 40 inches long be fixed into a globe 8 or 9 inches in diameter, and the whole be exhausted, the electric fluid, after passing in the form of a brilliant spark throughout the length of the tube, will, when it gets into the inside of the globe, expand itself in all directions, entirely filling it with a violet and purple light, and exhibiting a striking influence of the vast elasticity of the electric fluid.”

ELECTRICAL Fishes. All the phenomena of electricity which were known in the 17th century amounted only to the attraction of light bodies by the tourmalin when heated, and by amber, and a few other bodies, after friction. The light was discovered soon after, but the greatest discoveries, which indeed excited the wonder and the astonishment of the human species, such as the prodigious force of the Leyden phial, the identity of electricity, and the lightning, &c. belong entirely to the last century. Amongst these wonders we must undoubtedly reckon the electricity of fishes, which has been discovered within the last 40 years; for though the power of benumbing, or of giving a shock, was long known in one of those animals, namely, the torpedo, from which indeed it derived its name, yet that power was not known to be an effect of electricity before Mr. Walsh proved it within the above-mentioned period.

Four different inhabitants of the sea have hitherto been found to possess the peculiar property of giving shocks strong enough to stun, or actually to kill, small animals, and the most probable conjecture is, that nature gave them that property for the purpose of procuring their food, and perhaps, too, for deterring larger animals from approaching and annoying them. Three of these fishes are called the *torpedo*, the *gymnotus electricus*, and the *stirus electricus*. Of the fourth fish, which has not yet obtained a name, we have only a short and imperfect account, which we shall subjoin presently.

Whenever a communication is made by means of substances that are conductors of electricity, between one part and another of the body of any of these fishes, and a man, or other animal, is interposed, viz. forms part of the circuit; the man or other animal feels a shock analogous to that which is occasioned by the discharge of the Leyden phial.

If the circuit be formed of electrics, no shock will be felt; and if a man touch any of these animals with one hand only, without completing the circuit, he will, at most, only feel a slight tremor in the hand that touches the animal. The gymnotus alone affords a luminous spark, which becomes evident by making an exceedingly small interruption in the circuit of communication: It must be observed, however, that once, and once only, the torpedo afforded a spark which was seen by a distinguished Italian philosopher and his attendant, and he even heard the crackling noise of it. (Josephi Gardinii De Electrici Ignis natura Dissertatio, p. 100.) Excepting the above-mentioned properties, it is not known that these fishes have any other property in common with artificial electricity.

Agreeably to the plan of our work, we shall particularly describe the three principal electrical fishes, together with their anatomy, electrical properties, force, &c. under the articles TORPEDO, GYMNOTUS ELECTRICUS, and SILURUS ELECTRICUS. The short account of the fourth electrical fish is as follows.

This animal was found on the coast of Johanna, one of the Comoro islands, in lat. $12^{\circ} 13'$ south, by Lieutenant Wm. Paterfon, and he thus speaks of it in the Phil. Trans. vol. 76. "The fish is described to be seven inches long, two and a half inches broad, has a long projecting mouth, and seems of the genus tetradon. The back of the fish is a dark brown colour, the belly-part of sea-green, the sides yellow, and the fins and tail of a sandy green. The body is interspersed with red, green, and white spots, the white ones particularly bright; the eyes large, the iris red, its outer edge tinged with yellow."

Whilst the fish is living, strong shocks, like electrical shocks, are felt by a person who attempts to hold it between his hands. Three persons are mentioned in the account, as having experienced this property of one of these fishes, but the want of opportunity prevented the trial of farther experiments.

We need hardly add, with respect to all these fishes, that every electrical property vanishes with the entire death of the animal.

ELECTRICAL Fluid. The phenomena of electricity, so singular, so various, so extensive, and so powerful, as they are described in divers parts of this Cyclopaedia; are the effects of an unknown cause, which philosophers have called the *electric*, or the *electrical fluid*. That it is a fluid, and that it is elastic, there can hardly be a doubt; for if it be communicated from one body to another, it instantly expands itself all over the two bodies, and if again other bodies (always meaning such bodies as are capable of receiving and transmitting it; viz. *conductors*) be placed in contact with the above, the electric fluid will expand itself over these also, and so on; nor do we know any limits to its expansibility. But besides this fluidity, and this elasticity, whatever else has been advanced respecting the nature of this fluid, is mere hypothesis or conjecture, and of the principal of these hypotheses we shall now endeavour to give a succinct account.

When the attraction and the repulsion were the only electrical phenomena known to philosophers, they supposed that these were occasioned by a kind of unctuous effluvia, proceeding immediately from the electrified body; but when the light, the burning quality, and the peculiar smell of electricity were discovered; then the idea of their being produced by some modification of fire was naturally suggested, and accordingly the electrical fluid was commonly called the *electrical fire*, which name even at present is used by several writers on the subject of electricity. But notwithstanding the various effects, similar to those of common

fire, which are produced by electricity, an attentive examination of the concurring circumstances will easily show that electricity, and fire, or caloric, are things quite distinct from each other. In the first place it should be considered, that friction, or the sudden attrition of bodies, produces not only heat in a moderate degree, but in a great many cases, actual combustion, accompanied with light, &c. therefore it should not be wondered that the electric fluid, which passes with astonishing rapidity through bodies, should produce the above-mentioned effects; and it is to be remarked, that it is in its passage, or motion, alone, that the electric fluid produces effects analogous to those of fire. Secondly, if heat or fire, and electricity, were the same thing, they would be always together; or, more properly speaking, the effects of the one ought to be always accompanied with the effects of the other; but we find that a body simply electrified, or a Leyden phial containing a high charge, is not sensibly heated by it; nor does a body acquire any electricity by being heated; excepting that electricity which seems to be produced in consequence of an enlargement or contraction of parts, and which is observable in a few bodies only.

Some writers of eminence have laid great stress upon an experiment of Mr. Wilson, made some years ago at the Pantheon, where an immense apparatus was erected principally for the purpose of determining whether a point or a knob was the best termination for the conductors of lightning. The apparatus consisted of an electrical machine, which, though pretty large, was not, however, of any extraordinary size: but to this machine there was annexed an immense prime conductor, which consisted of a great number of military drums, covered with tinfoil, which formed a cylinder of above 155 feet in length, and more than 16 inches in diameter; and to this vast conductor were occasionally added 4800 yards of wire. The electric fluid drawn from this conductor, after it had been fully electrified by the machine, fired gun-powder; when it was drawn off by a sharp point. The particular construction was as follows: Upon a staff of baked wood a stem of brass was fixed, which terminated in an iron point at the top. This point was put into the end of a small tube of Indian paper, made somewhat like a cartridge, about an inch and a quarter long, and two tenths of an inch in diameter. When the cartridge was filled with common gun-powder, unbruised, a wire, communicating with the earth, was fastened to the bottom of the brass stem. Whilst the charge in the great prime conductor was kept up by the continued action of the machine, the top of the cartridge was brought very near the cylinder of drums, so that it frequently even touched the tinfoil with which it was covered. In this situation a small faint luminous stream was frequently observed between the top of the cartridge and the metal. Sometimes this stream would set fire to the gun-powder the moment it was applied; at other times it would require half a minute or more before it took effect. But this difference in time was supposed to be owing to some small degree of moisture in the powder or in the paper. Tinder was fired in the same manner, but much more readily. This experiment has, since that time, been imitated by Mr. Nairne with a Leyden phial.

Now the result of this experiment was supposed to corroborate the idea of the identity of electricity and fire; but there requires no great ingenuity to remark that the great quantity of electric fluid, which in this experiment must have passed through the metallic point, heated that point sufficiently to fire the gun-powder. It has been alleged, that in this case the passage of the electricity could not have power to heat that point, because, when that fluid is drawn off by a sharp point, it has less force than in any other case;

but it should be observed, that when surrounded by other bodies, as in the present case, a pointed body ceases to act as a point, and that more or less according to the nature of the bodies which surround it.

If we examine the propagation of heat and of electricity, their diffusibility becomes more apparent: for though heat passes through certain conductors of electricity (such as the metals) easier than through other bodies; yet sooner or later it penetrates every known substance, and an exceedingly small quantity of it diffuses itself alike throughout bodies of every kind; and that diffusion is performed very slowly; but the electric fluid pervades conductors only, and its propagation through them is performed in an immeasurable small portion of time. Mr. Henly, an ingenious electrician, whose labours considerably promoted that science, made the following observations. We constantly, he said, observe, 1. That if two bodies containing the inflammable principle in equal quantities (which is the case with bodies of the same kind, as glass and glass, metal and metal, &c.) be rubbed together, they acquire either very little electricity, or none at all. 2. That as one of the bodies contains a greater quantity of the inflammable principle than the other, they acquire a greater quantity of electricity, and such is the case when glass is rubbed with a metal. 3. That a certain degree of friction produces electricity, and that a more violent friction produces fire, but no electricity; and, 4. That, in general, bodies which are possessed of a greater quantity of the inflammable principle, give the electric fluid to bodies that have less of it, when they are rubbed together.

From these observations Mr. Henly concluded, that the electric fluid and fire are produced by similar operations, and are both extracted from bodies abounding with the inflammable principle; and therefore he was led to suppose that the inflammable principle, (at that time called *phlogiston*;) the electric fluid and fire, are only different modifications of the very same element; the first being its quiescent state of existence, the second its first active state, and the last its more violent state of agitation.

But to say that the electric fluid is a modification of the inflammable principle, without pointing out what that modification consists of, is the same thing as to say that one does not know what the electric fluid really is.

Certain philosophers have supposed the electric fluid to be nothing more than the ether mentioned by Sir Isaac Newton; but according to Newton's supposition, the ether is an exceedingly subtle and elastic fluid, which is dispersed throughout the universe, and the particles of which repel the particles of all other matter. But upon this supposition, as Dr. Priestley justly observes, the electric fluid is quite different from the ether, because it is not repulsive like the ether, but attractive, of all other matter.

Dr. Priestley, observing that the electric explosion taken in different kinds of air acted like other phlogistic processes, according to the language of that time, supposed that the electric matter either is, or contains, phlogiston; (Observations on different kinds of Air, vol. ii. sect. 13.) He might, however, have, with more probability, supposed, that in his experiments the phlogiston was extricated from the bodies which were immediately acted upon by the electric force; but since modern philosophers have utterly considered the supposed phlogiston to oblivion, we need not say any thing more about it.

The electric fluid has also been supposed to be of an acid nature, and the facts which have given origin to this supposition are, that electricity occasions the crystallization of an alkali in certain cases (see the article *ELECTRICAL Experi-*

ments;) and it slightly reddens certain blue vegetable colours. But it is more likely that the small quantity of acid which is thus manifested, is produced by the violent action of the electric fluid upon the air, or other contiguous bodies; for it is only in cases of its quick transition that these effects are produced.

An ingenious philosopher has endeavoured to establish a proposition, which (as he thinks) is warranted by the principal phenomena of electricity; namely, that the electric fluid consists of two principles; viz. of the purest and noblest hydrogen, a little rarefied, and of the elementary heat. All the experiments, he says, tend to prove, "intimam ignis electrici naturam minime contineri in acido quodam, ut ex aliquibus experimentis male digestis putarunt aliqui ceteroquin sapientes; sed hanc exurgere, et componi a duobus principiis, nempe a phlogisto, aut ut vocant Galli, hydrogeno, puriori, mobiliori, et admodum rarefacto, atque ex igne elementari sine calore latente, (calorico,) ubique per corpora univërfa diffuso, atque pro ipsorum capacitate in illis hospitante." De electr. ignis nat. Dissert. ab Josepho Gardinio, Mantuæ, 1792.

According to the most rational hypothesis, the electric fluid seems to be a fluid *sui generis*; viz. a fluid quite distinct from all other known fluids. It is imponderable, and invisible whilst in a quiescent state; and even the light which we see in its transition from one body to another is not, in all probability, the electric fluid itself; but the light which is elicited from other bodies or from the air: for in a perfect Torricellian vacuum no electric light is to be seen.

So far we have related the different hypotheses that have been advanced, with respect to the nature of the electric fluid, upon the supposition that the phenomena of electricity are produced by a single fluid; but there are several philosophers, who are of opinion that these phenomena are produced by two electric fluids, viz. the *vitreous* and the *resinous*. The peculiar merits of these two hypotheses, viz. of the hypothesis of a single electric fluid, and of that of two electric fluids, will be properly examined under the article *Theory of ELECTRICITY*.

The nature of these two supposed electric fluids has likewise been sought after with great attention by various labourers in the ample field of scientific inquiry; but no precise discovery has as yet determined any thing about them. It has been supposed that these two electrical fluids are fluids distinct from all others; but they have also been thought to be of an acid, and of an alkaline nature, viz. that the vitreous is of an acid, and the resinous of an alkaline nature. And indeed there are some experiments which seem to countenance this supposition; but we must refer the reader to the article *GALVANISM* for farther information concerning this particular; it being impracticable to convey a clear idea of the nature of the above mentioned experiments, without a previous statement of that new branch of electricity, which is at present successfully cultivated under the name of *Galvanism*.

ELECTRICAL Jar. See *LEYDEN PHIAL*.

ELECTRICAL Kite. See *KITE*.

ELECTRICAL Machine; a mechanism in which an electric body, such as glass, sulphur, resin, &c. is subjected to friction, in order to excite in it that power which is commonly known under the name of electricity.

When the attraction and the repulsion were the only phenomena of electricity known, and when those phenomena had been observed in small bodies only, such as natural pieces of amber, a turmalin, a diamond, and the like; a simple friction against the hand or the garment of the experimenter was sufficient to excite the electric virtue; but when the

ELECTRICAL.

the same property was discovered in sulphur, in resin, and in other bodies, which might be formed into pretty large masses, so as to produce effects more striking and decisive; then simple friction in the manner already mentioned was found inadequate to the purpose, and philosophers contrived to perform the excitation in a more commodious manner by mechanical means; and such mechanisms are what we now call electrical machines.

In the history of the original construction, and of the subsequent improvements of these machines, a contemplative mind is naturally led to admire the ingenuity of philosophers, as well as the alternate advancements of the science of electricity, and of the improvements of the machines; for if a new discovery pointed out a defect, or a useful improvement, in the machine; the improvement of the latter hardly ever failed to produce new discoveries, and so on.

The first mechanism which deserves the name of electrical machine, was contrived by Otto Guericke, burgo-master of Magd-bourg, and the celebrated inventor of the air-pump; a contemporary of Boyle.

Fig. 1. Plate VII. represents this first small and imperfect machine; but while we call it small and imperfect, we must not forget to acknowledge, that to the use, which its inventor made of this machine, we are indebted for the discovery of the light, the smell, and the cracking noise of electricity.

Previous to the description of this and the other electrical machines up to the present time, it will be necessary to premise a general idea of the parts of these machines, in order that the reader may be enabled to comprehend the objects for the attainment of which the different constructions were adopted, and may likewise be enabled to appreciate their peculiar advantages or defects.

An electrical machine being a mechanism capable of exciting an electric, so as to produce electrical phenomena, naturally consists of the following principal parts; viz. of the electric, the moving engine, the rubber, and the prime conductor; that is, an insulated conductor, which receives the electricity immediately from the excited electric body.

Formerly the electric was used of different substances, such as glass, rosin, sulphur, sealing wax, &c. which variety was adopted on two accounts, first, because philosophers had not quite determined to which of these bodies the preference might be given, and secondly, on account of producing a negative or positive electricity at the pleasure of the electrician; for before the electricity of the insulated rubber was discovered, sulphur, rough glass, sealing-wax, or other resinous body, was used for producing the negative electricity; whilst smooth glass served for the production of the positive or vitreous power. At present smooth glass seems to be the only substance universally used, and that on account of its power, of its durability, of its cheapness, and of its being easily formed into any shape which may best answer the views of the electrician. And when the machine has an insulated rubber, the operator may obtain either positive or negative electricity at pleasure without changing the electric.

The form of the glass has been much varied, but those which are at present generally used, and have been found preferable to all others, are cylinders, and circular plates. Globes are likewise used, but less frequently.

The cylinders are made with two necks; they are mostly used without an axis; for this is only an obstruction, and has no real use; and their more usual size is from four inches in diameter, and eight in length, to twelve inches in diameter and two feet in length; but some very powerful electrical machines have been made in London with cylinders of two feet in diameter and upwards. The globes are always

made with one neck, and the circular plates have been used from the small size of six inches in diameter to the largest size possible to be made.

With respect to the engine, which is to give motion to the electric, multiplying wheels have been generally used for machines containing a globe or a cylinder, and these communicate to the electric a quick motion, while they are conveniently turned by a winch. The usual method is to fix a wheel on one side of the frame of the machine, which is turned by a winch or handle, and has a groove on its circumference. Upon the brass cap which is cemented to the neck of the glass globe, or to one of the necks of the cylinder, a pulley is fixed, the diameter of which is about the third or fourth part of the diameter of the wheel; then a string, or strap, is put over the wheel and the pulley; and by this means, when the winch is turned, the globe or cylinder makes three or four revolutions for each revolution of the wheel. There is an inconvenience generally attending this construction, which is, that the string becomes sometimes so very slack, that the electric will not turn round when the winch is moved. To remedy this inconvenience the wheel should be made moveable with respect to the electric, so that it may be fixed at the proper distance; or else the pulley should have several grooves of different diameters on its circumference; in which case the string may be passed from a groove of smaller diameter to that of a larger, in proportion as it becomes slack, or extended. The motion of the electric, which has been found most productive of electricity, is about five revolutions in a second, which cannot conveniently be performed by means of a simple winch applied immediately to the cap at the neck of the globe or cylinder, and therefore multiplying wheels have been used. Yet when the cylinders are not very large, and the mechanism is nicely constructed with the best rubber, rendered active by the zinc amalgam, a simple winch has been found fully sufficient, and accordingly several machines have been constructed upon that simple plan, and are at present frequently used. In these machines the cylinder may be conveniently cauted to make about three revolutions in a second. The circular glass plate machines are always moved by a simple winch, which is fixed to the axis of the glass plate or plates; (for some of these machines contain two plates fixed on the same axis, parallel to each other.) The axis passes through a hole in the centre of the plate or plates, and is fixed thereto, in a situation perpendicular to the plate, by means of certain sockets on either side of the plate.

In some of the machines furnished with a globe or a cylinder, a metal wheel and pinion, or a wheel and an endless screw, have been used, instead of the above-mentioned pulley and string. And when this construction is new, and is properly executed, it answers very well; but it is apt to make a disagreeable rattling noise, and unless it be frequently oiled long wears away in consequence of the great friction of its parts.

The rubber, as it is at present more commonly constructed, consists of a leather cushion (the leather mostly used is bassil skin, or flannel, stuffed with hair) and having a piece of silk (either varnished or unvarnished) thrown over, which being fastened to the lower part of the cushion, passes between this and the glass, and projects a considerable way beyond the cushion, and over the glass. Another construction, which was recommended by Dr. Nouth, is likewise not unrequently used. It consists of a silk cushion stuffed with hair, and having a piece of leather thrown over, so that the leather is what immediately touches the surface of the glass, and to the upper edge of this leather, a piece of silk is generally

added, which rests upon the glass, and covers about one-third part of its surface.

In these or similar constructions, the amalgam is always to be used, and this should be confined to that part of the rubber which the glass globe or cylinder enters as it revolves. In short, that side of the rubber which the glass enters in whirling must be made as perfect a conductor as possible, in order to furnish the glass with a plentiful supply of electricity; and the opposite part must be as much a non-conductor as possible, in order that little or none of the fluid which is accumulated upon the glass may return to the rubber. In the construction of the rubber care must also be taken that it be free from points or sharp edges; and it should be supported by a spring, by which means it may adapt itself to the inequalities of the glass. It should also be insulated for the purpose of obtaining a negative electricity.

The prime conductor, or first conductor which is applied to the excited electric, is nothing more than an insulated conducting substance furnished with one or more points at one end, for the purpose of collecting the electricity immediately from the excited electric. (See COLLECTOR of Electricity.) When the conductor is of a moderate size, it is usual to make it of hollow brass, or of tin plates; but when very large, it is more commonly made of wood, or tin plates, or paste board, covered with tin-foil, or even with gilt paper. The conductor is generally made of a cylindrical shape; but be the form of it what it may, it should always be made free from points, or sharp edges, and if holes are to be made in it, which on many accounts are very useful, these should be well rounded, and made perfectly smooth. If any part of the prime conductor is to be made larger than the rest, this ought to be that which stands furthest from the excited electric; for at that end the electricity endeavours most to escape.

It has been constantly observed, that the larger the prime conductor is, the denser or stronger spark may be drawn from it; for the quantity of electricity discharged in the form of a spark is nearly proportional to the size of the conductor; and for this reason the prime conductors have been made much larger of late years than they were made formerly. Its size, however, may be rendered too large, so that the dissipation of electricity from its surface may be little short of the supply from the electric, in which case so large a conductor would only be an unwieldy and useless incumbrance. Beside the above-mentioned parts, the machine must have a strong frame to support the electric, the rubber, and the wheel. The prime conductor should be supported by pillars of glass, or of other solid non-conductors, and not by silk strings, which admit of continual motion. In short, the machine and the prime conductor should be made to stand as steadily as possible, otherwise the experiments cannot be conveniently and satisfactorily performed. We shall now proceed to describe the particular electrical machines.

Fig. 1. Plate VII. represents Otto Guericke's original machine. It consists of an horizontal frame, the peculiar construction of which is not mentioned in his work "De Vacuo Spatio;" for it is in that book that the electrical machine is described: *a c* and *b d* are two uprights, which support the axis of the globular electric, and such are all the parts of this machine with respect to the formation of the electric, which is of sulphur; he gives the following directions: Take, says he, a spherical glass phial of the size of the head of an infant; fill it with sulphur, which has been previously powdered in a mortar, and thus filled, expose it to the fire to liquify the sulphur, and when afterwards cooled, break the glass phial, in order to obtain the globe of sulphur. So little did he

imagine, as Dr. Priestley justly observes, that the glass globe itself with or without the sulphur would have answered his purpose as well. This globe, he adds, may be perforated with a hole quite through, and an iron axis may be fixed to it, and thus the globe is ready for use.

To shew the virtue (which he calls *virtutem conservativam*) of this globe, place the axis of it upon the two supports *a*, *b*, of the little machine *a b c d*, about a foot high from the base, and place small bodies of any kind under it, such as leaves of gold, silver, paper, &c. then grasp the globe or rub it with the hand sufficiently dry, and the sulphur will then attract the small bodies, &c.

Fig. 2. Plate VII. represents Mr. Hauksbee's electrical machine, the various parts of which will be easily comprehended by inspecting the figure. This machine has no rubber, no prime conductor, or wheel for making experiments; for no such things were wanted at his time; but it may be easily accommodated with them all. A conductor, for instance, may hang from the ceiling, a rubber may be supported by a spring fixed under the globe, and a table placed near the machine may receive the apparatus necessary for making experiments. The inconveniences of this construction are, that the operator cannot well turn the wheel himself. An assistant is necessary for it, who must sit to his work. This machine admits one globe only, but a considerable variety of globes, and cylinders, or spheroids, may be successively applied to it.

Fig. 3. Plate VII. represents the abbé Nollet's electrical machine, a construction much in use about the time that the peculiar phenomena of the Leiden phial were first discovered. In those early times electricians had no idea, that it was possible to make the electric revolve too fast. They, therefore, made the wheels of their machines very large, which of course required a large and substantial frame; the electric was rubbed by the hand, the prime conductor was a bar of iron, or a gun barrel, and sometimes a chain, suspended in silk lines from the top of the room, and the apparatus was placed upon an adjoining table.

The phenomena which were produced by the above-mentioned machines naturally excited a desire of exciting a much greater power of electricity; and with this view Dr. Watson contrived the machine represented by *fig. 4. Plate VII.*, in which four large globes might be whirled at once, and their power might be united.

N. B.—It is only for the purpose of not enlarging the plate, that the same prime conductor has been represented as belonging to two machines, *viz.* to *fig. 3.* and *fig. 4.*

This machine was furnished with proper rubbers for all the four globes, and these rubbers were adjustable by means of a screw for each rubber.

Fig. 5. Plate VII. represents a machine contrived by Mr. Wilson. Its construction is such that the same person may turn the wheel at the same time that he performs the experiments. But the rubber is not insulated, and both the rubber and the cylinder are not sufficiently distant from other bodies. The prime conductor stands upon the same frame, which was undoubtedly an advantage over the other machines of that time; but being supported by silk strings, it was liable to a constant shake, which rendered it unfit for a great many experiments.

Fig. 6. Plate VIII. represents an elegant sort of electrical machine, of a very compact form, and capable of considerable power. The machinery is contained in the brass box *a*, and it consists of a brass wheel, whose teeth move an endless screw, at the lower part of the axis, which comes out of the box, and supports the glass globe *d*; there being of a brass socket on the upper part of the axis, in which the neck of the globe

globe is cemented. The brass box *a* is screwed to the table by means of a clamp, which is always fixed to it; and it will be easily conceived that by turning the winch *b*, the globe *d* will be caused to turn horizontally: *e* is the rubber which is supported by a brass spring, and may be made to press more or less upon the glass globe, by means of an adjustment at *c*. The prime conductor *f* is supported by a separate stand upon a glass pillar, and is to be placed upon the table adjoining to the machine. The rubber of this machine is not insulated, yet this defect was obviated by removing the rubber *e*, and fixing another rubber upon an insulating stand, which was clamped to the table close to the machine. Upon the whole it must be acknowledged that this machine is both very portable and very useful, nor can anything work more pleasantly, as long as the work within the box *a* remains in proper order; but we have already observed that this construction is apt to wear out pretty fast, and is generally attended with an unpleasant rattling. This machine is also attended with another inconvenience, which is the upright position of the globe and the rubber, in consequence of which whatever is put upon the latter, as the amalgam, &c. is apt to drop out.

Fig. 7. Plate VIII. represents a machine contrived by Mr. Read, a philosophical instrument maker. This machine may be easily distinguished from the others which are represented upon the same table in the plate, by observing its bottom board, which is fastened to the table by means of the two clamps *o, o*. The cylinder *d* of this machine stands perpendicular to the horizon, and is supported by a brass arm *e*, which receives the upper end of the axis; and motion is given to it by means of a pulley at the lower end of the axis, and a wheel *g* which lies parallel to the table; a string going round both the wheel and the pulley. The prime conductor *a* is furnished with teeth or points by way of collector, and is screwed to the wire of the coated jar *b*, standing in a socket, between the cylinder and the wheel; so that the coated jar *b* serves as a Leyden phial, and as a stand for the conductor. The rubber *r* is supported by a brass spring, which may be adjusted by a screw that passes through the arm *e*. But this rubber cannot be insulated. This machine was, some years ago, much used for medical purposes; for when Mr. Lane's discharging electrometer *c* was annexed to it, the operator might administer as many shocks as he pleased, precisely of the same strength.

When this machine was used for simple electrization, or for other purposes where no shocks were required, then the coated jar *b* was removed, and another jar, not coated, was placed instead of it, which then served as a mere insulating stand to the conductor *a*.

Fig. 8. Plate VIII. exhibits Dr. Priestley's electrical machine, of which he gives the following description in his History of Electricity. "The machine," he says, "which I would advise a philosopher to construct for his own use, is the result of my best attention to this subject. I have used it above six months (how much I leave the reader to imagine) without seeing the least reason to make any alteration of consequence in it; and believe it to have almost all the advantages which an electrical machine designed for the closet can have.

"The frame consists of two strong boards of mahogany *a, a*, of the same length, parallel to one another, about four inches asunder, and the lower an inch on each side broader than the upper. In the upper board is a groove, reaching almost its whole length. One of the pillars *b*, which are of baked wood, is immovable, being let through the upper board, and firmly fixed in the lower, while the other pillar slides in the groove above-mentioned, in order to receive

globes or cylinders of different sizes; but it is only wanted when an axis is used. Both the pillars are perforated with holes, at equal distances, from the top to the bottom; by means of which, globes may be mounted higher or lower, according to their size; and they are tall, to admit the use of two or more globes at a time, one above the other. Four of a moderate size may be used, if two be fixed on one axis: and the wheel has several grooves for that purpose.

"If a globe with one neck be used, as in the plate, a brass arm with an open socket *c* is necessary to support the axis beyond the pulley; and this part is also contrived to be put higher or lower, together with the brass socket in which the axis turns. The axis *d* is made to come quite through the pillar, that it may be turned by another handle, without the wheel, if the operator chooses. The frame being screwed to the table, may be placed nearer to, or farther from, the wheel, as the length of the string requires, in different states of the weather. The wheel is fixed in a frame by itself *e*, by which it may have any situation with respect to the pulley, and be turned to one side, so as to prevent the string from cutting itself. The hinder part of this frame is supported by a foot of its own.

"The rubber *f* consists of a hollow piece of copper, filled with horse hair, and covered with a basil skin. It is supported by a socket, which receives the cylindrical axis of a round plate of glass *g*, the opposite part of which is inserted into the socket of a bent steel spring *h*. These parts are easily separated, so that the rubber, or the plate of glass that serves to insulate it, may be changed at pleasure. The spring admits of a twofold alteration of position. It may be either slipped along the groove, or moved in the contrary direction, so as to give it every desirable position with respect to the globe or cylinder; and it is, besides, furnished with a screw *i*, which makes it press harder or lighter, as the operator chooses.

"The prime conductor *k* is a hollow vessel of polished copper, in the form of a pear, supported by a pillar, and a firm basis of baked wood, and it receives its fire by means of a long arched wire, or rod of very soft brass, *l*, easily bent into any shape, and raised higher or lower, as the globe requires; and it is terminated by an open ring, in which are hung some sharp pointed wires *m*, playing lightly on the globe when it is in motion. The body of the conductor is furnished with holes, for the insertion of metallic rods, to convey the fire wherever it is wanted, and for many other purposes convenient in a course of electrical experiments. The conductor is, by this means, steady, and yet may be easily put into any situation.

"When positive electricity is wanted, a wire, or chain, as is represented in the plate *n*, connects the rubber with the table or the floor. When negative electricity is wanted, that wire is connected with another conductor, which must be placed upon a separate insulating stand near to the machine, while the conductor *k* is connected by another wire or chain with the table. If the rubber be made tolerably free from points, the negative power will be as strong as the positive.

"In short, the capital advantages of this machine are, that glass vessels, or any other electric body, of any size or form, may be used, with one neck, or two necks, at pleasure; and even several of them at the same time, if required. All the essential parts of the machine, the globe, the frame, the wheel, the rubber, and conductor, are quite separate; and the position of them to one another may be varied in every manner possible."

The progress of the science of electricity since Dr. Priestley contrived the above-described machine, has shewn the imperfection of several of its parts, and the useless complication

of the whole. The shape, and especially the long neck of the prime conductor, would not at present be used by any electrician; it being ill suited to the performance of experiments, and very apt to dissipate the electricity, when a great deal of that power is furnished by the electric, which is the case with most of the modern machines furnished with the zinc amalgam. The necessity of an intricate frame, capable of admitting more than one globe or cylinder, is also superfluous by the observation, that one well formed large cylinder produces a much greater quantity of electricity, than four or more small ones, and the friction is much more considerable in the latter than in the former case.

Fig. 9. Plate VIII. represents a compact machine, somewhat similar to the last, but much more commodious. It consists of a pillar of mahogany *a*, standing upright upon three feet. This pillar divides in two plates to receive a wheel *b* in the lower part of it, and in the upper part a pulley *c*, which is turned by a leathern strap *d* tightened by means of a small buckle. In the centre of the pulley is a strong iron spindle, turning in two firm brass sockets, fastened to each side of the pillar. In one of these sockets the extremity of the spindle turns upon a centre, by means of a piece of iron *e* screwed into it, while the other is held tight by a brass clasp, which may be made to hold it closer, or more loosely, at pleasure, by means of a screw *f*. The iron spindle terminates in a male screw, answering to a female screw in the brass cap of the globe *g*; and by this means any globe may be taken out, and another put into the machine with very little trouble, if these parts be always made to the same pattern. The rubber *h* is separated from the spring *i* by a plate of glass *j*, which effectually insulates it; but the chain *k* connects them together when positive electricity is wanted, as in the usual method of electrifying. The spring may be made to press more or less, by means of a screw *l*; and it may be raised higher or lower, to suit globes of different sizes, by means of a contrivance which is not represented in the plate. The prime conductor *m n o* is like that of the preceding machine, and it must be placed upon a table adjoining to the machine. When negative electricity is wanted, the chain *k* must be removed from the rubber, and hung upon the prime conductor, so as to connect it with the table; and a short brass rod, with a knob at its end, must be screwed into a small socket, which will be found in the rubber above the glass plate. This brass rod will then serve for a negative prime conductor. As this machine is apt to shake when in action, its three feet may be screwed to a large board, upon which the person who turns the wheel may also rest his feet.

It will be obviously remarked that the prime conductor of this machine has the same imperfections that have been mentioned in the description of the preceding machine.

Fig. 10. Plate IX. exhibits the electrical machine contrived and used by F. Beccaria of Turin, a distinguished electrician. This machine comprehends all the improvements, and is constructed with all the precautions, which the state of the science at that time could suggest. But no regard whatever was paid either to size or portability. T S is the glass cylinder, to the extremities of which two wooden caps were adapted, and the whole turned round the points of the screws V, V, which entered a little way the centres of the caps. One of these caps was furnished like a pulley, to receive the string which went round the wheel R. The form of the frame will be easily comprehended by inspecting the figure; and as for its strength and size, they may be easily derived by observing, that besides the wheel and cylinder it had a place between the handle of the wheel and the front, large enough to contain two men, *viz.* one who turned the wheel,

and another who rubbed the cylinder T S. And the two men with the whole machine were insulated; for the legs E, F, G, H, were of glass. The circular boxes, which are seen on the floor round the legs, are semicircular boxes of tin, two of which being placed round each leg formed a whole circle. When the machine was in use these tin boxes were filled with warm ashes for the purpose of keeping the glass legs dry. The axis of the wheel R worked in a particular frame, which might be screwed into the large frame at any required distance from the cylinder, in order to render the string sufficiently tight.

The prime conductor, which is not drawn in the plate, consisted of a cylinder of tin 12 feet long and one foot in diameter; it presented a conical termination to the middle zone of the cylinder T S, and had its opposite extremity of a semiglobular shape. This prime conductor was suspended upon silk strings.

The great disparity between the size of the cylinder and that of the whole frame, is what will easily strike the attentive observer; yet it must be acknowledged, that to a real philosopher who had nothing else in view, but the improvement of the subject, this machine must, at that early period, have afforded ample satisfaction; and, in fact, whoever will peruse Beccaria's instructive work, entitled "Eletticismo artificiale," will readily perceive how useful it proved to its inventor. It afforded either positive or negative electricity with equal facility; for as the whole machine was insulated, when positive electricity was required, a chain was appended to the machine which formed the communication between it and the ground; and when negative electricity was wanted, the chain was placed from the prime conductor to the ground, and then the whole machine became a negative conductor. We need not point out how many parts of this machine have been rendered useless, or defective, by subsequent improvements.

The form of electrical machines mostly used of late, is represented in *fig. 11, Plate IX.* ABC is the bottom board, which, when the machine is to be used, is fastened to the table YZ, by means of the clamp at C: D, E, are two upright pieces of wood, firmly fastened to the bottom board ABC, and supporting the glass cylinder FG, and the wheel H. The two necks of the cylinder are furnished with caps, one of which has an axis, which passes through a hole in the upright support E, and has a pulley firmly fixed to its outer extremity. The axis of the other cap runs in a small hole towards the upper part of the support D: O is the pillar which supports the rubber or cushion P; and is fixed with a joint to the bottom board. The middle part of this pillar is of glass, which renders the rubber insulated: Q is a brass screw, which, passing through the lower part of the pillar O, serves into a piece of wood which is firmly fixed in the bottom board. This serves to regulate the pressure of the cushion upon the cylinder. The rubber consists of a cushion of leather stuffed with hair, and fixed to a backboard, which is screwed to the upper part of the pillar O. A piece of silk S comes from the lower edge of the rubber, and passing between it and the cylinder, extends itself over the cylinder, until it nearly meets the points of the collector. The prime conductor W is separate from the machine; it is of a cylindrical form, with globular terminations, and is supported by a glass pillar upon a circular wooden foot. That end of the prime conductor which stands farthest from the cylinder is generally furnished with a thick wire, about four or five inches long, and terminating in a brass ball.

It is evident that with this machine positive or negative electricity may be had at pleasure; for when positive electricity is wanted, the rubber is connected with the ground, and

ELECTRICAL.

and when negative electricity is wanted, then the prime conductor is connected with the ground, and the negative electricity is obtained from the rubber. Sometimes another conductor is connected with the rubber.

When the glass cylinder is very large, such as of 18 inches, or two feet, in diameter, then the frame of the machine is made to stand upon the ground, with this difference from the above, that instead of the bottom board A B C, the two upright supports reach down to the ground, where they spread out into a double foot, and are, at about midway between the cylinder and the ground, fastened to each other by two strong horizontal bars. The pillar of the rubber is fastened to a projection in the upper one of those bars. The stand of the prime conductor is likewise high enough to rest upon the ground.

Fig. 12. Plate IX. represents Nairne's electrical machine, a most compact, simple, and, at the same time, powerful machine, useful for electrical experiments in general, but particularly adapted to the purposes of medical electricity. A is the glass cylinder; B, B, two glass pillars which support the cylinder A; C is the handle by which the cylinder is turned; G, and R, are two metallic conductors for the positive and the negative electricities. These conductors are supported by the glass pillars D, D; E is the bottom board into which the pillars B, B, that support the cylinder, are firmly fixed. Underneath this board are fastened pieces of wood forming four grooves; F, F, are two pieces of board, part of which are inserted into two of the four grooves under the board E. In these pieces the pillars D, D, that support the conductors, are fixed; H is a brass knob, one of which is soldered on the outside of each conductor.

The cushion or rubber is attached to the side of the conductor R, next to the cylinder; K is a piece of silk, one end of which is glued to the under part of the cushion, and it is turned over, so that part of the silk stands between the cushion and the cylinder, and projects over the latter, as at K, until it nearly reaches the collecting pointed wires which are fixed to the side of the other conductor.

L, L, are the heads of two wooden screws which pass through the board E, and are to be screwed until their lower ends press against the upper part of the sliding pieces F, F, when these are slipped into the grooves under the said board. One of these screws serves to keep the rubber in contact with the cylinder; for when the sliding piece F of that conductor, which carries the rubber, is pushed into the groove, so that the rubber may be pressed against the cylinder, the screw L will confine it in that situation. The other screw, L, serves to keep the conductor G steady.

The ends N, N, of the conductors may be removed, and then the opening of a coated electric jar, fastened within each conductor, is discovered, as is represented in *fig. 14. Plate X.* where one conductor only of this machine is to be seen. In the inside of each jar a piece of cork is fitted, and in the cork a small glass tube cast d, and likewise a brass wire with a ball, as seen in *fig. 14.*

The machine is fastened to the table by means of a strong iron clamp; and is worked, as the figure indicates, by a simple winch, without any multiplying wheels. There is a remarkable nice apparatus accompanied with this machine, which may be adapted to all cases of medical electricity. The principal parts of this apparatus are represented in *figs. 13 and 14. Plate X.*

In *fig. 13.* part of the electrical machine is shown, in order to exhibit the flexible prolongations, which are fixed to the conductors for the purpose of giving sparks to any part of the human body: d, d, are two compound joints, each of

which has not only a vertical, but also an horizontal motion, when applied to the conductor: f, f, f, are three metallic tubes, connected by means of four pieces of wood, and two pliable joints. One of those tubes is screwed to the joint d, and to the last a large ball b is screwed, which communicates the spark. To the same tube a piece of wood g is fastened, having a hole at right angles to the tube, and K is a glass handle, the upper part of which fits that hole; so that by applying the hand to the lower part of the glass handle, the spark may be given to any part of the body. In the figure a person is represented, who directs the communications with the conductors, to his shoulders, by means of the glass handles k, k.

Fig. 14. represents a person passing shocks through his leg. In this case the end cover from one of the conductors is removed; the chain b is suspended to the knob of the jar, and is made to communicate with the chain O, which is furnished with a wire at the other end p, and to this wire a piece of wood with a hole is attached, which fits the top of the glass handle k; n is the discharging electrometer, fixed for the purpose, upon the conductor, and another wire O, with another glass handle k, is fixed to it; then the two wires p, p, being applied to any part of the body through which the electric shock is to be passed, and the machine being worked, the shocks will, without any alteration of the apparatus, be repeatedly sent through that part, &c. for suppose that the conductor, which is represented in the figure, is the positive conductor, the external surface of the jar will be charged positively, whilst the fluid of the inside will pass through the chain b, to the table, &c. and when the jar is charged enough for the discharge to pass from the conductor to the knob of the discharging electrometer n, the discharge will take place, and the shock will pass through the part which is interposed between the two wires p, p.

The two additional grooves under the bottom board of the machine are used only for the convenience of packing the machine into as small a box as possible; and for this purpose the sliding pieces F, F, which support the pillars of the conductors, are slipped into the two grooves which are situated nearer to the handle side of the machine.

"The *figs. 15, 16, Plate X.* and *17, Plate IX.* exhibit an extremely portable electrical machine and its parts, invented by the Rev. W. Pearson, of Lincoln. This machine is intended for medical purposes, and especially for the administration of electricity in cases of suspended animation. Upon repeated trials it has proved sufficiently useful, and its peculiar advantages are, great portability, and sufficient power; it is guarded so as not to be readily affected by moisture; it is capable of being used without a table or stand, in cases of necessity; it is rendered fit for use upon the shortest notice, and it is not very liable to be broken. In *fig. 15.* the machine is represented as viewed by an eye situated directly over it. A B C D is a small box $6\frac{1}{2}$ by $7\frac{1}{2}$ inches within, and 6 inches deep, made of half inch board: upon the bottom of the box lies a plate of glass also $9\frac{1}{2}$ by $7\frac{1}{2}$ inches, cemented to the wood at the four corners by common electrical cement; this plate is coated on both surfaces with tin-foil seven inches by five, as represented at Q, *fig. 16.* (except that the slips of tin-foil at H and I are pasted or gummed upon the under side only.) and is used as a substitute for a jar of 35 inches of coated surface, it being of no consequence what the shape of the glass be, provided it have a proper quantity of coating. M E N is a cylinder of glass of four inches diameter, the body of which is $7\frac{1}{2}$ inches long; at M and N are brass or boxen caps, cemented as in other machines, upon the small cylindrical ends of which the cylinder revolves, by means of the simple winch C, which may

ELECTRICAL.

be taken off or put on at pleasure, either by screwing, or by being inserted upon a square shoulder. The central points of revolution of N and M are at about $2\frac{1}{2}$ inches from the top of the box, the first inserted into a circular hole in one end of the box, and the other *let down* in an open place made down through the other, which has a detached piece of similar wood to fit it, and to keep the cylinder in its place. L is the cushion, and E the silk placed in the usual way; D is a screw with a milled bead, which, by the assistance of a tapped nut, placed fast in the inside of the box at four inches from the bottom, presses against the elastic part of the support of the cushion which is hid from the eye; this support, which may be of elastic wood, coated above D with tinsel, or of any elastic metal, is screwed fast to the back of the box near the bottom in the inside. The chain at D is hung on the screw at pleasure, as the wood is found to be in a good or bad conducting state.

"F is a piece of light wood turned very smooth, and neatly covered with tinsel, its ends being rounded. This piece, which I shall call the collector, is furnished with about a dozen fixed pins of brass, projecting against the side of the cylinder, as represented in the figure, as near as may be without touching it. The collector is six inches long, and somewhat more than an inch in diameter, and is supported by two solid glass pieces C, C, of an inch and three-quarters in length, and nearly half an inch in diameter, cemented into the side of the box at $4\frac{1}{2}$ inches from the bottom, and each at an inch from the end of the collector: by this means the collector becomes insulated, and has a chain to be hooked on an eye of wire, fixed on any part thereof, so as to fall occasionally upon the upper insulated coating of the plate of glass in the bottom of the box; the chain, however, must not be so long as to extend beyond the coating by any motion of the box.

"B is a glass tube of about one-eighth of an inch bore, and about 3 or $3\frac{1}{2}$ inches long, with a ring of brass or horn, that has a male screw cemented upon the middle of it, to screw into another ring that has a female screw, and is cemented into the front side of the box at $4\frac{1}{2}$ inches from the bottom. Through this tube passes a brass wire, as thick as will easily move in it, about $4\frac{1}{2}$ inches long, tapped about an inch at each end, and a little smoothed; on each end of this wire is a tapped nut, which screws back or forwards to or from the ends of the tube, so as to hold the wire in any situation that may be required, with regard to the distance of its ends from those of the tube. The wire has also two brass balls, one of which has its diameter less than that of the tube, that it may move through the circular hole into the box, to prevent its falling on the glass plate, which it might do if screwed off and on within the box. O, O, are the directors, with handles of glass, each six inches long, besides the balls and wires.

"There is yet one part of the apparatus which it was not necessary to exhibit in the plate; *viz.* the insulating stool; this is made exactly of a size to cover the box, and has four feet of glass, almost six inches long. Underneath that part of the stool which covers the collector, slides a little drawer, which contains the tube, with its appendages, milled nut, chains, handles of the directors, and amalgam, and must be taken from the stool when used. When packed, the four feet of the stool go exactly into each corner, and the edge of the drawer just within the side of the box, by which means the stool is kept in its place as a cover; and lastly, the wires of the directors pass through the stool, which is of inch plank, at the middle near the two ends, and by screwing into the fixed nuts in the edges of the box's ends at K and K, until the balls touch the wood of the stool, fix the whole so

firm that a handle, such as is used in a chest of drawers, fixed on the centre of the stool, serves for carrying the whole apparatus by.

"With respect to the use, the machine being freed from moisture and dust, and amalgam applied to the cylinder, the shock is administered in the following manner; *viz.* let the small chain fall from the collector upon the upper coating of the glass plate, and place the inner ball at the required striking distance, suppose a quarter of an inch, as the case may require, and fix it there by means of the adjusting nuts, and the quantity of the charge will be limited in the same manner as by Lane's electrometer; then connect one chain with the conducting wire which passes through the tube, and the other with a brass ring connected with the slip of the under coating at H, or at I, as is most convenient, and hook the opposite ends upon the wires of the directors, whereby a spark may be sent through any particular part of the body. When the spark only is required, the small chain is removed from the collector, and also the long chain connected with the hook at H, is taken away; the inner ball is then fixed so as to touch the collector by means of the adjusting nuts; in which case the coil stop, the wire in the tube, and the second long chain connected therewith, form together one conductor. After the exterior end of this chain is attached to the wire of one of the directors, the spark may be directed into any particular part; when the eye is the part affected, a pointed wire must be used instead of the wire carrying the ball, which must be made to screw into the socket of the director. When a spark is taken out of the body, the patient must stand on the stool, and hold the chain, connected as before, in his hand; and then the operator or assistant may take sparks from him, as in other machines."

The last species of electrical machines are those which, instead of a globe or cylinder, contain one or more flat circular plates, fixed to an axis and turned by a simple wheel.

The honour of having invented the plate electrical machines has been claimed by two distinguished persons, *viz.* by Dr. Ingenhousz, physician to the emperor of Germany, and by Mr. Ramsden, an exceedingly ingenious mathematical instrument maker, in London. Dr. Priestley was of opinion, that each of these gentlemen, independent of the other, constructed a machine, in which a circular glass plate was the electric. It has been, however, also confidently asserted, that Dr. Ingenhousz conceived the original idea, and Mr. Ramsden executed it. The glass plate of those machines which Mr. Ramsden first constructed was about nine inches in diameter. The plate turned vertically, and rubbed against four cushions, each an inch and a half long, placed in the opposite ends of the vertical diameter. The prime conductor was a brass tube, having two horizontal branches, which came within about half an inch of the circumference of the glass plate, so that each branch took off the electricity excited by two of the cushions. This original machine could not afford the negative electricity, as the rubbers could not be easily insulated. To remedy this defect, the table upon which the machine stood, and likewise the person who worked it, were placed upon a large insulating stool, and the prime conductor was connected with the ground; then the table, the operator, and whatever else stood upon the insulating stool, were in a negative state; but this negative power being communicated to a surface considerably large in proportion to the size of the machine, was of course very weak, and altogether the contrivance was but a clumsy one.

Since the first years of its invention, this plate machine has been frequently varied, and has received several essential improve-

improvements. Its size, as well as its power, has been greatly increased; and, in fact, one of the most powerful electrical machines extant, is of this kind, and belongs to the Teylerian museum at Haarlem. It was constructed under the direction of Dr. Van Marum, who performed a vast number of very interesting experiments with it.

This machine consists of two circular glass plates, each 65 inches in diameter, which being fixed parallel to each other, and 7½ inches asunder, on a common axis, are turned by means of a winch, without any accelerated motion, and are rubbed by eight rubbers, all being fixed in a proper frame, the construction of which is clearly shown in *Plate I**, and *Plate X.* of *Electricity*; for the electrical machines, which are delineated in those plates, differ in no essential part from that which is at present under consideration. Each plate is rubbed on both surfaces; two rubbers being on one side, and two on the opposite side of each plate. The prime conductor is divided into two branches, which enter between the plates, and by means of points, collect the electric fluid from their inner surfaces only. Two men are in general employed to work this machine; but when it is to be kept in action for a long time, then four men are put to it.

Since its first construction this machine has undergone several alterations, and has been considerably improved.

The power of this Teylerian machine is very extraordinary, in all probability exceeding that of any other electrical machine that was ever constructed. And the following particulars will convey some idea of that power.

A very sharp steel point presented to the prime conductor of this machine, drew a luminous stream of electricity about half an inch long. When a sharp steel point was fixed to the conductor, so as to project three inches from its surface, on working the machine that point threw out streams of light about six inches in length, when a ball of three inches in diameter was presented to it; and the luminous streams were only two inches long when another point was presented instead of the ball.

The sensation, commonly called the spider's web, on the face of the bystanders, when this machine is in action, is frequently felt at the distance of eight feet from the prime conductor. A thread six feet long, suspended perpendicularly, was sensibly attracted by the prime conductor at the distance of 38 feet. A pointed wire, presented to the prime conductor, appeared luminous even at the distance of 28 feet. When another conductor was presented to the prime conductor of this machine, after the manner shown in *Plate X.* of *Electricity*, and a communication was made between the former and the ground, by means of a long brass wire $\frac{1}{8}$ of an inch in diameter; it was found that whilst a stream of electric fluid passed from the latter conductor to the former, the brass wire gave small sparks to conducting bodies that were placed near it. The sparks between the two conductors were generally 21, but sometimes even 24 inches long. This spark was crooked, and darted many lateral brushes, as is shown in the above-mentioned *Plate X.* A single spark from the prime conductor melted a considerable length of gold leaf. A Leyden phial, containing about one square foot of coated surface, was fully charged by about half a turn of the winch, so as to discharge itself; and by repeated trials it was found, that in one minute's time this phial discharged itself 76, 78, and often even 80 times.

The difficulty of obtaining a negative power of electricity in the common plate electrical machines, and the necessity of having a smaller machine at hand than the above described one, induced Dr. Van Marum to contrive a small machine which might easily and expeditiously afford either a negative

or a positive power; and after some consideration and a few trials, he contrived a machine which answered that object remarkably well. It is only an improvement upon the plate machine. See *fig. 18.* *Plate XI.* which shews a perspective view of it. The axis of the glass plate of this machine is supported by a single strong column A, which for that purpose is provided at top with a bearing-piece K, on which two brass collar-pieces D, D, are fixed, and carry the axis. O is a counter-piece of lead fixed to the end of the axis close to the winch, to prevent too great friction in the collar next to it. The other extremity of the axis carries the circular glass plate, which is 31 English inches in diameter.

The large ball H is supported by a glass pillar, and performs the office of prime conductor; it has a semi-circular branch, the extremities of which are furnished with two cross brass pieces, somewhat like the letter T, which, by means of points, receive the electricity from the excited plate. This semi-circular branch has an axis which passes through the ball H, and turns in it; so that the arch E E may be placed either in a vertical direction, which is the position represented in the figure, or it may be situated horizontally. P is a copper tube terminating in a ball; and it moves like a radius upon the stem of the ball S. I I is another arch of brass wire, half an inch in diameter, fixed to the extremity of the bearing-piece K, upon which it turns, so that it may be placed in any situation. The rubbers Y, Y, are separately insulated upon the glass pillars W, W, and are applied to the glass plate nearly in the direction of the horizontal diameter of the plate.

The superiority of this machine over other plate machines of the usual construction, principally consists in the contrivance of altering the position of the semi-circular branch E E; for by this means, the collecting terminations of E, E, may be placed in contact with the rubbers, and thus the prime conductor will instantly exhibit negative electricity; whereas in the position represented in the figure, the prime conductor H will exhibit positive electricity. But in this case, when the conductor is positively electrified, the rubbers must be made to communicate with the ground, therefore the semi-circular arch I I has been added, which must be turned so as to touch the rubbers, and form that communication. And when the negative power is wanted, then the arch E E is turned so as to touch the rubbers, and the arch I I is turned against the naked surface of the plate to receive and carry off the positive electricity. Mr. Nicholson, some years ago, discovered a method of rendering the prime conductor of a cylinder machine either positive or negative, at pleasure. *Phil. Trans.* for 1789. See *EXCITATION.*

After the description of those various machines, it may be naturally asked, which of them might be recommended in preference to the others. The answer to which is, that not every machine is adapted to all purposes; therefore, an electrical machine must be chosen according to the object in view, *viz.* whether it be wanted for all kinds of experiments in the large way, or for delicate experiments in a private study, or for medical purposes, &c. We may nevertheless point out certain peculiarities and certain observations, which may help to direct the choice of an electrical machine.

Upon the whole it appears, that the cylinder, or the circular plate, is the best shape for the electric of a machine; for they are easily procured, especially the cylinders, and admit of a vast variety of sizes; but it must be observed, that there is a considerable difference between the mounting and the working of a cylinder machine and a glass plate machine. With equal powers, the mounting of a plate

machine is considerably more expensive, and requires a much greater accuracy of workmanship than the mounting of a cylinder machine. With respect to the use, the plate machine is not so easily managed as the cylinder machine. It has, in the first place, more rubbers than one to take care of, or to keep in order, and on account of the great friction, it is rather hard to work. On the other hand, the plate machine furnishes a more abundant quantity of electric fluid than that with a cylinder; and it is to be remarked, that if the two machines furnish sparks of the same length, the spark from the conductor of the plate machine is much more alive and more pungent than the spark from the cylinder machine; hence the former will charge a battery quicker than the latter. This superior density of the spark from a plate machine, seems to be owing to this; namely, that the plate is rubbed on both surfaces, and the electricity is taken away by the collector from one only of those surfaces; whereas in the other kind of machines the outer surface only of the cylinder is rubbed, and the electricity is received immediately by the collector; but the farther consideration of this phenomenon belongs to another part of this work. See the article EXCITATION.

In the preceding account of the various electrical machines, we have omitted to notice one species of these machines, viz. those whose electric consists of silk stuff, such as is called satin, or luteffring, or the like; and our reasons for this omission are, that all those which have been occasionally described in journals, and other works, are very cumbersome and defective; besides which, they have little power in comparison to the glass machines, and soon wear out, or are put out of order. Were we not furnished with more substantial electrics, such as glass, sulphur, shell-lac, &c. we might then turn our thoughts towards constructing a machine with silk; but being furnished as we are with the above-mentioned electrics, the silk machines are far from deserving our attention.

We shall now conclude this article with a few directions necessary for the preservation and for the proper management of an electrical machine.

It is hardly necessary to observe, that every species of electrical machine will naturally require some particular precaution; but the following directions are more or less applicable to all kinds of machines furnished with a glass electric.

Moisture, and dust; but particularly the former, being detrimental to the power of an electrical machine, it becomes necessary to guard from both as much as may be practicable; hence when not actually in use, the electrical machine should be kept in a dry and clean place, and at least the glass part of it should not be suffered to remain dirty and soiled. If the machine has been long neglected, the operator, in order to render it ready for use, must in the first place remove the rubber; he must then place the machine at a moderate distance from the fire; so as to render every part of it very dry, but not too warm. This done, and the dust removed, the glass part of the machine must be repeatedly rubbed with a clean and warm handkerchief or towel; the rubber likewise must be cleaned, removing all the old amalgam that may have adhered to it. The glass cylinder, or plate, in its rotation, frequently contracts some dark spots or concretions upon its surface, which tend to diminish its power. These spots, which adhere pretty fast to the glass, may be removed by applying a finger's nail to each spot, or by rubbing them off with a piece of coarse canvas. Previously to the replacing of the rubber, the following operation generally contributes to increase the excitation. It consists in touching the cylinder with the bottom of a tallow candle in streaks parallel to the axis of the cylinder, then rub the cylinder

again with a dry and warm linen cloth; taking care that this cloth be not very old, for in that case it is apt to leave filaments about the glass, and about the rest of the machine. This done the rubber is fixed in its place, and its support is adjusted, so that the rubber may bear upon the glass with a proper degree of pressure. Formerly the amalgam, which greatly increases the power of excitation, was spread upon the rubber, before the rubber was put in its place; but experience has shown, that it is much better to fix the rubber clean in its place, and then to apply the amalgam upon a piece of leather to the surface of the cylinder whilst this is revolving in its usual directions; for by this means the revolution of the cylinder, or plate, will carry away from the leather a sufficient quantity of amalgam, and will deposit it upon the rubber. The leather with the amalgam needs not be kept in contact with the glass longer than while the cylinder makes eight or ten revolutions; moving, at the same time, the piece of leather with the amalgam from one end of the cylinder to the other. Now if the cylinder be turned, and a hand or the ends of the fingers be presented to it, a crackling noise, which is accompanied with luminous brushes in a dark room, indicates that the cylinder is in good action; then the prime conductor being situated in its proper place, you may proceed to perform the experiments. During the performance, the electrified part of the machine is apt to attract dust from all quarters, to obviate which the room ought to be previously swept and dusted, and likewise the operator ought to have a clean cloth at hand to wipe off all particles of dust and filaments, which in spite of all his precautions will frequently run to the cylinder, to the conductor, &c.

The amalgam remains to be described. Mr. Canton, as far as we are informed, first applied the amalgam of tin and mercury to the rubber of an electrical machine, which was undoubtedly a capital improvement; for by this means an electrical machine will have its power more than quadrupled. The tin amalgam is easily made, for if you triturate tin-foil and mercury, (in the proportion of one of tin to two parts of mercury,) in a mortar, or even in the palm of your hand, the amalgam will be formed in a minute or two.

The amalgam of mercury and any metallic substance that may be amalgamed by it, contributes to increase the electric power of glass, but some are more efficacious than others. *Mosaic gold* has also been found efficacious for the purpose of excitation. The zinc amalgam, however, which was first recommended by Dr. Higgins, has upon the whole been found the most efficacious. This amalgam, which consists of one part of zinc with four or five parts of mercury, is, according to Mr. Cavallo, prepared in the following manner. "Let the quicksilver," he says, "be heated to about the degree of boiling water, and let the zinc be melted in a crucible or iron ladle. Pour the heated quicksilver into a wooden box, and immediately after pour the melted zinc in it. Then shut up the box, and shake it for about half a minute. After this you must wait until the amalgam is quite cold, or nearly so, and then you may mix some grease with it by trituration. If the melted zinc be poured into the quicksilver when cold, a very fair portion of the former will be amalgamed, the rest remaining in lumps of different sizes."

Mr. Cuthbertson gives the following preparation of the amalgam in his *Practical Electricity*. "Take," he says, "one part of tin and zinc, melt them in a crucible, and pour them on two parts of mercury, which is put into a wooden box made for the purpose; shake the box till the metals are cold. The amalgam is then to be pulverized in a metal mortar to a very fine powder, and afterwards mixed with a sufficient quantity of hog's lard, to make into a paste."

ELECTRICITY, (from the Greek *ἤλεκτρον*, *amber*;) is the name of an unknown natural power, which produces a great variety of peculiar and surprising phenomena, the first of which are supposed to have been observed in a mineral substance, called *amber*, whence they have been denominated *electric phenomena*. These phenomena have been particularly examined, and are classed under distinct and comprehensive denominations, such as the attraction, the repulsion, the light, the shock, &c. of electricity: and several rules, or natural laws, have been derived from the concurring results of a great many experiments. These phenomena, these laws, the hypotheses that have been offered in explanation of their cause, and, in short, whatever belongs to them, is collectively called the *subjects*, or the *science of electricity*. The minute and peculiar descriptions of all these particulars belong to diverse parts of this Cyclopaedia; but a concise view of the whole subject will be found in the present article, whence a comprehensive idea of it may be derived, which may afterwards be enlarged by recurring to the separate articles, under their peculiar denominations.

If a clean and dry piece of glass, or of amber, be rubbed, by stroking it four or five times with a clean and dry hand, and be afterwards presented to small and light bodies of any kind; these will be alternately attracted and repelled, and attracted and repelled again, and so on, by the glass or the amber, until the power entirely ceases. If this experiment be performed in a dark room, various luminous sparks will be perceived between the small bodies and the glass or the amber. Now in this experiment the glass or the amber is said to be the *electric*, *viz.* a body capable of acquiring the above-mentioned power of attracting, &c. and when actually possessed of that power, is said to be excited; friction in this case being the cause of that excitation. The attraction and the repulsion, which are of a peculiar nature, (that is, different from all other known kinds of attraction and repulsion;) together with the light, &c. are called *electric phenomena*; the hand, which has excited the electric by its friction, is called the *rubber*; and when a machine is formed, which contains the electric and the rubber, so disposed, that, by an easy motion, the former may be commodiously excited by the friction of the latter, this is called the *electric machine*.

If to the amber, or to the glass, a piece of metallic wire be affixed, having a metallic ball at its end, and after having excited the amber or the glass, this be so suspended as that the above-mentioned metallic ball be presented to the light bodies, an alternate attraction and repulsion will take place between the light bodies and the ball, exactly as in the former experiment it took place between the light bodies and the amber, or the glass, itself; therefore the electric virtue will pass through the metallic wire; hence the metallic wire is called a *conductor of electricity*.

If the last experiment be repeated with this difference, *viz.* that, instead of the wire, a silk string be interposed between the ball and the electric; the light bodies will not be attracted and repelled by the ball, which shews that the electric virtue will not go through silk; hence silk is said to be a *non-conductor of electricity*.

All the bodies we are acquainted with are either conductors or non-conductors of electricity; but in various

degrees. And it has been observed that all those bodies, which are non-conductors, may be excited like the above-mentioned glass, or amber, also that all those bodies, which are conductors, cannot be excited; in consequence of which *electric*, and *non-conductors*, mean the same kind of bodies; and likewise *non-electric* and *conductors* denote the same bodies, but of the other class. A body, surrounded entirely by non-conductors, is said to be *insulated*; thus a piece of metal, suspended in the air by means of a silk string, is insulated, because the only bodies that touch it, *viz.* the silk and the air, are non-conductors.

Rubbing or friction is one of the means of exciting an electric; but there are several other sources of that power independent of friction.

Some bodies are rendered electrical by heating and cooling, like the *tormalin*; others are rendered electrical by coagulation and cooling after fusion, or by pouring them when melted into another electric, like sulphur. Certain effervescences, and evaporation, or the conversion of water into steam, and *vice versa* the conversion of steam into water, do also produce electricity. The ambient air, the clouds, with the rain, snow, and hail, which fall from them, and fogs, are generally, or always, electrified in various degrees. The thunder and the lightning are electrical phenomena arising from the electricity of the clouds; and this electricity of the clouds seems principally to arise from the evaporation and condensation of vapour.

A remarkable electrical power is likewise possessed by four aquatic animals, all inhabitants of the sea; and these are, the *torpedo*, the *gymnotus electricus*, the *stirus electricus*, and another fish, which has not as yet been sufficiently examined, nor has it received a name.

Lastly, electricity is likewise produced by the disposition of certain metallic substances in a particular order, and especially when other substances are interposed among these metallic ones; and it is to be remarked, that the power of this source of electricity may (by increasing the number of the above-mentioned orderly dispositions) be augmented to an unlimited degree. This mode of producing electricity is of modern discovery, and is commonly known under the name of *Galvanism*, which see.

We have hitherto spoken of electricity as if it were a single power. It is now necessary to shew, that there are two electrical powers analogous, yet contrary, to each other, and they are, (in all cases of the production of electricity, as well as in the effects,) to be found closely connected with each other. In order to shew the nature and the difference of these two powers, we must recur to the above-described experiment, with the glass or with the amber; for though either of these bodies, when excited by the friction of the human hand, will produce similar electrical appearances; yet their powers are different and opposite to each other. Their difference consists in the following particulars.

1. If any light pendulous bodies, such as bits of cork suspended by threads, and insulated, be electrified by touching them with the excited piece of glass; then, on removing the glass, those light bodies will stand at some distance from each other, shewing a mutual repulsion. The same effect will take place, if another parcel of such pendulous light bodies be electrified by touching them with the excited piece of amber, or with an excited piece of resin, which produces the same effect. Now if the above-mentioned two parcels of pendulous and electrified bodies be brought sufficiently near to each other, they will instantly attract each other, and after this attraction, these bodies will no longer exhibit any sign of being electrified. It follows, from this, that the electricity of the excited glass is different from that of the

excited resin or amber; and accordingly the former has been called the *vitreous*, and the latter the *resinous electricity*. The first particular then in which the two electricities differ from each other is, that bodies electrified with either kind of electricity repel each other, but bodies electrified with the vitreous electricity, will attract bodies electrified with the resinous electricity.

The peculiar circumstance, which takes place in the last-mentioned case; (*viz.* that when bodies possessed of one kind of electricity, attract bodies that are in an equal degree possessed of the other kind of electricity, all signs of electricity are thereby annihilated,) suggested a supposition, that probably one of these powers is an excess, and the other a defect of something which bodies naturally possess; and upon the probability of this supposition, the vitreous electricity was also called the *plus* or the *positive electricity*, and the resinous was also called the *minus* or the *negative electricity*. This supposition or hypothesis explains the above-mentioned circumstance of the attraction; for an excess on one side is compensated by a defect on the other, and the bodies are left in a natural state.

2. If a pointed conducting body, such as a needle, be presented to the excited glass in a dark room, that point will appear illuminated with a bright globe, or star-like appearance; but if the pointed body be presented to an excited piece of amber or of resin, that point will be illuminated with a pencil, or brush-like appearance of rays of light.

3. And lastly, in various cases, in which the vitreous electricity passes from a body overcharged with it, to another body overcharged with resinous electricity; an evident current is observed from the former to the latter; but not *vice versa*; which tends to corroborate the above-mentioned hypothesis of positive and negative electricity, and likewise indicates that the vitreous is the positive, whilst the resinous is the negative electricity.

The method of ascertaining whether a given electrified body is possessed of the vitreous or of the resinous electricity, is easily derived from the above-mentioned distinctions. For instance, let A be the given electrified body. Take any other insulated and easily moveable body B, such a light piece of cork suspend by a thread, and electrify it by touching it with an excited piece of glass, which of course communicates to it the vitreous electricity. Let now the body B be brought close to the body A, and if a repulsion takes place, the two bodies must be possessed of the same kind of electricity, and since B is electrified with the vitreous electricity, A must likewise be possessed of the vitreous electricity. If when B is brought close to A, an attraction takes place, then A must be possessed of the resinous electricity. The instruments properly constructed for ascertaining the particular kind of electricity in an electrified body, are called *electrometers*.

That the two kinds of electricity do always accompany each other is proved by a variety of facts, the principal of which are as follows.

1. If the person who rubs a piece of glass, or amber, &c. be insulated, after the excitation of the glass, the person as well as the glass or other electric will be found electrified; but with this difference, that if the electric acquires the vitreous electricity, the person will be found electrified with the resinous electricity, and *vice versa*. In short, whenever two bodies are rubbed against each other, and any electricity is thereby excited, both bodies are necessarily electrified, but with contrary electricities.

2. Whenever a body is electrified, the contiguous air, or any other body situated within a certain distance of the

former, will also appear electrified, but with the contrary electricity. Thus, suppose that a piece of glass G be excited by friction with the human hand, let two small pendulous bodies be brought pretty near it, and these, by their mutual repulsion, or divergency, will shew that they are electrified, and if their state of electricity be examined in the manner already mentioned, they will be found possessed of the resinous electricity; *viz.* contrary to that of the excited glass. This contrary electricity is stronger or weaker, according as a body is placed nearer to, or farther from, an electrified body; and the limit, within which this contrary electricity may be perceived, is called the *sphere of action* of the electrified body.

3. The same individual body will not, when rubbed, acquire always the same kind of electricity; for certain rubbers will excite in it the resinous, and others will excite in it the vitreous electricity. Thus, if a stick of sealing-wax be rubbed with leather, the sealing-wax will acquire the resinous, and the leather will acquire the vitreous electricity; but if it be rubbed with a piece of tin-foil, then the sealing-wax will acquire the vitreous, and the tin-foil will acquire the resinous electricity.

Here it is necessary to observe, that whenever the rubber is said to acquire electricity, (as the leather, or the tin-foil, or any other conducting body,) it is always understood, that this rubber is insulated; otherwise the electricity which it acquires will be carried away as soon as it is generated.

We must now state the principal laws of communicated electricity; and here it must be observed, that most of the phenomena of electricity, and its grandest effects, belong to its transition, or to its being communicated from one body to another; thus the transition of electricity from one body to another occasions the light, the hissing, the cracking noise, and even the tremendous atmospheric thunder; by its quick passage it melts metallic bodies, sets fire to inflammables, destroys animal and vegetable life, and so forth.

Whenever a body is electrified, either by excitation or by the contact of another electrified body, that power is confined upon it only by electricities, and it remains upon that body a longer or a shorter time, according as the electricities which confine it are more or less perfect. If a finger, or any other conductor, be presented to an excited electric body, it will receive a spark from that body, which spark consists of a certain portion of the electricity of that electric. In this case, the electricity of the latter will not all be conveyed to the finger or other conductor, because as that body is a non-conductor, it cannot convey the electricity of all its surface to that side to which the conductor has been presented. Hence, if a conducting substance be successively presented to different parts of an excited electric, it will receive a spark at every approach, and that without repeating the excitation, until all the power of that electric is exhausted, and then a new excitation is necessary for the purpose of reviving it.

If a conducting body, not insulated, be exposed to an excited electric at a moderate distance, it acquires on that side the electricity contrary to that of the electric. This electricity becomes stronger the nearer that body is brought to the electric, and at last the conductor receives a spark from the electric (on account of the attraction existing between the two electricities), and thus the balance is restored. If the conductor, which is presented to the electric, be insulated, it will appear electrified at both extremities; but with this difference, that the side contiguous to the electric will appear possessed of the electricity contrary to that of the electric, and the opposite side will appear possessed of the same kind of electricity. There is a point not quite

quite in the middle of that body, which does not appear to be electrified at all. These two different electricities of the conductor become stronger the nearer that body is brought to the electric, and at last the former receives a spark from the latter, and becomes entirely possessed of the same kind of electricity with the electric. All these effects will take place also when some other non-conducting substance, besides air, is interposed between the excited electric and the conducting body; such as a thin plate of glass, of resin, of sealing-wax, of sulphur, &c. but in this case no spark can pass from the excited electric to the conductor, unless it forces its way by burbling the interposed non-conductor. In fact, the noise of a spark arises from its burbling or displacing the air which is interposed between the excited electric and the conductor which is presented to it.

Now, since in the last mentioned case the spark cannot pass from the excited electric to the other body, unless it bursts the interposed electric or non-conductor, it follows, that if the interposed electric be pretty strong, so as to resist the effort of the two electricities, a great quantity of electricity may be accumulated on both sides of it; and this is what constitutes a charged electric; or, as it is more commonly called, from the place of its discovery, a *Leyden phial*. The following illustration will render this subject of charged electricities more intelligible. Let a large pane of glass be covered on both sides with some metallic body or other conductor, for instance, with tin-foil, but so that the tin-foil may on either side be about two inches short of the edge of the glass. Let one of these coverings or coatings be made to communicate with an electric powerfully excited, and a quantity of electricity will be communicated to that coating, at the same time that the action of that electricity will induce the contrary electricity on the opposite coating, provided that this communicates with the ground. Now it is evident, that a spark cannot pass from one coating to the other, so as to compensate or to annihilate the two contrary electricities, unless it breaks a hole through the pane of glass, or passes over its uncoated edge; which indeed will actually take place if the electricities be accumulated upon the coatings beyond the resisting power of the glass. But before this burbling takes place, let the pane of glass be removed from the vicinity of the electric, and it will remain charged; that is, a great quantity of vitreous or positive electricity will remain adhering to one side of it, and an equal quantity of the resinous or negative electricity will remain adhering to the other side. These two electricities seem to be kept close to the glass by their mutual attraction, and yet cannot come together because that attraction is not powerful enough to break the glass. And it is in consequence of that attraction that if one coating of the glass be touched whilst the other remains insulated, the electricity cannot be removed; but if a conducting communication be made from one coating to the other, an explosion, attended with a vivid spark, will take place between that communication or circuit, and that coating which has been touched last, which arises from the passage of the electricity from one side of the pane of glass to the other, in consequence of which the two contrary electricities are annihilated, and the glass is said to be *discharged*. It will be easily comprehended, that whether the coated glass for this experiment be in the form of a flat plate, or of a bottle, or of a jar, or of any other kind, the effect must be always the same, provided the coatings of the two sides, or of the inside and outside of a bottle, do not come too near the edge or opening of the bottle; for in that case the electricity would go from one coating to the other by passing over the surface of the glass, in which case the glass is said to have discharged itself. It is

not known where the charge does actually reside. It certainly does not reside in the coating, for the coating may be removed and replaced again without discharging the glass; the coating only serving to form a communication between the various points of the surface of the glass. Nor do we know by what mechanism the electricity which is communicated to one side induces the contrary electricity on the other side of the glass, or of any other electric; for any other substantial electric may be coated and charged like glass. We are only acquainted with the effects, and with these we must for the present remain satisfied.

The thinner a plate of glass or of other electric is, the higher charge it may acquire; but it is at the same time more liable to be broken by a spontaneous discharge; therefore, for this experiment of charging, &c. the glass must be chosen of a moderate thickness. By increasing the quantity of coated electric surface, an immense force of electricity may be accumulated, which, when it is afterwards discharged, produces astonishing effects. For this purpose several coated jars are connected together, so as to be charged and discharged like a single jar, and this combination is called an *electrical battery*.

If the above-mentioned circuit of communication between the two coatings of a charged phial or jar, or plate, &c. be formed by the parts of a human being, a shock attended with a disagreeable sensation will be felt through the interposed parts; as for instance, if he touches one coating with one hand, and then touches the opposite coating with the other hand, he will feel an unpleasant shock, which is more or less painful according as the charge is higher or lower.

If various persons join hands, and while the person at one end of the file touches one coating of the charged jar, the person at the other end touches the opposite coating, all the file of persons will feel the shock at the very same perceivable instant of time. The charge of a Leyden phial has been found to pass through a circuit of several miles in an unappreciable small portion of time; but a small quantity of electricity has been observed to employ a very short portion of time in passing through a pretty long conductor, but not of the best kind.

From the above-mentioned sensation which an animal body receives from the discharge of a charged electric, that discharge is often called simply *the shock*; thus it is said that the shock is passed through a wire, or through any thing else. The effects of this shock or discharge are various according to the height of the charge; and when it is proportionate to the object in view, surprising effects are produced by it. Metallic bodies are fused, electric substances are broken with violence, animals are killed, inflammable substances are set on fire; and, in short, all the effects usually produced by the lightning may be imitated by it. If the circuit of communication be formed by means of a wire and a separate conductor, or the hand of a human being be situated very near the wire which forms the circuit, but so as itself to form no part of the circuit; on making the discharge through the wire, a small spark will be seen between the wire which forms the circuit and the conductor or hand that stands close to it; so that the conductor, or hand, &c. though actually out of the circuit, will feel some effect of the discharge. This effect is called the *lateral shock*, or *lateral explosion*. A coated glass is capable of receiving and of holding a greater charge in condensed, than in rarefied, air, or even than when standing under the usual atmospheric pressure. If the communication between the two sides of a charged phial be made by the interposition of imperfect conductors, as a slender piece of wood, a wet packthread, &c. the discharge will be made silently, or without explosion,

and its force is thereby weakened considerably. The force of the discharge is also weakened by the length of the circuit, though that circuit may consist of the very best conductors; which shews that the electricity finds some obstruction in passing even through the best conductors known. We must now return to the phenomena of the electricity which is communicated to conductors.

An insulated conductor, having received some electricity from an excited electric, or from another electrified conductor, (in which case it is said to be *electrified by communication*.) will act in every respect like an excited electric; excepting that when it is touched by another conductor communicating with the earth, the former gives one spark to the latter, and by that means all its electricity is discharged, because the electricity belonging to all its parts is easily conducted through its own substance to that side of it, to which the other conductor has been presented. Hence it appears that, in general, the electricity, which is discharged from an electrified and insulated conductor, is much more powerful than when discharged from an excited electric; for the conductor, especially when very extensive, may acquire a vast quantity of electricity, by receiving spark after spark from an excited electric, and may afterwards, when touched, discharge it all at once. When an insulated conductor is touched by another insulated and electrified conductor, the electricity will be divided between the two conductors, but not equally; excepting when the two conductors are equal, similar, and similarly situated.

If their surfaces are equal and dissimilar, that which is more extended will acquire a greater share of electricity than the other. Whether the conductors are hollow or solid, it makes no difference.

If the two conductors are equal and similar; but one of them is situated very near another conductor, but without touching it, then that conductor which is so situated will acquire a greater share of electricity than the other, which is supposed to remain only exposed to the ambient air.

When electricity is communicated to a capillary stream of water or other fluid, issuing out of a vessel, the stream is accelerated by it, but if, instead of being capillary, this stream be of a considerable size; then electrization will not accelerate it.

Electrization promotes the evaporation of bodies which are actually evaporating; but not in a great degree. If the face or any other part of the body be exposed, within a small distance, to an excited electric, or to a conductor strongly electrified, it will feel a peculiar sensation, as if a spider's web were drawn over it. The nostrils thus presented will perceive a peculiar smell, much resembling that of phosphorus, and if a body be kept some time within those effluvia, it will afterwards retain that smell during some minutes. If the tongue be exposed to a stream of electricity issuing out of an electrified body, it will be affected with a slight but peculiar kind of subacid taste.

It was for a long time believed that electricity communicated to animal and vegetable bodies, accelerated the pulsation of the former, and promoted the growth of the latter; but it is at present much doubted whether it really produces any of these effects. Nevertheless electrization, in medical cases, has been found useful at least as a safe and active stimulant.

An electric spark, (that is, a separate quantity of electricity,) will go a greater or lesser distance through the air, in order to reach a conductor, according as its quantity is more or less considerable, as the parts from which it flies, and those upon which it strikes, are more or less acute, and as the conductor is more or less perfect. The noise, and

the light with which the spark is attended, is greater or less, according to the quantity of electricity; according as the parts from which it flies, and those upon which it strikes, are more blunt or more sharp; and according as the conductors are more or less perfect. Thus, for instance, a sharp pointed body will throw off electricity to, and will receive it from, a greater distance, than a body of any other shape; but that passage then occasions no noise, and is attended with very little light; because, in this case, the electricity does not come in a separate large body, but in a continued stream. If a pointed wire be concealed in a glass tube, which projects a short way beyond it, or if it be covered with tallow, bees-wax, sulphur, &c. then it will take a strong spark from an electrified conductor. When a point, proceeding from an electrified body, projects into the ambient air, a remarkable current of air, or wind, proceeds always from it, whether the point and the conductor be electrified with the vitreous or with the resinous electricity, which arises from the particles of air being repelled by the point as soon as they become possessed of the same kind of electricity.

With respect to the electricity of the atmosphere, the particulars which have been ascertained are, that the air, at a small distance from the ground, from houses, trees, &c. is always electrified generally with positive electricity, but not always in an equal degree. The thunder and the lightning have also been ascertained to be electrical phenomena; but other meteors, such as the northern lights, water spouts, shooting stars, &c. have only been conjectured to be produced by electricity.

Thus we have drawn a general and comprehensive sketch of the subject of electricity. But for a minute and extended description of all the particulars which belong to it, the reader is referred to the articles of each peculiar denomination; such as CONDUCTORS, ELECTRICS, EXCITATION, LEYDEN PHIAL, LIGHTNING, &c.

ELECTRICITY, *Medical*. See *MEDICAL Electricity*.

ELECTROMETER, (from the Greek words *ηλεκτρον*, *amber*, and *μετρον*, *measure*), an instrument useful for measuring the quantity, and determining the quality, of electricity in an electrified body; viz. the quantity and quality of that natural power, the effects of which were first observed in a mineral substance, called *amber*. The invention of electrometers is not much older than about the middle of the last, (viz. the 18th) century; but the greatest variety of them, adapted to different purposes, has been invented within the last 40 years; and according to the various purposes, as also on account of their shapes, these instruments have obtained a variety of names, such as *pith*, or *cork-ball electrometers*, *quadrant electrometers*, *bottle electrometers*, *atmospherical electrometers*, *electro-micrometers*, *electrical balances*, *discharging electrometers*, &c. A description of all these electrometers, together with their gradual improvements, and their uses, is as follows:

A simple thread held by one extremity, and presented to an electrified body, seems to have been the first instrument of the kind. It only shewed the presence of the electricity, by its being attracted by the electrified body. Dr. Desaguliers called it the *thread of trial*. The Abbé Nollet used two threads, which shewed the intensity of the electricity by the angle of their divergency, formed by their shadows upon a board placed behind them.

Mr. Canton added a cork ball, or a ball of pith of elder, to the extremity of each thread, which formed a considerable improvement; the threads acquiring thereby a greater degree of steadiness, and becoming less apt to lose their electricity, by having their extremities covered with the abovementioned balls. *Fig. 1. Plate XII.* replicates this, Mr. Canton's, electrometer,

ELECTROMETER.

trometer, in its most usual state. A B represents the side of an oblong box about six inches long, but less than an inch broad. It is formed out of a single piece of wood, and has a sliding dove-tail cover over its whole length. When the cover is removed, and the box is inverted, the cork or pith-balls C, D, with their threads, come out of it, and remain suspended, as in the figure. The balls are nicely turned in a lathe, and should not be larger than an eighth of an inch in diameter. The linen threads are fastened to the balls by passing them through with a needle, and making a knot at the end of each. These threads are little short of the length of the box A B, and are fastened to a little ring at the extremity of the box, so that when not in use, they, with their balls, are placed in the cavity of the box, and the cover is slipped over them. Previous to their being passed through the balls, the threads have been sometimes wetted in a weak solution of common salt, in order to render them better conductors.

A cork, or pith-ball electrometer, is also frequently used without the box A B. In that case, it being nothing more than a thread with a ball at each end, it may be suspended by its middle to a wire at the end of the prime conductor of an electrical machine, or elsewhere. If this instrument be held by the end A of the box, and be thus presented to an electrified body, the balls C, D, will recede from each other, the threads forming an angle larger or smaller according to the intensity of the electricity. If, while the electrometer is thus diverging, an excited stick of sealing-wax or of glass be brought sideways of the balls, these will come close to the wax or to the glass, when they are possessed of the opposite kind of electricity; but will recede from the glass, or sealing-wax, or other electrified body, when they are possessed of the same kind of electricity.

If the operator, holding the box by the end A, and extending his arm as high as he can, exposes the electrometer to the ambient air in an open place, or on the top of a house, he may easily ascertain the presence and the quality of the electricity of the air, or of a fog, by the above described method.

When, for the conveniency of certain experiments, this electrometer must be insulated, then the box A B is placed upon an insulating stand, as in *fig. 2*.

This useful instrument was rendered much more commodious, and was adapted to the purposes of atmospherical electricity in a manner more certain and more efficacious by Mr. Cavallo, who first described it in the *Phil. Trans.* These improvements, under the denominations of a *pocket electrometer*, the *atmospherical electrometer*, and the *electrometer for rain*; are as follow:

Figs. 4. and 5. represent the "pocket electrometer." The handle or case of this instrument consists of a glass tube, about three inches long, and three or four tenths of an inch in diameter. Half of this tube is covered with sealing-wax, as is easily perceived in the figure. From that extremity of this tube, which is not covered with sealing-wax, a small loop of silk proceeds, which serves occasionally to hang the electrometer on a pin, or nail. A cork is adapted to the other extremity of this tube, which being cut tapering at both extremities, can fit the opening of the tube with either extremity. Two linen threads proceed from one end of this cork, which are a little shorter than the length of the tube, and two little cones of cork or of the pith of elder are fastened to their extremities. When this electrometer is to be used, that end of the cork which is opposite to the threads is pushed into the mouth of the tube; then the tube forms the insulating handle of the cork or pith-ball electrometer, as represented in *fig. 5*. But when the electrometer is to be carried in the pocket, then the threads are put into the tube,

and the cork stops the aperture of the tube with its other extremity, as represented in *fig. 4*.—*Fig. 3.* represents a case to contain the above-described electrometer. It is like a common tooth-pick case, excepting that it has a piece of amber fixed on one end A, which may occasionally serve to electrify the electrometer negatively; and on the other extremity it has a piece of ivory fixed upon a piece of amber B C. This amber B C serves only to insulate the ivory, which being thus insulated, if it be rubbed against woollen cloths, will acquire the positive electricity; and is of course useful for electrifying the electrometer positively.

Fig. 6. represents an instrument peculiarly adapted to the purposes of exploring the electricity of the atmosphere. A B represents a common jointed fishing-rod, without the last or smallest joint. From the extremity of this rod proceeds a slender glass tube, or solid glass stick C, which is covered with sealing-wax, and carries a cork, D, at its extremity, to which cork a pith-ball electrometer E is suspended. H G I is a piece of twine fastened to the other extremity A of the rod, and supported at G, by a short string F G. At the end J of the twine, a pin is fastened, which, when pushed into the cork D, renders the electrometer E uninsulated.

"When I would observe," Mr. Cavallo says, "the electricity of the atmosphere with this instrument, I thrust the pin I into the cork D, and holding the rod by its lower end A, project it out of a window on the upper part of a house, into the air; raising the end of the rod with the electrometer, so as to make an angle of about 50 or 60 degrees with the horizon. In this situation I keep the instrument for a few seconds, and pulling the twine at H, I disengage the pin from the cork D, which operation causes the string to drop in the dotted situation K L, and leaves the electrometer insulated, and electrified with the electricity contrary to that of the atmosphere. This done, I draw the instrument into the room, and examine the quality of the electricity, without obstruction, either from wind or darkness.

"With this instrument I have made observations on the electricity of the atmosphere, several times in the course of each day during several months, and from them I have deduced the following general observations, which seem to coincide with those which I have made with the electrical kites.

"1. That there is in the atmosphere, at all times, a quantity of electricity; for whenever I use the above-described instrument, it always acquires some electricity.

"2. That the electricity of the atmosphere, or fogs, is always of the same kind, namely, positive; for the electrometer is always negative, except when it is evidently influenced by heavy clouds near the zenith.

"3. That in general the strongest electricity is observable in thick fogs, and also in frosty weather; and the weakest, when it is cloudy, warm, and very near raining; but it does not seem to be less by night than in the day time.

"4. That in a more elevated place, the electricity is stronger than in a lower one; for, having tried the atmospherical electrometer, both in the stone and in the iron gallery on the cupola of St. Paul's cathedral, I found that the balls diverged much more in the latter, than in the former less elevated place; hence it appears, that if this rule takes place at any distance from the earth, the electricity in the upper regions of the atmosphere must be exceedingly strong."

Fig. 7. represents the electrometer for the rain. A B C I is a strong glass tube about two feet and a half long, having a tin funnel, D E, cemented to its extremity, which funnel defends part of the tube from the rain. The outside surface of the tube from A to B is covered with sealing-wax; so also

ELECTROMETER.

also is that part of it which is sheltered by the funnel. F D is a piece of cane, round which several brafs wires are twisted in different directions, so as to catch the rain easily, and at the same time to offer little or no resistance to the wind. This piece of cane is fixed into the tube, and a slender wire, proceeding from it, goes through the bore of the tube, and communicates with the strong wire A G, which is thrust into a piece of cork fastened into the end A of the tube. The extremity G of the wire A G, is formed into a ring, from which is suspended a more or less sensible pith-ball electrometer, as occasion requires. This instrument is fastened to the side of the window-frame, where it is supported by strong brafs hooks, at C B; and this part of the tube is covered with several folds of silk stuff, in order to adapt it more safely and commodiously to the hooks. The part F G projects out of the window, with the end F elevated a little above the horizon. The remaining part of the instrument comes through a hole in one of the lights of the sash, within the room, and no more of it touches the side of the window than the part C B. This instrument should be placed so as to be easily taken off, and replaced; for it will be necessary to clean it now and then; particularly on the approach of a shower of rain.

“When it rains,” says Mr. Cavallo, “especially in passing showers, this instrument, standing in the situation above described, is frequently electrified; and, by the divergency of the electrometer, the quantity and quality of the electricity of the rain may be observed. With this instrument I have observed, that the rain is generally, though not always, electrified negatively, and sometimes so strongly, that I have been able to charge a small coated phial at the wire A G.”

A commodious way of using electrometers in a variety of delicate experiments, such as in examining tourmalins, precious stones, &c. is to have a stand made on purpose, and holding both single and double-thread electrometers, as in *fig. 8*. B is the base, made of common wood: A is a pillar of sealing-wax, or of glass, to the top of which a wooden head is fixed. From this circular piece of wood, or head, four brafs arms proceed, suspending four electrometers, two of which, D, D, are nothing more than silk threads, about four or five inches long, each of which carries a very small downy feather at its extremity. The other two electrometers, C, C, are cork or pith-ball electrometers, the construction of which is a variety of those which have been already described: *ab* represents a stick of glass, about four inches long, covered with sealing-wax, and shaped at top in the form of a ring. To the lower extremity of this glass stick two fine linen threads are fastened, with pith or cork balls at their lower extremities. In the figure these electrometers are represented as being actually electrified. The glass stick *ab* serves as an insulating handle, by which the electrometer may be supported, when it is used without the stand. Those with the downy feather D D, when electrified, one with the positive, and the other with the negative electricity, will continue in that state for a very considerable time, during which, if a small body slightly electrified be gently approached to one or the other of the feathers, the fine filaments of the latter will be attracted or repelled, according as that body is possessed of the same, or of the contrary electricity.

Fig. 9, represents Mr. Henly's quadrant electrometer upon a little stand; and *fig. 10*, represents it upon the prime conductor of an electrical machine. It consists of a perpendicular stem or pillar A B, formed at top like a ball, and furnished at its lower end with a brafs ferrule, by which it may be fixed in one of the holes of the prime conductor, or upon a perpendicular wire, fixed on purpose to the inside

coating of an electrical battery, or upon the knob of a Leyden phial, or lastly, upon its own stand, when it is not actually in use. To the upper part of the stem a graduated ivory semi-circle E, is fixed, and about the middle of this semi-circle there is a brafs arm, which contains a pin, or the small axis of the index. The index C consists of a very slender stick, which reaches from the centre of the semi-circle E to the brafs ferrule, and a cork ball D nicely turned in a lathe is glued fast to its lower extremity. The wood proper for this electrometer is box wood, and both the pillar and the index should be well rounded and polished. When the electrometer is not electrified, the index hangs parallel to the stem A B, and the ball D touches the brafs ferrule, as in *fig. 9*. But when electrified, the index recedes more or less from the stem according to the intensity of the electricity, as in *fig. 10*. This instrument is peculiarly useful for observing the progress of the charge of a Leyden phial, or of a battery.

Beccaria recommended to inclose the upper part of the index of this electrometer between two semi-circles; other electricians have also made other alterations, which we shall now describe; though, upon the whole, Mr. Henly's original construction seems to answer as well as any other.

Mr. Canton's construction is represented in *fig. 11*; *a* is a small cork-ball fixed to the extremity of a very slender stick of ivory *bcd*, which, when electrified, is repelled by the brafs tube *es*, and as this stick of ivory, *bcd*, moves upon an axis at *c*, the angle of divergency is indicated by its extremity *d*, upon the graduated arch *fg*. This electrometer being very sensible, is peculiarly useful for indicating the small charge of a Leyden phial, or the charge of a battery in its commencement.

Fig. 12, represents Mr. Brook's electrometer (*Phil. Trans.* for the year 1782). It is a complicated and expensive instrument. “B is the foot or base, consisting of a square board $9\frac{1}{2}$ each way, having three screws for the purpose of setting the instrument upright: D is a solid piece of glass, which supports and insulates the instrument. The arms G 1, and *g*, with the ball F, turn round on the wire H, (which is of solid brafs, as may be also the arm *g*), and when in use are put nearly at right angles with G 2 and H, being turned to the off side so as to be as much as possible out of each others' atmospheres, or the atmosphere of a jar, battery, prime conductor, &c. The arms G 1 and G 2 are hollow tubes of copper, not so heavy as wires. The balls I 1, I 2, are made of copper, and hollow, so as to be as light as possible: K represents a kind of face or dial-plate to the instrument with its index, which (by means of multiplying motion under the dial-plate) is carried once round, whilst the arm G 2, with its ball I 2, moves through a quarter of a circle, or 90 degrees. This motion is given to it by the repulsive power of the charge, &c. of electricity between the two balls I 2 and L. The ends of the index from its centre are of different lengths. The longest end reaches to a graduated circle divided into 90 equal parts, answering to 50°, which the arm G 2 moves through. The shortest end reaches to a smaller circle, divided into 60 equal parts, answering to 60 grains weight, or 60 divisions on the arm G 1, with its sliding weight *m*, each of which is equal to one grain, and the whole face is covered with a watch glass, to prevent the electricity from flying off at the points.

“The top of the glass stick D is cemented into a brafs cap M. This cap enters the ball L at the lower part, and screws into the upper part of the ball L at *a*. The top part of this cap M is tapered off to a cone about an inch and a half long or high. The lower end of the wire H has a hole made

ELECTROMETER.

made conically into it, so as to receive the upper part or conical end of the cap M, which permits all the upper part of the electrometer to turn round any way that may be necessary. The kind of ferrule O, with its base, is perforated for the lower end of the wire H to go through. The bent arm *b*, which supports the cup N, is screwed into the base of the ferrule O, and turns freely round upon the wire H. The cup N is to receive the ball P of the arm H. This arm shortens or lengthens, as may be wanted, by a wire sliding into a tube. The end of the wire is slit, forming a forcing in the tube to be steady. In this arm is a kind of rule joint at *d*, that the arm may give way entirely if wanted. The semi-circular end of the arm is a spring, and slips on to a ball from the prime conductor, jar, or battery; and serves to connect that prime conductor, or jar, or battery, with the electrometer.

“The arm G screws not to the ball F, but to a solid piece within the said ball, and the whole, like the arms of an unequal balance, move round an axis close to the surface of the ball F, so that the arm G *t* moves angularly round that axis, and the ball I *r* rides above the ball *r*, in virtue of the electrical repulsion.

“In order to make the divisions of G *r* exactly a grain each, first slide the weight *m* toward the ball F, till it is an exact counter balance to the weight in F. At one end of the weight *m* let the divisions begin; then suspend any tolerable pair of scales, so that the bottom of one of them may rest on the top of the ball *r*; then lay the ball I *r* into the scale, and slide the weight *m* near to I *r*, and put as many grains into the other scale as will just raise the ball I *r* in the scale; then mark the arm G *t* at the same end of the weight *m*, and divide the space between the two marks into as many parts as there are grains in the scale, which may be divided and sub-divided into halves and quarters.

“The arm G *z* being repelled, shews when the charge is increasing, &c. and I *t* tells what such a repulsive power is between two balls of the size of these in grains, according to the number the weight *m* rests at when lifted up by the repulsive power of a charge. The longest end of the index K shews how many degrees of a circle G *z* is repelled, and by many trials, according to the number of grains, the arm G *t* shews, when it is lifted up, and the weight *m* put at different places, such respective number of grains may be marked on the least circle on the dial-plate where the shortest end of the index points; so that when all the grains are thus marked on the dial plate, thus ascertained by the arm G *t*, all these parts of the instrument, that is, the ball F with the arms G *t* and *g*, may be taken off, and the instrument is then graduated to be used without them; “but I do not know,” Mr. Brook says, “how the grains can be so exactly marked and ascertained as by these parts being on the instrument: nor do I mean to confine the number of grains or divisions on G *t*; but, I think, my experience seems to tell me, that no glass to be charged, as we call it, with electricity, will bear a greater charge than that whose repulsive force between two balls of this size equals 60 grains weight, before it will be perforated or struck through. Nay, I have not found many instances where it would stand 50 grains; and I think it is very hazardous to go more than 45 grains.”

“Thus, by knowing the quantity of coated surface, and the diameters of the balls, as I *r* and *r*, I would say, so much or so much coated surface charged to so many or so many grains repulsion between two balls of such or such a size would melt a wire of this or that size, or do such a thing, kill such an animal, &c. and if balls, wires, or arms

of this size are found too small, larger may be made on the same plan.”

By this means electrometers may be made to speak a common and an intelligible language.

The lower part of Mr. Brook's electrometers may likewise be called an *electrical balance*.

Notwithstanding the intricacy of the construction of Mr. Brook's electrometer, it must be acknowledged, that if not exactly upon that, at least upon some such plan, these instruments should be constructed; for an equal division of the arc, or semi-circle, into equal parts will not indicate equal increments of the repulsive force: to eliminate which truly, Mr. Acharad says, that the arc of the electrometer should be divided according to a scale of arcs, the tangents of which are in arithmetical progression.

The pith or cork-ball electrometers, above described, though very useful within doors, are, when used for atmospheric electricity, much disturbed, and even rendered perfectly useless by wind, rain, and the moisture of fogs. To avoid these defects, Mr. Cavallo, in the year 1777, made a most useful contrivance; which, in fact, opened the way to farther improvements, and rendered this kind of instruments both sensible and useful far beyond that of any former construction. The contrivance consisted in enclosing the electrometer in a glass vessel, and furnishing it with other parts; which rendered it capable of being exposed to the wind and to the rain, without the least obstruction. The construction of this instrument (a description of which Mr. Cavallo presented to the Royal Society, and is published in the *Philosophical Transactions*) is represented by the *figs.* 13, 14, and 15, *Plate XIII.* in its real size.

The principal part of this instrument is a glass tube, CDMN, cemented at the bottom into the wooden piece, AB, by which part the instrument is to be held, when used for the atmosphere; and it also serves to screw the instrument into the wooden case, ABO, *fig. 1*, when it is not actually in use. Both the foot, A B, and the case may also be made of brass or other metal. The upper part of the tube, CDMN, is shaped tapering to a smaller extremity, which is entirely covered with sealing-wax, melted by heat, and not dissolved in spirit of wine. Into this tapering part a small tube is cemented, the lower extremity, G, of which (being also covered with sealing-wax) projects a short way within the tube, CDMN. Into this smaller tube a wire is cemented, which, with its lower extremity, touches the flat piece of ivory, H, which is fastened to the tube by means of cork, and with its upper extremity, which projects about a quarter of an inch above the tube, screws into the brass cap, EF; which cap is open at the bottom, and serves to defend the waxed part of the instrument from the rain, &c. *Fig. 3.* represents a section of this brass cap, shewing its internal form; together with the manner in which it is screwed to the wire that projects above the small tube, L. The small tube, L, and the upper extremity of the large tube, CDMN, appear like one continue piece, on account of the sealing-wax, which covers them both. The conical corks, P, of this electrometer, which by their repulsion shew the electricity, &c. are as small as can conveniently be made; and they are suspended by exceedingly fine silver wires. These wires are shaped in a ring at the top, by which they hang very loosely on the flat piece of ivory, H, which has two holes for that purpose. By this method of suspension, which is applicable to other electrometers, the friction is diminished greatly, whence the instrument is rendered extremely sensible. IM and KN are two narrow slips of tin-foil, stuck to the inside of the glass, CDMN,

ELECTROMETER.

CDMN, and communicating with the wooden bottom, A B. These serve to carry away the electricity, which, when the corks, P, touch the glass, is communicated to it, and which, being accumulated, would disturb the free motion of the corks.

With respect to practical utility, this instrument may be used for observing the artificial as well as the atmospheric electricity. When it is to be used for artificial electricity, this electrometer is set upon a table, or other convenient support: then it is electrified, by touching the brass cap, E F, with an electrified body; and this electricity will sometimes remain upon the electrometer longer than an hour. In this state, if any electrified substance be brought near the cap, E F, the corks, P, of the electrometer, by their converging or by increasing their divergency, will shew the species of that body's electricity.

"It is necessary to observe," Mr. Cavallo says, "that to communicate any electricity to this electrometer, by means of an excited electric; e. g. a piece of sealing-wax (which we suppose as being always electrified negatively) is not very readily done in the usual manner, on account of the cap, E F, being well rounded, and free from points or sharp edges. By the approach of the wax, the electrometer will be caused to diverge; but as soon as the wax is removed, the wires immediately collapse. The best method to electrify it is to bring the excited wax to near the cap, that one or both the corks may touch the side of the bottle CDMN; after which, they will soon collapse and appear unelectrified. If now the wax be removed, they will again diverge, and will remain electrified *positively*."

"In this operation, the wax does not impart any of its electricity to the electrometer, but only acts by means of its atmosphere; viz. when the excited wax is first brought near the brass cap, E F, (agreeable to the well-known law of electricity, and according to Dr. Franklin's hypothesis,) it determines the electric fluid naturally belonging to the corks towards the cap: hence the corks repel each other. Now, if in this state they touch the tin-foil on the sides of the glass, CDMN, they acquire from it a quantity of electric fluid, equal to that which, by the action of the excited wax, was driven towards the cap: consequently they collapse, and appear unelectrified. Notwithstanding this appearance, the cap is actually overcharged; so that when the wax is removed, the overplus of electric fluid which the corks had acquired from the glass and tin-foil, and which was crowded upon the cap, on account of the negative atmosphere of the wax, now diffuses itself equally through the cap, the wires, the corks, &c.; and therefore the corks repel each other with positive electricity."

"If, instead of the sealing-wax excited negatively, an electric possessed of positive electricity be used, the electrometer acquires the negative electricity, and the explanation, *mutatis mutandis*, is the same as above."

"By considering this remark, it will appear that when this electrometer is electrified either positively or negatively, and an electrified body is brought towards the brass cap, the electricity of that body will be of the same kind with that of the electrometer, if the corks increase their divergency; but it will be of the contrary kind, if the corks come nearer to each other."

When this instrument is to be used for observing the electricity of the fogs, the air, the clouds, &c. the observer must uncrew it from its case, and holding it by the bottom, A B, must present it to the air in an open, free, and, if possible, an elevated, place; raising it a little above his head, so that he may conveniently observe the corks, P, which

will immediately diverge, if there be any sufficient quantity of electricity; and it may be easily ascertained whether this electricity is positive or negative, by bringing an excited piece of sealing-wax, or other excited electric, towards the brass cap, E F. Upon the whole, the peculiar advantages of this electrometer, as enumerated by its inventor, are 1st, The smallness of its size; 2d, Its being always ready for experiments, without the fear of entangling the threads, or of having an equivocal result by the sluggishness of its motion; 3d, Its being not disturbed by wind or rain; 4th, Its superior sensibility; and, 5th, Its retaining its electricity longer than any other electrometer.

Mr. Sauffure took great pains to point out some supposed imperfections of the above-described electrometer, and to improve it by making several specious alterations and additions, which, if not actually detrimental, evidently are of no real advantage. In the first place, he says, that the fine wires, by which the balls are suspended, should not be so long as to reach the tin-foil which is pasted on the inside of the glass; yet he directs to put four pieces of tin-foil within the glass. Secondly, Mr. Sauffure has altered the shape of the glass, making it broader, and with a neck very short, which prevents the electrometer's retaining the electricity for any considerable time. Thirdly, he has made the bottom of the electrometer of brass, for the purpose of using it like a condenser. For example, he says, if it be placed on an imperfect conductor, as, dry wood or marble, and if the instrument be electrified strongly, and afterwards the top is touched, the electricity will appear to be destroyed; but on lifting up the instrument by the top, the balls will again open, because the imperfect conductor formed with the base a kind of electrophorus, by which the electric fluid was condensed and lost its tension, till the perfect conductor was separated from the imperfect one; whereas, if the conductor had been more perfect, it would have been deprived of its electricity immediately, on the application of the hand. We cannot see of what practical use this equivocal and uncertain operation can be. Fourthly, Mr. Sauffure has added a very long pointed wire to the top of its electrometer, for the purpose of imbibing the electricity of the atmosphere. This may in some cases be of advantage, but in others it must be very disadvantageous; for, as it appears from the above-mentioned observations of Mr. Cavallo, this electrometer is electrified with the electricity contrary to that of the atmosphere, whereas, when the electricity of the atmosphere is very strong, the pointed wire, by imbibing some of it, may render the action of the electrometer equivocal. Lastly, Mr. Sauffure has placed a divided scale within the electrometer, for the purpose of measuring the angle of divergency; but to any person who is in the least conversant with the use of such instruments, it will easily appear that, by the eye, the angle of divergency may be estimated sufficiently for the purpose; whereas, with a scale, a considerable time is required to steady the electrometer, and to place the eye in a proper point of view; and during this time, the electricity of the corks, &c. will be considerably diminished.

A capital improvement to the bottle electrometer was made by the Rev. Abraham Bennet, and is described in the Philosophical Transactions for the year 1787, p. 26. Instead of the wires with the corks, Mr. Bennet used two slips of gold-leaf, which are sensible to an astonishing degree, manifesting the electricity in a ready and unequivocal manner, free from an inconvenience which frequently takes place with the cork or pith-ball electrometers. The inconvenience is, that in these electrometers, when they are electrified, the

balls

ELECTROMETER.

balls sometimes adhere to each other for a considerable time before they will separate, and then they separate with a kind of jerk all at once.

The figures 16, 17, and 18, represent Mr. Bennet's gold-leaf electrometer; the 16th and 17th being sections of the instrument. The 18th represents the instrument joined together, and ready for use. "It consists," says Mr. Bennet, "of two slips of gold-leaf, *a, a*, suspended in a glass, *b*. The foot, *c*, may be made of wood or metal; the cap, *d*, of metal. The cap is made flat on the top, that plates, books, evaporating water, or other things to be electrified, may be conveniently placed upon it. The cap is about an inch wider in diameter than the glass, and its rim about three quarters of an inch broad, which hangs parallel to the glass, to turn off the rain, and keep it sufficiently insulated. Within this is another circular rim, about half as broad as the other, which is lined with silk or velvet, and fits close upon the outside of the glass: thus the cap fits well, and may be easily taken off, to repair any accident happening to the gold-leaf. Within this rim is a tin tube, *e*, hanging from the centre of the cap, somewhat longer than the depth of the inner rim. In the tube a small peg, *f*, is placed, and may be occasionally taken out. To the peg, which is made round at one end and flat at the other, two slips of leaf gold are fastened with paste, gum-water, or varnish. These slips suspended by the peg, and that in the tube fast to the centre of the cap, hang in the middle of the glass, about three inches long, and a quarter of an inch broad. In one side of the cap there is a small tube, *g*, to place wires in. It is evident, that without the glass the leaf-gold would be so agitated by the least motion of the air, that it would be useless; and if the electricity should be communicated to the surface of the glass, it would interfere with the repulsion of the leaf-gold; therefore two long pieces, *h, h*, of tin-foil are fastened with varnish on opposite sides of the internal surface of the glass, where the leaf-gold may be expected to strike, and in connection with the foot. The upper end of the glass is covered and lined with sealing-wax as low as the outermost rim, to make its insulation more perfect."

Mr. Cavallo, in describing this electrometer of Mr. Bennet, in his Treatise on Electricity, 4th edition, says, "As it is rather difficult to fasten the slips of gold-leaf to this electrometer, and to cause them to hang parallel, I have contrived a method which remedies that defect. When the slips are cut and are lying upon paper, or on the leather cushion upon which they are cut, I make them equal in length, by measuring with a pair of compasses, and cutting off a suitable portion from the longest. I then cut two bits of very fine gilt paper, each about half an inch long, and a quarter of an inch broad; and by means of a little wax, stick one of them to one extremity of each slip of gold-leaf, so as to form a kind of letter T. This done, I hold up in the fingers of one hand one of those pieces of paper with the gold leaf suspended to it, and hold the other with the fingers of the other hand; then bringing them near to each other, and having adjusted them properly, *viz.* so as to let them hang parallel and smooth, I force the pieces of paper, which now touch each other, between the two sides of a sort of pincers made of brass wire, or of very thin and hammered brass plate; which pincers are fastened to the under-part of that piece which forms the top or cover of the glass vessel."

Mr. Bennet, immediately after the description of his excellent electrometer, says, "The following experiments will shew the sensibility of this instrument:—1st, Powdered chalk was put into a pair of bellows, and blown upon the cap, which electrified it positively when the cap was about the

distance of six inches from the nozzle of the bellows; but the same stream of powdered chalk electrified it negatively at the distance of three feet. In this experiment there is a change of electricity from positive to negative, by the dispersion or wider diffusion of the powder in the air. It is also changed by placing a bunch of fine wire, silk, or feathers, in the nozzle of the bellows; and is wholly negative, when blown from a pair of bellows without their iron pipe, so as to come out in a larger stream. This last experiment did not answer in dry weather so well as in wet. The positive electricity of the chalk, thus blown, is communicated, because part of the powder sticks to the cap; but the negative is not communicated, the leaf-gold collapsing as soon as the cloud of chalk is dispersed.

"2dly, A piece of chalk drawn over a brush, or powdered chalk put into the brush, and projected upon the cap, electrifies it negatively; but its electricity is not communicated.

"3dly, Powdered chalk blown with the mouth or bellows, from a metal plate placed upon the cap, electrifies it permanently positive; or if the chalk is blown from the plate, either insulated or not, so that the powder may pass over the cap, if not too far off, it is also positive; or if a brush is placed upon the cap, and a piece of chalk drawn over it, when the hand is withdrawn, the leaf-gold gradually opens with positive electricity, as the cloud of chalk disperses.

"4thly, Powdered chalk, falling from one plate to another placed upon the instrument, electrifies it negatively."

Several other experiments were also made with Mr. Bennet's electrometer, out of which we shall collect the principal. "The instrument being placed in a dusty road, and the dust struck up with a stick near it, electrified it positively. Wheat flour and red lead are strongly negative in all cases where the chalk is positive. The following powders were like chalk: red ochre and yellow, rosin, coal ashes, powdered crocus metallorum, aurum mosaicum, black-lead, lamp-black, (which was only sensible in the two first methods,) powdered quick-lime, amber, lapis calamiaris, Spanish brown, powdered sulphur, flowers of sulphur, iron filings, rust of iron, and sand. Rosin and chalk, separately alike, were changed by mixture: this was often tried in dry weather, but did not succeed in damp. White lead also sometimes produced positive, and sometimes negative electricity, when blown from a plate.

"If a metal cap be placed upon the cap, with a red-hot coal in it, a spoonful of water thrown in electrifies the cup negatively; and if a bent wire be placed in the cap, with a piece of paper fastened to it, to increase its surface, the positive electricity of the ascending vapour may be tried by introducing the paper into it."

The sensibility of this electrometer may be considerably increased by placing a candle upon the cap. By this means, the electricity of an electrical machine in one room may be perceived in the next room. Powders, in this case, will also electrify it at a much greater distance, &c.

When this electrometer was placed at the distance of six feet from the string of a kite, having a wire through the string, and raised in cloudy weather, the gold-leaf continued to strike the sides of the electrometer, for more than an hour together, with a velocity increasing and decreasing with the density or distance of the unequal clouds which passed over.

"No sensible electricity is produced by blowing pure air, projecting water, by smoke, flame, or explosions of gunpowder."

ELECTROMETER.

The only defect of the above-described most useful gold-leaf electrometer is its not being portable, unless it be carried always upright; and with this imperfection the instrument has remained for about 20 years; until very lately, when Mr. Cavallo contrived to render it perfectly portable: and this contrivance he has permitted to be published, for the first time, in the present article.

The figures 19 and 20 are two sections of this instrument, Fig. 21 represents it in perspective. The letters of reference indicate the same parts in all the three figures. A B is a glass tube, cemented into the perforated brass bottom, or ferrule, G. DC is a short and narrower glass tube, which fits the upper part of the tube A B, by means of a piece of leather, which is cemented to that part of it which is intended to enter into A B. A third smaller glass tube, FE, is cemented into DC, and projects a little way above and below DC. The surfaces of these three tubes, from F to H, are all covered with sealing-wax. A brass wire, I, is cemented into the smallest tube, FE, and communicates with an oblong slip of brass plate, Ea, which is a little thicker than common writing paper, and about a quarter of an inch broad, well polished and rounded off at the edges. In the figures 19 and 20, this slip of brass is seen edge-ways: *oc* is a slip of gold-leaf, stuck at *o* to the brass plate Ea; and when electrified, making an angle *coa* with it, which is larger or smaller according to the intensity of the electricity. Ea remains always stiff and immovable: *bc* is a piece of cork, fitted tight to the lower aperture of the glass tube, A B. There is a slit in this cork, through which the lever, or brass arm, *big*, moves round the axis or pin, *r*, which passes through the cork at right angles to *bg*. From *b* to *s* this brass arm is as broad as Ea; but from *s* to *g* it spreads the other way, viz. from *i* to *g*. Now it is easy to comprehend, that if a finger's nail be applied at *g*, through the aperture of the brass foot, G, and be pressed against that end of the arm, this arm, *bg*, may be placed in the situation represented in fig. 20; in which case, the gold-leaf will be enclosed between the arm, *bs*, and the slip, Ea, and in that state the instrument may be turned in any direction; for the elasticity of the cork, *bc*, is fully sufficient to retain *bg* in that position. The instrument then is slipped into a paper, or brass tube, which covers the whole, and fits the outside of the brass foot at G. When the instrument is to be used, the nail of a finger applied to the brass arm at *i*, and pushed against it, will place it in the situation of figs. 19 and 20; and then the slip of gold-leaf, being disengaged, is ready to act; moving, as already mentioned, between Ea and *bs*. To the wire, I, which projects above the small tube, FE, a bail, or another longer and pointed wire, may be affixed; or, in short, this wire, I, may be made to communicate with any thing, like any other bottle electrometer.

If by any accident the gold-leaf, *oc*, happens to be damaged, the tube, DC, is taken out of the tube, A B, and a new slip of gold-leaf is fastened at *o*, upon the brass plate, Ea. But on replacing DC into A B, the former must be turned, so as to place the surface of the brass slip, Ea, quite parallel to the surface of the arm, *bs*. Thus the gold-leaf electrometer is rendered perfectly portable; and the experience of some months has shewn that the gold-leaf, *oc*, suffers not the least derangement by being enclosed between the two brass surfaces of Ea and *bs*.

Fig. 22. represents an instrument, invented by Mr. Coulomb, for measuring the force of electric repulsion by the torsion of a wire. Its inventor calls it an *electrical balance*. The instrument is of glass, and its shape is sufficiently shewn in the figure; excepting the upper part of \mathcal{E} , which is a

brass flat plate, and a ferrule, which is cemented to the upper part of the glass tube. D is a piece of thick wire, laid upon the horizontal plate E, and holding a very fine wire which passes through a hole in E, and proceeds all the way down through the middle of the long tube, and until it reaches about the middle of the lower or larger tube, where it holds, suspended in an horizontal situation, the needle A B, which is made of silk covered with sealing-wax, and carries at its extremity, B, a ball of the pith of elder. A graduated circle is fixed in the inside of the large glass tube in the same plane with the needle A B, and within this circle another pith ball C is fixed, similar to the ball B. When these balls are electrified they repel each other; and this repulsion, which occasions the torsion of the wire that supports the needle A B, is measured by the divisions of the graduated circle.

Mr. Cuthbertson's electrometer, or combination of electrometers, is represented in fig. 23. "A B is a long square piece of wood about 18 inches by 6, in which are fixed two glass supports D, E, mounted with brass balls. Under the brass ball E is a long brass hook; the ball *b* is made of two hemispheres, the lower one being fixed to the brass mounting, and the upper turned with a groove to fluit upon it, so that it may be taken off at pleasure; it is screwed to a brass tube about 4 inches long, fitted on the top of D; from its lower end proceeds an arm carrying the piece F C, consisting of two hollow balls and a tube, which together make nearly the same length as that fitted on D: G H is a straight brass wire, with a knife-edge centre in the middle, placed a little below the centre of gravity, and equally balanced with a hollow brass ball at each end, the centre or axis resting upon a proper shaped piece of brass fixed in the inside of the ball *b*; that part of the hemisphere towards H is cut open, to permit that end of the balance to descend till it touches E; and the upper hemisphere *b* is also cut open. To the under side of *a* is hooked a brass wire about 4 inches long, hanging freely in a hole at the top of F. The arm G is divided into sixty grains, and is furnished with a slider to be set at the number of grains the experiment requires: *k* is a common Henry's electrometer, screwed upon the top of *b*.

"It is evident from the construction, that if the foot stand horizontally, and the ball G be made to touch F, and the slider set at *o*, it will remain in that position, but if it should by any means receive a very low charge of electric fluid, the two balls F, G, will repel each other; G will begin to ascend, and on account of its centre of gravity being above the centre of motion, and the slider so loose as to slide forward towards *b*, as soon as G H is out of its horizontal situation, the ascending will continue with an accelerated motion till H strikes upon F. If the balance be set again horizontal, and the slider set at *o* to grains, it will cause G to rest upon F with a pressure equal to that weight, so that more electric fluid must be communicated than the above low charge, before the balls will separate; and as the weight towards G is increased or diminished, a greater or less quantity of electric fluid will be required to effect a separation.

"When this instrument is to be applied to a jar or battery, for which purpose it was invented, one end of a wire must be inserted into a hole in the ball F, and the other into a hole of any ball proceeding from the inside of a battery or jar; *k* must be screwed upon *b*, with its index pointing towards H; the reason of this instrument being added, is to shew, while the index continues to rise, that the charge of the battery is increasing, because the other part of the instrument does not act till the battery has received its required charge.

"If this instrument be examined with attention, it will be found to consist of three electrometers, and answers three different purposes; namely, a Henry's electrometer, Lane's discharging

charging electrometer, and Brook's steelyard electrometer; the first is not improved, but the two last, which were very defective when first invented, I flatter myself, are here brought to perfection: as the only use of Henly's electrometer to this instrument is, as I have said before, to shew that the battery continues to receive a still stronger charge, it required no improvement; but Lane's electrometer, in its primitive state, could by no means answer the required purpose for batteries, because the ball intended to discharge the battery was necessarily placed so near to the ball of the battery, that dust, and many conducting particles, always floating in the air, were attracted, and repelled between the two balls, so as to render a regular intended high charge impossible; whereas in this, they are placed at four inches distance, and when the desired height of charge is obtained, and not before, the ball of the electrometer moves of itself nearer to the ball, which is connected with the outside of the battery, and causes a discharge. The defects in Brook's steelyard electrometer were, 1st, that it could not cause a discharge; and, 2dly, the difficulty of observing the first separation of the balls caused great error; if it were not placed in an advantageous light (which the nature of the experiments does not always permit) it could not be seen without the attention of an assistant, which cannot always be commanded. But this instrument, which I have described, requires no attention or assistance; for, as soon as the separation takes place between G and F, the ball H descends, and discharges the battery of itself.

“By this combination and improvement, we possess, in the present instrument, all that can ever be required of an electrometer; namely, by *k* we see the progress of the charge; by the separation of G F we have the repulsive power in weight; and, by the ball H, the discharge is caused when the charge has acquired the strength proposed.” Cuthbertson's Pract. Elect.

We might now add to this article the descriptions of several other electrometers; but as their use is inferior to those which have been already described, we think it useless to detain the reader with any such accounts, many of which are only imperfect varieties of the above described instruments; should, however, the reader wish to examine those electrometers such as they are, we refer him to the following works.

Darcy's electrometer. Aët. Par. for 1749. Richman's electrometer. N. A. Petr. vol. iv. p. 301. Comus's electric platometer. Roz. Journ. vol. vii. p. 520. Townsend's electrometer. Adams's Essay on Electr. Terry's electrometer. Roz. Journ. xxiv. p. 315. Boyer Brun's electroscope for a conductor. Roz. Journ. xxviii. p. 183. De Luc's fundamental electrometer. Idées for la met. Chappé's electrometer. Roz. Journ. xxxiv. p. 370. Cadet's electrometer. Annales de Chim. xxxvii. and Nich. Jour. v. p. 31. Marchaux's delicate electrometer. Gilb. xv. p. 98.

The use of the electrometers, which we have described, is undoubtedly very extensive; some of them being capable of measuring the highest charges of electricity known, and they may be extended farther still, should future experimenters endeavour to adapt them to the prodigious force of lightning or to some other natural or artificial power of electricity; whilst others are capable of indicating very small quantities of electricity; yet there are several cases where the electricity is so very feeble, as to be incapable of affecting any electrometer whatever: nevertheless electricians have devised means of discovering even this feeble electricity, which may be considered as distinguishable into two states; *viz.* either the quantity of electricity is really very small, and in that case Mr. Cavallo's multiplier will render it sensible; or the

electricity is diffused over a large space, so as to have its intensity too weak to affect an electrometer, and in that case the condenser will collect it into a narrower compass, &c. See MULTIPLIER, and CONDENSER.

ELECTROPHORUS, (from the Greek words *ελεκτρος*, amber, and *φορεω*, I bear,) is a machine consisting of two plates, one of which is a resinous electric, and the other a metallic plate. When the former is once excited, by a peculiar application of the latter, (which will be described presently.) this machine will furnish electricity for a very considerable time; so much so, that many persons, imagining that it would never lose its power, called it *the machine for exhibiting perpetual electricity*. It was invented by a much distinguished Italian philosopher, (Mr. Volta of Como,) about the year 1774, or rather earlier. Fig. 1. Plate XIV. represents this machine, whose two plates are A, and B. The lower one, B, is a circular glass plate, covered on the upper side with sulphur, or shell-lac, or other resinous electric. The upper plate, A, is of brass, or of wood covered with tin-foil, and has a glass handle, which screws (by means of a brass or wooden ferrule) perpendicularly into the centre of it. This metallic plate must have a pretty thick edge, well rounded off.

In the first place, the plate B is excited by rubbing its coated side with a piece of new white flannel, or with a dry hand, and when powerfully excited is set upon a table with its coated side uppermost. Secondly, the metal plate is laid upon the excited electric, as represented in the figure. Thirdly, the metal plate is touched with the finger, or with any other conductor, and this contact is attended with a spark. Lastly, the metal plate A being held by the extremity of its glass handle I, is separated from the electric plate; and being elevated above that plate, will be found strongly electrified with an electricity contrary to that of the electric plate; and it will give a strong spark to any conductor that is brought near it. By setting the metal plate upon the electric one, touching it with the finger, and separating it successively, a great number of sparks may be obtained apparently of the same strength, and that without exciting the electric plate anew. If these sparks be repeatedly given to the knob of a Leyden pibal, this will presently become charged. Having thus given a general idea of the construction, the management, and the effects of this machine, we must now examine all these particulars, and whatever belongs to them, separately, and in a more extensive manner.

It can hardly be doubted, that an excited plate of glass will form an electrophorus plate capable of producing the usual phenomena; but the reason why resinous electrics are generally used for this purpose in preference to glass, is, that the glass plate, owing to its readily attracting moisture, and partly to the smoothness of its surface, loses its electricity much sooner than an excited piece of sealing-wax, or sulphur, or of many other resinous electrics. Various experiments have been instituted for the purpose of determining the substance which would answer best for an electrophorus. A composition of rosin and sulphur, or sulphur alone, answers very well; but the first is attended with an unpleasant smell in melting and making it, and both, if long used, impart an unpleasant effluvia to the hand that rubs, or uses it. Sulphur alone is also apt to crack, so as frequently to require renovation.

Mr. Adams used a composition consisting of two parts of shell-lac and one of Venice turpentine. The cake of these two ingredients had no glass plate. Rosin, with bees'-wax, in the proportion of four or five parts of the former to one of the latter, is the cheapest composition, and answers tolerably well; but is inferior to Mr. Adams's composition. Mr.

Cavallo

ELECTROPHORUS.

Cavallo says, in his treatise on Electricity, "I tried several substances either simple or mixed, and at last I observed that the strongest in power, as well as the easiest I could construct, were those made with the second sort of sealing-wax, spread upon a thick plate of glass. A plate that I made after this manner, and not more than six inches in diameter, when once excited, could charge a coated phial several times successively, so strong as to pierce a hole through a card with the discharge. Sometimes the metal plate, when separated from it, was so strongly electrified, that it darted strong flashes to the table upon which the electric plate was laid, and even into the air, besides causing the sensation of the spider's web upon the face when brought near to it, like an electric strongly excited. The power of some of my plates is so strong, that sometimes the electric plate adheres to the metal, when this is lifted up; nor will they separate, even when the metal plate is touched with a finger, or other conductor.

"It is to be remarked, these plates sometimes will not act well at first; but they may be rendered very active by scraping with the edge of a knife the shining or glossy surface of the wax. This seems analogous to a well known property of glass, namely, that new cylinders, or globes, made for electrical purposes, are often very bad electricians at first, but that they improve by being worked, *i. e.* by having their surface a little worn. Paper also has nearly the same property."

The second sort of sealing-wax mentioned by Mr. Cavallo, is a harder sort than the best, which, perhaps, owing to its greater softness and pliability, cannot be excited so powerfully, nor does it retain the electricity so long as the harder sort.

The resinous coat was at first generally spread upon a glass plate, but soon began to be laid upon a metal plate; and as this was found more useful on various accounts, the glass plate has for several years been laid aside. When the electrophorus is of a moderate size, *viz.* less than nine or ten inches in diameter, the resinous cake may be made to adhere to a brass plate; but when larger (and some of these electrophorus cakes have been made as large as a yard in diameter) then they are made without any stiff metallic plate in Mr. Adams's manner, or have only a piece of tin-foil stuck to their lower surface.

The excitation of an electrophorus plate may be performed various ways. The small plates may be excited by friction with a dry hand, or by rubbing against the woollen garments of the operator. When large, they may be excited by rubbing with a piece of clean and dry flannel, or with a hair skin, or cat skin; meaning the skin with the hair on. Even a clean and hard hair brush will answer that purpose. But when the excitation has once commenced, or when the electricity of an electrophorus is decreasing, its force may be augmented in the following manner, and without friction. Place the metallic plate upon the resinous cake, touch it in the usual manner; then take up the metallic plate, and discharge it on the knob of a Leyden phial: repeat the operation several times, which will charge the phial. Now lay the bottle upon the resinous cake; hold the bottle by the knob, and move it so as to touch the various parts of the surface of the cake with its outside coating, which operation will augment the force of the electrophorus. This done, the whole operation may be repeated; that is, the metal plate is again laid upon the resinous plate, the phial is charged, &c., by which means the resinous cake may be rendered as powerfully electrical as possible. The rationale of this operation is so obvious, as to require no particular explanation.

The activity of these plates, though not continuing for ever, as some persons were at first inclined to believe, does, however, last a very great length of time, but always in a decreasing state. Sometimes these plates have been found capable of charging a phial, and of giving sparks a week after they had been excited, and even longer; but they have been observed to affect an electrometer full a twelvemonth after excitation, provided they are properly preserved.

The experiments which shew how both the surfaces of the resinous plate are affected by the super-imposition of the metal plate, &c. as made by Mr. Cavallo, are as follow: "If," he says, "after having excited the sealing-wax, I lay the plate with the wax upon the table, and the glass uppermost, *i. e.* contrary to the common method, then, on making the usual experiment of putting the metal plate on it, and taking the spark, &c. I observe it to be attended with the contrary electricity; that is, if I lay the metal plate upon the electric one, and while in that situation, touch it with an insulated body, that body acquires the positive electricity, and the metallic, removed from the electric plate, appears to be negative; whereas it would become positive if laid upon the excited wax. This experiment, I find, answers in the same manner, when an electric plate is used which has the sealing-wax coating on both sides, or one of Mr. Adams's, which has no glass plate.

"If the brass plate, after being separated from the wax, be presented with the edge towards it, lightly touching it, and thus be drawn over its surface, I find that the electricity of the metal is absorbed by the sealing-wax, and thus the electric plate loses part of its power; and if this operation be repeated five or six times, the electric plate loses its power entirely, so that a new excitation is necessary in order to revive it.

"If instead of laying the electric plate upon the table, it be placed upon an electric stand, so as to be accurately insulated, then the metal plate set on it acquires so little electricity, that it can only be discovered with an electrometer, which shews that the electricity of this plate will not be conspicuous on one side of it, if the opposite side is not at liberty either to part with, or acquire more of the electric fluid. In consequence of this experiment, and in order to ascertain how the opposite sides of the electric plate would be affected in different circumstances, I made the following experiments.

"Upon an electric stand *E*, *fig.* 2, I placed a circular tin plate, nearly six inches in diameter, which, by a slender wire *H*, communicated with an electrometer of pith-balls *G*, which was also insulated upon the electric stand *F*. I then placed the excited electric plate *D*, of six inches and a quarter in diameter, upon the tin plate, with the wax uppermost; and on removing my hand from it, the electrometer *G*, which communicated with the tin plate; *i. e.* with the under side of the electric plate, immediately opened with negative electricity. If, by touching the electrometer, I took off that electricity, the electrometer did not afterwards diverge. But if now, or when the electrometer diverged, I presented my hand open, or any other uninsulated conductor, at the distance of about one or two inches over the electric plate, without touching it, then the pith-balls diverged; or if they diverged before, came together, and immediately diverged again with positive electricity:—I removed the hand, and the balls came together;—approached the hand, and they diverged; and so on.

"If, while the pith-balls diverged with negative electricity, I laid the metal plate (holding it by the extremity *K* of its glass handle) upon the wax, the balls came, for a short time, towards

towards

ELECTROPHORUS.

towards one another, but soon opened again with the same; *i. e.* negative electricity.

“If, while the metallic rested upon the electric plate, I touched the former, the electrometer immediately diverged with positive electricity, which if, by touching it I took off, the electrometer continued without divergence. I touched the metal plate again, and the electrometer opened again; and so on for a considerable number of times, until the metal plate had acquired its full charge. On taking now the metal plate up, the electrometer G instantly diverged with strong negative electricity.

“I repeated the above-described experiments with this only difference in the disposition of the apparatus; *i. e.* I laid the electric plate D, with the excited sealing-wax, upon the circular tin plate, and the glass uppermost; and the difference in their result was, that where the electricity had been positive in the former disposition of the apparatus, it now became negative, and *vice versa*; except that when I first laid the electric plate upon the tin, the electrometer G diverged with negative electricity, as well in this as in the other disposition of the apparatus.

“I repeated all the above-mentioned experiments with an electric plate, which, besides the sealing-wax coating on one side, had a strong coat of varnish on the other side; and their result was similar to that of those made with the above-described plate.

“As to the explanation of these experiments, they seem to depend upon these two well-known principles; *viz.* that a body brought within the sphere of action of an electrified body, does actually acquire the contrary electricity; and that the existence of one kind of electricity upon the surface of any substance whatever, causes the existence of the contrary electricity upon some other substance near it.”

The writers of the Encyclopædia Britannica, in noticing the above-mentioned experiments of Mr. Cavallo, say, “He tells us, that, *if instead of laying the electric plate upon the table, it is set upon an electric stand, so as to be accurately insulated, then the metal plate set on it acquires so little electricity, that it can only be discovered by an electrometer.* In what manner these gentlemen came to mistake a plain fact so egregiously, is not easy to determine.”

Finding such a formal contradiction made to a matter of fact which may be easily tried, we had the curiosity to try the experiment, and found, from the result of it, that Mr. Cavallo's account was perfectly correct, and the above-mentioned writers were perfectly mistaken.

What we have already mentioned with respect to the action of the electrophorus plate may be easily applied to each particular phenomenon separately considered. Should the reader wish to examine farther observations and conjectures concerning them, he may consult the Phil. Trausf. vol. 66, p. 513, vol. 67, p. 116, and p. 389, and vol. 68, p. 1027, and 1049. See *VINDICATING Electricity*.

About the year 1777 an account was received in London of certain experiments made by professor Lichtenberg of Göttingen, with the electrophorus. The experiments are performed in the following manner. The resinous plate of an electrophorus is first excited; then a piece of metal of any shape, (as a pair of scissars, a piece of brass tube, &c.) is laid upon the electrophorus plate; and to this piece of metal a spark is communicated of the electricity contrary to that of the plate; this done, the piece of metal is removed by means of a stick of glass, or sealing-wax, or other electric; and the powder of rosin, kept in a linen bag, is shaken over the electrophorus. This powder will be found to fall about those points upon the plate which were touched by the above-mentioned piece of metal, and to form several beautiful

radiated configurations about those points. The rest of the plate remains almost entirely free from the powdered rosin. This is the case when the plate is excited negatively, and a spark of the positive electricity is communicated to the piece of metal laid upon it. But if the plate be excited positively, and a spark of negative electricity is given to the piece of metal; then the powdered rosin will fall upon those parts of the plate which in the preceding case were left uncovered by it, and will leave a radiated configuration round each of the points which were touched by the piece of metal. In short, the electricity of the spark which is communicated to the piece of metal seems to spread itself in a ramified manner over the plate, and round the points of contact, &c.; and the powdered rosin which is shaken over it is attracted only by those parts of the surface of the electrophorus which are electrified positively. Prof. Lichtenberg in his work, “*De nova methodo naturam ac motum fluidi electrici investigandi commentatio prior*,” wherein these experiments were first described, did not attempt to give any explanation of the phenomena; in consequence of which, Mr. Cavallo instituted a series of experiments with a view of investigating the cause of the above-described phenomena; and he discovered that powdered rosin, by its being shaken out of the linen bag, was actually excited, and acquired the negative electricity; therefore, in the experiments with the electrophorus, it was not wonderful that the rosin thus excited negatively, should be attracted by those parts of the plate which were electrified positively. Mr. Cavallo likewise tried various other powders in a similar manner, as well as otherwise; and found that some of them acquired the positive, whilst others acquired the negative electricity. See his Treat. on Elect. p. iv. ch. vii. *ALSO EXCITATION.*

Mr. Bennet repeated and diversified Prof. Lichtenberg's experiments. He took a glass plate, 15 inches square, covered on one side with a thin resinous black coating, with tinfoil passed on the other side; and suspended it by a loop against the wall, that the grosser particles of the powder that was shaken near it might fall to the ground, and no more of it might adhere to the plate than was attracted by the electricity diffused thereon. A small Leyden phial was weakly charged, and after its knob had been drawn over the plate, a cloud of chalk was projected by rubbing the lump upon a brush near the electrified surface of the plate. This produced a plain white line without any ramifications. When the experiment was performed with the Leyden phial charged a little higher, ramifications appeared about the plate at a considerable distance from each other. When the phial was charged as highly as it could bear, the ramifications were close and broad, resembling white feathers with a very broad shade.

A circular brass plate, with an insulating handle, was placed upon the resinous plate which stood upon the table, and a spark from the charged phial was communicated to the brass plate, which was then removed by its insulating handle; and chalk was projected, which produced a very regular circle of ramifications, proceeding from the circumference of the space covered by the brass plate, and within the circle there were various irregular figures, somewhat like stars. A shock made to pass through the above-mentioned plate generally produced more distinct ramifications, and sometimes without any stars within the circle.

By varying the powders as well as the bodies, which are laid upon the plate, the configurations may be varied without limit. If powders of different colours are mixed and projected as above, or out of a pair of bellows, some of the colours will prevail in some places, and other colours in other places; and especially if two figures of contrary elec-

tricity.

tricities are made upon the same plate; and most of all when both the electrical states of the figures and of the powders are contrary to each other. For example, if minium, whose electricity is strongly positive, and sulphur, which is strongly negative, be powdered together, and the mixed powder be projected out of a pair of bellows upon the figures contrarily electrified; the powders will be separated, and the sulphur will fall upon the positive figures, whilst the minium falls upon the negative figures; producing several curious configurations, agreeably to the well known electrical law, *viz.* that bodies, possessed of different electricities, attract each other, whilst bodies possessed of the same kind of electricity repel each other. See *ELECTRICAL Experiments*.

ELECTRUM, Ηλεκτρον. This term has been applied by the Greek and Roman writers to various substances; from which circumstance much confusion has arisen, and the knowledge of the ancient naturalists has been on several occasions very unjustly called in question: at the same time, however, many of the classical writers, especially among the Romans, have fallen into mistakes on the subject, for the purpose of explaining which, it is worth while to enter somewhat minutely into an investigation of the question, "What is the *electrum* of the ancients?"

The answer given by Pliny to this question is, that the word *electrum* denotes two substances, the one the fossil, now called amber, and the other a certain metallic alloy, at present no longer in use, composed of four parts of gold and one part silver. Bearing this general explanation in mind, we shall proceed to consider the principal passages among the ancient writers in which it occurs.

The word itself is probably derived from Ηλεκτρα, a name applied by Homer and other early Greek writers to the sun. Thus Achilles prepared for battle is represented as,

Τουχας παμφανων ἑς Ηλεκτρα σπέρων.

Radiant in arms at the sun Hyperion.

Homer, the most ancient Greek writer, whose works are extant, is also the first who mentions *electrum*: the word is not to be found in the *Iliad*, but occurs thrice in the *Odyssey*. A Phœnician merchant is described as possessing χρυστον ὄρμον, μετα δ' ηλεκτρον ἑρπον, a golden necklace set with beads of amber. Eurymachus presents Penelope with ὄρμον ποδουδαϊαλον, ηλεκτρον ἑρπον, a curiously-worked necklace, set with beads of amber. Lastly, Telemachus, on visiting the palace of Menelaus, admires the splendour of the echoing halls, radiant

Χρυσῶ τ' ηλεκτρο τει, καὶ ἀργυρῶ νη' ἐκσφοντος.

With gold and amber, with silver and ivory.

Pliny indeed quotes this passage as a proof that Homer was acquainted with the metallic *electrum*; but, in my opinion injudiciously, for not to mention that the former passages clearly relate to amber, it is not evident that the *electrum* and ivory here bear the same relation to each other as the gold and silver do: the one is yellow, and therefore mentioned with the gold, as the other is white, and therefore mentioned with the silver, but it does not by any means follow that either is metallic.

The next writer, in chronological order, is Hesiod: in whose poem, called *the Shield of Hercules*, the word Ηλεκτρον occurs. In the passage alluded to it is immediately associated with ivory, and, therefore, probably, as in Homer, means amber.

It may, perhaps, be objected, that as amber is not to be procured in quantity any where except on the coast of Ducal Prussia, it is very unlikely that in such early times it should have been so well known among the Greeks, and so common an article of ornament. But this objection will va-

nish, when we recollect that at the period now referred to, the commerce of the Phœnicians was in full activity; and that enterprising people, who, after establishing colonies in Spain, opened a trade with Britain for the tin of Cornwall, might very possibly extend their researches even into the Baltic. What serves as a striking confirmation of this is, that the oldest Greek writers who mention the country of amber, are much nearer the truth in this respect, than those who wrote after the decline of Phœnicia, and acquired their knowledge of the Western countries of Europe only from the timid coasting voyages of their countrymen, to whom the pillars of Hercules were the extremity of the world in that direction. On this subject the testimony of Herodotus is of great importance; and the more so, as the account which he gives is not to serve any theory of his own, since he expressly says, that he himself does not believe it. After describing the Scythians and other Northern tribes, he proceeds thus: (Lib. iii. § 115.) "Of the western extremities of Europe, I can report nothing with certainty, for, that a river flowing into the North sea, and from which, as I am informed, amber is procured, should be called by the Barbarians Eridanos, I can by no means allow; nor am I acquainted with the islands called Cassiterides, from which tin is procured. Indeed the very name of the river shews that there is some mistake, for Eridanos is not a Barbarian but a Greek word, and invented by some poet. It is certain, however, that both tin and amber come from that extremity of the world."

From this important document we learn, that in the time of this historian both tin and amber were procured from the north-western part of Europe (with respect to Greece); that the latter was said to be obtained from a river called Eridanos, flowing into the North sea, and that the only, or at least the principal, reason why Herodotus doubted the truth of this, was because the name Eridanos was Greek and not Barbarian. Unquestionably the word, in its present form, is Greek; but the root of it is as certainly (to use the phraseology of Herodotus) Barbarian, being the same as the English river Rodon, and the French river Rhone, *Rhodanus*, and, in fact, there is a river at this very day called Rhodanus, which flows into the Vistula, near Dantzic, traversing the country in which the present amber mines of Prussia are situated; which striking coincidence will surely justify us in considering this as the true Eridanus of the earliest Greeks.

Carthage appears about this time to have succeeded to the establishments in the West, formerly possessed by the mother-country Phœnicia; and, induced by commercial jealousy, suppressed as much as possible all information respecting the countries lying west of Italy; hence these regions again became the seat of Greek fiction and fable, almost as much as in the time of Homer. The true Eridanus of the Baltic was brought within the pillars of Hercules, and represented by Æschylus as a river of Iberia, and the same as the Rhodanus; on its banks were situated by the same poet the filters of Phæton, who, lamenting his death, were turned into poplar trees, from which exuded tears of amber. The romance was adopted by Euripides, but the scene was transferred from the Rhone to the Po, as being probably the remotest great river of the West with which he was acquainted. The later poets, both of Greece and Rome, acquiesced in the authority of Euripides, and Eridanus continued ever after to be the poetical name of the Padus, while Strabo and the geographers denied its very existence; τον Ηρδανον, τον μηδαμω γην; οντα being the very words of the above-mentioned writer.

The obscurity which thus involved, and by degrees entirely concealed, the knowledge that had been possessed by the ancient Greeks of the native country of amber, was not satisfactorily

factorily removed till the Romans extended their conquests to Britain and the north of Germany. In the reign of Tiberius, a regular commerce in Roman ships appears to have been carried on between the northern ports of Gaul and the district lying between the Elbe and Vitula; and Nero procured thence such an abundance of amber, that it was largely employed in ornamenting the amphitheatre.

But during the period in which this ignorance of the real country of amber prevailed, the substance itself appears to have been very common, so that it was used as a frequent term of comparison, just as glass is with us. We say water as clear as glass. Callimachus says, το δ', ως αλεκτρον, υδωρ, water as clear as if it were made of amber; and Virgil, "purior electro, annis," a river purer than amber; and Lucian, πλακτες, η Σιδωνιας υδωρ διαφανεστερον, more transparent than amber or Sidonian glass.

It appears, that both the Greeks and Romans were persuaded that amber was a concrete vegetable juice, (whence indeed the latter people called this very substance succinum, a *succo*), and this circumstance would induce them to receive with less suspicion any of the harder resins of India, such as copal and lac, as real varieties of amber: and in this way is probably to be explained the assertion of Pliny, that amber was procured from Africa, India, and Egypt, which countries yield little, if any, of the real amber, but abundance of the hard resins. At present we possess a very satisfactory method of distinguishing amber from the resins, by its insolubility in alcohol; but prior to the discovery of this fluid, the distinction between these two substances was not very likely to be perceived. The Egyptian name of amber, according to Pliny, was sacal; but sachal is an Arabian word still in use, and is rendered in the Lexicon Copto-Arab, by the words *gummi nel resina*, which is no small confirmation of the above hypothesis. It would be foreign to the purpose of the present article, to pass from the consideration of the term electrum to that of amber, which being originally appropriated to the substance now called ambergris, came through ignorance to be confounded in process of time with the amber of the Baltic. I shall therefore proceed to state some of the principal passages in which electrum is considered as a metal or metallic alloy.

In the Antigone of Sophocles, v. 1049, occurs the following passage:

Κερδαίνει, εμπροσθε τον προ Σαρδων
Ηλεκτρον, ει Βαλασθε, και τον Ινδικον
Χρυσον ταφω δεικνους ουχι κρυπτε.

Dispose of my Sardinian electrum and Indian gold as you please, but on no account commit his body (of Polyneices) to the tomb.—Eustathius and all the scholiasts consider electrum as here meaning gold, especially as it is said to come from Sardis, in the vicinity of which was the river Pactolus, so celebrated for its golden sands; but if this interpretation be admitted, it is surely a strange tautology in the poet to make mention afterwards of Indian gold. Is it not possible that Sophocles may have mistaken Sardis for Sardinia? Apollonius, in his Argonautics, represents the Enderus as flowing into the Σαρδωνιον πελαγος, the Sardinian sea.

Of less dubious import, is a passage occurring in Strabo's description of the gold-mines of Spain, εκ δε τω χρυσω ε φομενη και καθαριμενη συνετηναι τιμιωτη, το καθαριμα πλακτερον υνωι, &c. Moreover the gold being cemented and purged by a certain aluminous earth, that which remains is called electrum, and this being a mixture of gold and silver, the latter is separated by cementation, and the gold is left.

A still more particular account is given by Pliny, (Hist. Nat. xxxiii. § 23.) of the metallic electrum. All gold, says

he, is naturally alloyed by silver in various proportions; some containing a tenth, some a ninth, and some an eighth part. Wherever the silver amounts to a fifth of the mass, the compound is called electrum; this alloy may also be prepared artificially, by adding to gold the requisite proportion of silver. But if this latter exceeds a fifth of the whole, the mass ceases to be malleable. The nature of electrum is to reflect a richer lustre by lamp light than pure silver does. That which is native has also the additional property of detecting poisons, iridescent rings passing rapidly over the surface of the cup, accompanied by a noise like that of hot metal plunged in water.

Electrum was not only used for ornamental plate, but was occasionally employed for coin, at least for medals. Thus Lampridius, in his life of Alexander Severus, says, that that prince caused medals to be struck in honour of Alexander the Great, both of electrum and gold. (Electreos aliquantos, sed plurimos tamen auro.)

From what has been said, it appears to be at least very dubious, whether the alloy of gold and silver, known to the Romans by the name electrum, was at all in use among the Greeks. The Romans themselves appear to have preferred the white lustre of silver to the yellow radiance of gold, &c. probably this taste, together with the imperfection of the art of assaying, as practised by them, aided also by an idle superstitious notion of the efficacy of electrum in detecting poison, contributed to give to this alloy a temporary celebrity. Modern taste, however, prefers the native lustre of the noble metals in all their purity to any alloy of them with each other, nor is it probable, that the Roman electrum will ever again be met with at the mint or on the sideboard.

ELECTUARY, or ELECTARY, ELECTUARIUM, in Pharmacy. Vossius observes, that all the remedies prescribed for the sick, as well as the confections taken by way of regale, were called by the Greeks ελεκταρια, and ελεκτα, of the verb λικω, I lick; whence, says he, was formed the Latin electarium, and afterwards electuarius. This conjecture he supports from the laws of Sicily, where it is ordained, that electuaries, syrups, and other remedies, be prepared after the legal manner. The Bollandists, who relate this etymology, seem to confirm it. Act. Sanct. Mart. tom. ii. p. 131.

Electaries are medicines chiefly composed of powders of various kinds, mixed up with syrup or honey into such a consistence, that the powders may not separate by keeping, and that a dose may be taken upon the end of a knife, and prove not too stiff to swallow.

The ingredients of electaries are chiefly the milder drugs, those which may be taken a good deal *ad libitum*, such as the milder aperients, or aromatics and alteratives, in which a certain latitude may be allowed in the dosing without material risk.

The ancient physicians bestowed prodigious pains on the composition of particular electaries, and multiplied the ingredients to a most preposterous degree; heaping together gums, resins, aromatics, animal substances, inert mucilaginous vegetables, salts, &c. &c. with the most indiscriminating profusion. They also made the distinction between electuaries and opiates, meaning by the latter term electaries, of which opium formed a part. This distinction has long been dropped, and indeed a very great reform has been made in all the more modern pharmacopœias, by suppressing a great part of the electaries, and rendering the rest much more simple, and of course their modus operandi more intelligible.

The great defect of all electaries is their liability to mould by keeping, and thus to acquire both unpleasant sensible properties, and also to have the virtues of some of their in-

gredients much impaired. This disposition to mould is particularly found in those electrics which are composed of succulent vegetables, pulps of fruits, and the like; and though the moulding is somewhat checked by the quantity of sugar added, it cannot always be done effectually unless these preparations are kept very dry, whereby they harden and lose that kind of consistence which is essential to their use.

The electrics that are the best for keeping, are those which are composed principally of aromatic powders, or gum-resins; and these, if properly prepared, may be preserved for years unaltered.

Though electrics, in the present mode of practice, are generally made from extemporaneous prescription, a few are retained in the Pharmacopœia, together with some *confectious*, which differ from the electrics only by name.

ELECTUARY of Cassia, is composed of the fresh extracted pulp of cassia, half a pound; manna, two ounces by weight, tamarind, one ounce by weight, and rose-syrup, half a pound. It is prepared by beating the manna, and dissolving it, in a water-bath saturated with sea-salt, in the rose-syrup; then adding the pulps, and, with the same degree of heat, evaporating the whole to an electuary of proper consistence. The dose for an adult is from ʒj to ʒiſs.

ELECTUARY of Scammony consists of scammony, in powder, 1½ ounce by weight, cloves and ginger, of each six drams by weight, oil of caraway, half a dram by weight, and rose-syrup, as much as is sufficient. The spices, being powdered together, are mixed with the syrup; and then the scammony is added, and lastly the oil of caraway. The dose for an adult is from ʒj to ʒj.

ELECTUARY of Senna is composed of senna, eight ounces by weight, figs, 1lb. tamarind, cassia, and prunes, of each ½ lb. coriander four ounces by weight, liquorice three ounces by weight, and double-refined sugar, 2½ lbs. The senna is powdered with the coriander pods, and 10 ounces of the powder is sifted out. The remainder is boiled with the figs and the liquorice, in four pints of distilled water, to one-half; then the liquor is pressed out and strained. It is then evaporated to the weight of about 1½ lb., and the sugar added to make a syrup: then this is added by degrees to the pulps, and lastly the powder is mixed in it. The dose for an adult is from ʒs. to ʒiſs.

ELEEMOSYNA CARUCARUM, or *pro Aratrix*, or *Aratri*, in our *Ancient Customs*, a penny which king Ethelred ordered to be paid for every plough in England, towards the support of the poor. Sometimes it is also called *elemosyna regis*, because first appointed by the king.

ELEEMOSYNÆ is also used for the piousness belonging to churches. See **ALMS**, and **FRANK Almoign**.

ELEEMOSYNARIA. See **AMBR**.

ELEEMOSYNARIUS, in our *Old Writers*, is used for the almoner, or peculiar officer who received the elemosynary rents and gifts, and distributed them to pious and charitable uses. There was such an officer in all religious houses. The bishops also used to have their almoners, as now the king has. Linn. Provinc. lib. i. tit. 12. See also **De-Cange**, Gloss. Lat.

ELEEMOSYNARY CORPORATIONS. See **CORPORATIONS**.

ELEGANCE, **ELEGANCY**, from *eligo*, I chuse, denotes a manner of doing, or saying things politely, agreeably, and with choice.

With choice, so as to rise above the common manners; politely, so as to strike people of delicate taste; and agreeably, so as to diffuse a relish which gratifies every body.

ELEGANCE, in *Painting*, is a quality which embellishes and heightens the beauty of objects in a picture, of what-

ever nature they may be, and that either in form, in colours, or both, without destroying the general air of truth. It is a diminutive of grace which may unite with the grand, whilst elegance seems to militate against it. Many attempts have been made to discover and define wherein elegance consists, but none are satisfactory; and what particular combinations of lines or colours will best produce its effect, remain hitherto undetermined.

Sir Joshua Reynolds, who possessed more of it, and has more exemplified it in his works than any artist that ever lived before him, or since, has observed, in his Discourses, that correctness is its basis. In saying this, he must not be understood to mean literally a correctness of imitation of particular forms in nature; but that general character of form in man and other objects, round which all of the same species vary. He observes also, "that to suppose it to proceed from incorrectness or deformity is poison to the mind of a young artist, and may lead him to neglect essential studies to pursue a phantom that has no existence but in the vain imagination of affected speculators."

This argument, however just it may appear, will be found extremely difficult to reconcile with the fact, that elegance in design does exist without correctness; indeed, in works where extreme incorrectness is evident to the commonest observer, and even in better works, in too many of this great man's own productions, this union is too visible; and elegance is rarely to be found in the works of those who have made correctness their principal study. It seems, therefore, that it may most justly be said to proceed from a refinement upon the general form, and therefore a variation from it; but which ought not to have been termed a deformity, since we see it in nature constantly exemplified; and no one is inclined to regard an elegant woman as a piece of deformity. Sir Joshua in this appears to have followed too closely the accustom'd inclination of a systematizer, and having laid down a rule that nature, in a general sense, is the only guide, attaches particular circumstances to it that have no relation, in fact, not willing to give up, for a moment, his general principle.

It is to be lamented, in contradiction to his sentiment, that the productions of his elegant mind and pencil are too often convincing proofs, that elegance may exist with certain deviations from correct imitation of general Nature; nay, almost, that it scarce can exist without some encroachment on that form, and substituting something ideal for something real, fabric, and to give more pleasure than a representation of the absolute forms ever can to a cultivated mind.

We therefore are no nearer the definition of its nature than before he wrote; and if he who possessed so much larger a portion of this agreeable quality than any one else, and was so well able to define and illustrate his conceptions by language; if he has failed in an attempt to explain, in some degree, the nature of elegance, it becomes almost a hopeless case that we may ever see it performed with success.

We are better able to inform our readers what does not, rather than what does, assist in producing its effect; though, indeed, we may also speak of some of those characteristics of it which are apparent in the works of those who have most excelled in their attempts to obtain it, without pretending clearly to guide the judgment of others who may seek to embellish their works with so pleasing an ornament.

Heaviness of line or form, grossness and violence of colours, are each a strong antipathy to elegance, it cannot reside with them. On the contrary, lightness of form and execution, a gentle flow of line, not too violent or too tame in its varieties, are useful in obtaining its character; the figure

figure that aspires to it should not be over-clothed; parts of the figure should appear, in some measure, acting under the drapery. Too violent an opposition of colours militates against it; though brilliancy of hue may well accompany it, positive colours are not admissible; where it is required, a broken hue of a softer shade better corresponds with its nature. Altogether it depends upon, or rather it is, a pleasing arrangement of forms and colours; but what particular unions of lines will best give those forms, or what ordering of colours it requires, we will not attempt to define.

That there is such a quality we are all sensible, and are sensibly affected by it. Yet as in nature so we believe it to be in art. If not felt inherently and untriflingly, we fear it will never be acquired to any sufficient degree to make it valuable.

How few in number are the young persons with whom so long continued and such zealous pains are taken to render them in their manners elegant and graceful, out of the immense mass who are daily coming forward in the fashionable world, who possess it? And how soon do the affected airs, which education has unhappily taught many (mistaking them for elegant) to assume, become apparent and disgusting, where what we are accustomed to term natural elegance is not inherent!

Sir Joshua Reynolds possessed it by nature; his earliest works participate of it. Not finding any difficulty himself in entering into its principles, he naturally enough supposed that those who took the same pains to inform themselves that he did, would also acquire it, (for he has said it may be acquired,) yet numberless are the artists who acknowledge and feel the full value of it in the work of others, and who, labouring with all their might to obtain it, never present a glimpse of it in their own works. That late excellent artist, Opie, has often, in conversation with the writer of this article, dwelt with rapture on the elegance of works from Reynolds' pencil, and ardently expressed his wish to obtain possession of the faculty himself. All who are acquainted with his works, know how far he was from blending elegance with the other great qualities they contain. It seems, therefore, that though those who have a share of it by nature may improve their stock; those who are not so fortunate, will rarely, perhaps never acquire it.

The ancient works possess it largely, as statues, bas-reliefs, and paintings, particularly the ornamental. Among the moderns, Reynolds, Correggio, Parmigiano, and Guido Rheni, best exemplify it: Raphael is sometimes elegant, but expression was his object, and he who aims at that principally must not too often sacrifice to elegance.

ELEGANCY, in *Oratory*, is one of the three parts of general ELOCUTION, and respects the purity and perspicuity of the language. By the former a discourse is rendered correct, and by the latter intelligible; and both extend to the selection of single words, as well as to their construction in sentences. See PURITY, and PERSPICUITY.

Poetical elegancies, *elegantia poetica*, are of service to scholars in making their verses; by being too regular in the grammatical construction, we lose certain licences, wherein the elegance of language consists. Elegance, though irregular, is better than regularity without elegance.

ELEGARDA, in *Ancient Geography*, a town of Asia, in Armenia Major. Ptolemy.

ELEGIA, in *Botany*, from *ελεος*, lamentation, perhaps in allusion to the sad or mourning colour of the whole plant. Linn. Mant. 2. 162. Thunb. Restio 4. Prod. 14. Schreb. 675. Mart. Mill. Dict. v. 2. Class and order, *Diacia Triandria*. Nat. Ord. *Calamariæ*. Linn. *Junci*, Jusl.

Gen. Ch. Male, *Cal.* Spathe within spathe, remote,

single-valved, coriaceous, lanceolate, deciduous; spadix thread-shaped, jointed, with a catkin at each joint; catkin lax, with one stalked floret to each scale; scales setaceous, membranous, flat, longer than the florets; proper perianth of six setaceous, closely unequal, lax leaves. *Cor.* none. *Stam.* Filaments three, very short; anthers incumbent, oval, larger than the perianth.—Female in a separate plant. *Cal.* Spathe as in the male, but shorter; spadix as in the male; catkin racemose, compound; proper perianth of six leaves, the three outermost lanceolate, channeled, petal-like, equal. *Cor.* none. *Pist.* Germen superior, rather oblong; styles three, thread-shaped, the length of the perianth; stigmas simple. *Peric.*, according to Thunberg, a capsule of three cells. *Seeds* ferule, oblong.

Eff. Ch. Male, Catkin compound; florets stalked; perianth of six unequal leaves. Corolla none. Female, Catkin compound; perianth of six leaves. Capsule of three cells.

E. juncea. Linn. Mant. 2. 297. Thunb. Prod. 14. (Restio Elegia; Linn. Syst. Veg. ed. 14. 882. R. thyrifer; Rottb. Descr. 8. t. 3. f. 4.) the only species, a native of the Cape of Good Hope. A hard rushy plant, with exactly the habit of a *Restio*, to which genus Linnæus finally referred it, but Thunberg insists on its remaining distinct. The roots are perennial. Stems several, four feet high, simple or branched, rigid, a little waved, round, smooth, not so thick as a goose-quill, brownish green, with several remote joints. Leaves none, except a few smooth, brown, imbricated, pointed scales towards the root, and a similar one at each joint of the stem; these last fall off, and leave their black annular base at the joint. Catkins in a terminal ovate head, with broad, tumid, ovate, brown spathe, enveloping the catkins. The anthers are large and conspicuous, brown bordered with white. Female catkins of a darker brown hue, especially when in fruit.

ELEGIA, in *Ancient Geography*, Ilija, a place of Asia, in Melitene, seated on the left bank of the Euphrates, at the entrance of this river in mount Taurus.

ELEGIAC, in the *Latin Poetry*, something that belongs to *elegy*, which see.

Elegiac verses, *Ελεγιοι*, are alternately hexameter, and pentameter.

Quintilian esteems Tibullus the chief of the elegiac poets; but the younger Pliny gives the preference to Propertius. They have each of them reason on their side; and one might make a third choice, as just as either of them. See ELEGY.

ELEGIT, in *Law*, a judicial writ given by the Statute Westm. 2. 13 Edw. 1. c. 18, either upon a judgment for a debt, or damages; or upon the forfeiture of a recognizance taken in the king's court. By the common law a man could only have satisfaction of goods, chattels, and the present profits of lands, by the two writs of "fieri facias" or "levari facias;" but not the possession of the lands themselves; which was a natural consequence of the feudal principles, that prohibited the alienation, and of course the incumbering of the sief with the debts of the owner. And when the restriction of alienation began to wear away, the consequence still continued; and no creditor could take the possession of lands, but only levy the growing profits, so that if the descendant aliened his lands, the plaintiff was out of his remedy. The statute therefore granted this writ (called an *elegit*, because it is in the choice or election of the plaintiff whether he will sue out this writ or one of the former) by which the defendant's goods and chattels are not sold, but only appraised, and all of them (except oxen and beasts of the plough) are delivered to the plaintiff, at such reasonable appraisement and price in part of satisfaction of his debt. If the goods are not sufficient, then the moiety, or

one half of his freehold lands, which he had at the time of the judgment given (2 Inst. 395.), whether held in his own name, or by any other trust for him (stat. 29 Car. II. c. 3.), are also to be delivered to the plaintiff; to hold, till out of the rents and profits thereof the debt be levied, or till the defendant's interest be expired; or, till the death of the defendant, if he be tenant for life, or in tail. During this period, the plaintiff is called tenant by *elegit* (see TENANT). This is evidently a mere conditional estate, defeasible as soon as the debt is levied. Till the statute above-mentioned, lands were not, by the ancient common law, liable to be charged with, or seized for, debts; because by these means the connection between lord and tenant might be destroyed, fraudulent alienations might be made, and the services be transferred to be performed by a stranger; provided the tenant incurred a large debt, sufficient to cover the land. And therefore, even by this statute, only one half was, and now is, subject to execution; that out of the remainder sufficient might be left for the lord to distrain upon for his services. And upon the same feudal principle, copyhold lands are at this day not liable to be taken in execution upon a judgment. (1 Roll. Abr. 888.) But in case of a debt to the king, it appears by magna carta, c. 8, that it was allowed by the common law for him to take possession of the lands till the debt was paid. Moreover, by the statute "de Mercatoribus," passed in the same year with the former, the whole of a man's lands were liable to be pledged in a statute merchant, for a debt contracted in trade; though only half of them was liable to be taken in execution for any other debt of the owner.

This execution, or seizing of lands by *elegit*, is of so high a nature, that after it the body of the tenant cannot be taken; but if execution can only be had of the goods, because there are no lands, and such goods are not sufficient to pay the debt, a "*capias ad satisfaciendum*" may then be had, after the *elegit*; for such *elegit* is in this case no more in effect than a "*feri facias*." (Hob. 58.) So that body and goods may be taken in execution, or land and goods; but not body and land too, upon any judgment between subject and subject in the course of the common law. Blackitt. Comm. book iii.

ELEGY, *Ελεγίον*, a mournful, and plaintive kind of poem. Vossius, after Didymus, derives the term from *ἔλεος*, *to say alas!*

The first inventor of the elegy is not known: some say it was one Theocles of Naxos, or according to others, of Eretia, who, in the heat of his phrensy, first produced this kind of composition. But there is no wonder that we are at this time in the dark as to the matter. Horace assures us it was a point not settled among the grammarians even in his time, who the author was.

"Quis tamen exiguos elegos emiserit auctor,
Grammatici certant, & adhuc sub judice lis est."

The chief writers of elegy among the Greeks are, Callimachus, Parthenius, and Euphorion; and among the Latins, Ovid, Catullus, Tibullus, and Propertius.

The Flemish have distinguished themselves among the moderns for this kind of Latin verse. The elegies of Bidermann, Grotius, and especially Sedronius and Vallius, seem worthy of the purest antiquity. The countess de la Suze has distinguished herself for elegies in the French tongue.

In the English, we have nothing considerable of the elegiac kind, but what we have of Milton, except Hammond's love elegies, and Grey's elegy, written in a country churchyard. The elegies of Hammond have had admirers among

men of great eminence in literature and criticism; and perhaps if we did not make an exception in favour of Grey, we should offend two-thirds of the lovers of poetry in this kingdom. The English and French elegies are chiefly in Alexandrine verses.

In process of time, elegy degenerated from its original intention; and not only matters of grief, but also joy, wishes, prayers, expostulations, reproaches, and almost every subject, were admitted into elegy.

The office of elegy is well delivered by M. Boileau:

"La plaintive elegie en long habits de deuil,
Sçait, les cheveux epars, gemir sur un cerceuil:
Elle peint des amans la joye, & la tristesse;
Flate, menace, irrite, appaise une maitresse."

"In mourning weeds sad elegy appears,
Her hair dishevell'd, and her eyes in tears:
Her theme, the lover's joys, but more his pains;
By turns she sings, soothes, threatens, and complains."

The diction of elegy ought to be clean, easy, perspicuous, expressive of the manners, tender, and pathetic; not oppressed with sentences, points, &c. No apostrophes are allowed; and the sense ought to be generally closed in every distich, or two lines; at least, in Latin compositions.

ELEGY, a kind of *nome*, or air, for flutes, in high favour with the ancients, invented by Sacadas the Argian. Rouffseau.

ELEMENTARY, something that relates to the principles or elements of bodies.

The elements of a body are also called the elementary principles thereof. See PRINCIPLE.

The whole space, included within the concave, or orbit of the moon, is called the elementary region, as being the seat, or sphere, of the four vulgar elements, and the bodies compounded thereof.

ELEMENTARY *Air, Fire, Geometry, Music*. See the subtitles.

ELEMENTS of the Planets, in *Astronomy*, certain quantities which are necessary to be known, for the purpose of determining the theory of their elliptic motion. (See ELLIPTIC Motion.) Astronomers reckon seven of these quantities. The five which relate to the motion of the ellipse are, first, the duration of the sidereal revolution; second, half the greater axis of the orbit; third, the eccentricity, from which is derived the greatest equation of the centre; fourth, the mean longitude of the planet at any given epoch; and, fifth, the longitude of the perihelion at the same epoch. The two other elements relate to the position of the orbit; and are, first, the longitude (at a given epoch) of the nodes of the orbit with the ecliptic; second, the inclination of the orbit to this plane. There are thus forty-nine elements to determine for the entire system, as will be seen by the table at the end of this article.

To determine the elements of the orbit of a planet by three observations.

The time of the revolution of the planet must in the first place be supposed known, so that the mean motion of the planet may be given in the intervals of the observations. If these intervals are considerable, the motion of the aphelion should likewise be known, as the observations are supposed to relate to an ellipse fixed and immovable; but as in general the intervals employed are not very long, the error arising from the motion of the aphelion is inconsiderable.

The three observations should be distant from each other about a quarter of a revolution, that is, two near the apices, and

and the other nearly in the mean distance, or two in the mean distances, and the other in the apsidæ. The aphelion is determined with the greatest accuracy when two longitudes are taken in the apsidæ, but the equation of the centre is obtained with most advantage by taking two observations in the mean distances, for then it is determined by the double of its value. These observations may be taken after several entire revolutions of the planet, provided its motion, and that of its aphelion, are pretty well known. We suppose likewise that the eccentricity is nearly known, and the place of the aphelion. (For the method of finding the former when entirely unknown, see EXCENTRICITY.)

The three observations should be reduced to the plane of the orbit and not to the ecliptic: it should be remarked that astronomers always publish their observed longitudes reduced to the ecliptic; in this case, therefore, a reduction is necessary, to have the place of the planet in its own orbit.

These three longitudes, which are destined to determine the three principal elements of the orbit, should be connected by all the known inequalities arising from the attractions of the other planets, and likewise for aberration, which always augments the longitudes of the planets in their oppositions.

This method may be divided into three parts. In the first we will suppose the eccentricity known, and that we wish to find the place of the aphelion; in the second, we change the eccentricity, and deduce a new place of the aphelion; and in the third we investigate, by means of a third observation, which of the two eccentricities ought to be preferred.

The time of the revolution of the planet being supposed known, we have exactly the number of degrees of mean anomaly between the observations, for the mean anomaly is always exactly proportionate to the time.

But though we may always know the sum or the difference of two mean anomalies, or two mean distances from the apside, one taken on one side and the other on the other, it is not so with these anomalies taken separately, for to determine these two, we should know both the place of the aphelion, which is the point from which they are reckoned, and the mean place of the planet: but the observation gives only the true place; the eccentricity must therefore be known, which serves to find the mean anomaly, the true anomaly being given.

This consideration affords a method of discovering by two observations if the place of the aphelion of a planet, as found in the tables, is exact, supposing the eccentricity known, for having two observed longitudes, we have (by subtracting the place of the aphelion) two supposed true anomalies, and must then compute the mean anomaly with the eccentricity supposed known, by the two following proportions.

1. The square root of the distance from the perihelion is to the square root of the distance from the aphelion, as the tangent of half the true anomaly to the tangent of half the excentric anomaly.

2. The difference between the excentric anomaly and the mean anomaly is equal to the product of the eccentricity by the sine of the excentric anomaly.

If these two mean anomalies differ from each other as much as the interval requires, they are exact, and consequently the supposed place of the aphelion correct.

If the two supposed true anomalies do not give the same mean anomaly as they ought to do, that is, if they do not give the same interval of time which is derived from observation, it is a proof that they are not correct, and this trial will indicate that the place of the aphelion, taken from the tables, or by conjecture, is not exact. In this case we must make

another supposition, giving to the place of the aphelion a few minutes more or less, and recommencing the same calculation, and we shall find by the result of the second supposition what quantity should really be adopted, and what the place of the aphelion is, which must be adopted to represent the interval of the two first observations (with the known eccentricity or that employed in the first hypothesis.)

By *first hypothesis* we mean, a supposed eccentricity, with such a corresponding place of the aphelion as accords with the interval between the two observations. To arrive at this hypothesis it was necessary to take several suppositions for the place of the aphelion.

If the place of the aphelion, found by the first hypothesis, was exactly determined, it is a proof that the eccentricity was rightly assumed; for to convert true anomaly into mean anomaly the eccentricity is employed as in the rules given above.

If we suppose another eccentricity, and repeat the same computation, we shall have for the second hypothesis a different result for the place of the aphelion, employing always the same observations; in this manner we may make a table of different eccentricities, and on the side of every one write the place of the aphelion, which corresponds to each hypothesis of eccentricity.

To determine now, which is the true eccentricity that should be chosen, we employ the third observation, which is distant about 90° from the other two; on which the following remark should previously be made. The interval of time between the aphelion observation, and that 90° on either side being known, the difference between the two mean anomalies is known; but if a mistake has been committed in the eccentricity, or what is the same thing, in the equation of the centre, all the error will fall upon the anomaly, which is 90° from the aphelion, because the equation there is the greatest; and this error will be nothing in the aphelion observation, where the equation of the centre is nothing, or at least very small. Thus, the difference between the mean anomaly near the aphelion and the mean anomaly at 90° distance, will be affected by the whole of the error committed in the equation of the centre. It may be seen, therefore, by this difference of anomaly, what equation should be employed to make the difference of anomaly equal to that computed from the elapsed time between the two observations, and thus the equation will be determined.

We are to take, then, the eccentricity of the first hypothesis with the known place of the aphelion, as determined for this first eccentricity; we then form two true anomalies, and two true longitudes of which, one is sufficiently distant from the other for the equation to be as different as possible. These are to be converted into mean anomalies, and if the difference of these mean anomalies is exactly that which it should be, the hypothesis is exact, and no farther calculation is required; but it is hardly possible to succeed the first time in assuming the true eccentricity. We choose then another eccentricity, with the place of the aphelion answering to it, that is to say, the *second hypothesis*; we then examine which agrees best with the given interval, and by the rule of proportion, we find a third, which will exactly answer to the interval, or to the known difference of mean anomaly between the two observations. By another proportion we find, what is the longitude of the corresponding aphelion. This eccentricity and aphelion will correspond to the three observations, and thus the problem will be solved.

Example.—Suppose three oppositions of Mars observed in 1743, 1751, and 1753, which give the longitudes of Mars upon his orbit as seen from the sun, for mean time as follows,

applying to the three longitudes on the ecliptic the reductions — 17", — 50", + 13".

Mean time of observation.	Long. in orbit.	Diff. of mean Anom.
1743, 15th Feb. 10 ^h 17' 40"	4 ^h 27' 16" 15"	
1751, 14th Sep. 8 23 0	11 21 34 10	6 ^h 21' 30" 44".4
1753, 16th Nov. 10 28 33	1 24 47 37 1 26 6 50.6	

The places of the aphelion, taken from Halley's tables, are 5^h 1^o 23' 37", 5^h 1^o 33' 37", 5^h 1^o 36' 0", from which are derived three true anomalies, 11^h 25^o 52' 38", 6^h 20^o 0' 33", 8^h 23^o 11' 28". Convert the two first into mean anomalies, supposing the two following hypotheses for the excentricity, supposing it first 1417 parts, and next 1427, the mean distance of the sun from the earth being always supposed equal to 10,000 parts.

First Hypothesis.—Take the excentricity 1417 according to the tables of Halley; the mean distance of Mars to the sun being 15236.9 reduced to that, which it would be if the mean distance of Mars was unity, and take likewise the aphelion such as it is in the tables; this forms the first supposition, the two true anomalies give these two mean anomalies, 11^h 25^o 3' 15".1, 6^h 16^o 35' 21".6, the difference is too great by 3' 22".2, for, according to the time elapsed between the two observations, it should only be 6^h 21^o 30' 44".4 according to the tables of Halley.

In continuing the same hypothesis of excentricity, make another supposition for the aphelion, by increasing by 10' the place of the aphelion employed in the first supposition. This gives two true anomalies less by 10' than the former ones. These converted into mean anomalies, are 11^h 24^o 51' 15".5, and 6^h 16^o 27' 0".8, the difference is 6^h 21^o 35' 45".3, that is, too great by 5' 1".

Thus by changing the aphelion 10', the error, which was 1' 22".2, becomes 5' 1", that is, has augmented 3' 38".8. Make this proportion,

$$3' 38".8 : 10' :: 1' 22".2 : 3' 45".$$

To render therefore this error nothing, we must diminish the place of the aphelion 3' 45", instead of augmenting it 10'.

By this calculation, we are assured that the excentricity, taken from the tables and employed in this first hypothesis with the aphelion diminished 3' 45", will satisfy the interval of the two observations.

We have now to repeat the same operation with another excentricity.

Second Hypothesis.—Take the excentricity 1427 greater than that of Halley by 10 parts, supposing the greater axis to remain the same, and the aphelion as it is found in the same tables. Convert the two true anomalies into mean anomalies, which give 11^h 25^o 2' 52".6, and 6^h 16^o 34' 0".2; whose difference, 6^h 21^o 31' 7".6, is greater by 23".2 than the truth. Make a second supposition, by augmenting the place of the aphelion 10', and there will result two other true anomalies, 11^h 24^o 50' 52".2, and 6^h 16^o 25' 40".1, whose difference is too great by 4' 3".5.

Thus by augmenting the place of the aphelion 10' in this second hypothesis of excentricity, the error, which was 23".2, becomes 4' 3".5, that is, has increased 3' 40".3. To diminish it, therefore, 23".2, or to reduce it to nothing, make this proportion 3' 40".3 : 10' :: 23".2 : 1' 3".2, which quantity, taken from the place of the aphelion of the tables, will reconcile this second hypothesis with the interval between the two observations.

The aphelion, therefore, of the tables diminished by 3' 45"

for 1417 excentricity, or diminished by 1' 3".2 with 1427, satisfies the two first observations. It remains now, by means of the third observation, to determine which of these two hypotheses is nearest the truth, and to determine such an excentricity and place of aphelion as shall represent the three observations.

The interval of time between the second and third observation gives for the difference of mean anomaly 56^h 6' 50".6 according to the tables. Convert the true anomalies into mean anomalies in the second and third observation, with 1417 excentricity, the aphelion of the tables being diminished 3' 45", and next with 1427 of excentricity, the aphelion being diminished 1' 3".2. The mean anomaly for the third observation will be, in the first hypothesis, 8^h 12^o 46' 17".8, and in the second 8^h 12^o 39' 17".8. Thus between the mean anomalies of the second and third observations in the first hypothesis, the difference is greater by 57".7 than 56^h 6' 50".6; and in the second hypothesis the difference is too little by 2' 25".8. Adding together these two differences, which are in contrary directions, it will appear that a change of 10' in the excentricity produces 3' 23".5 of variation in the motion of the mean anomaly for this interval of time, and by the same proportion it will be found, that 57".7, which is the error of the first hypothesis, gives 2".84. We must, therefore, add 2' 84" to 1417, the excentricity of the first hypothesis, which will give 1419.84 for the excentricity, which will represent equally the third observation, provided it is combined with a suitable aphelion.

To correct the place of the aphelion,

$$3' 23".5 : 2' 41".8 :: 57".7 : 45".5.$$

For since the first hypothesis of excentricity 1417, with the place of the aphelion, diminished by 3' 45", gave 57".7 too much, and the second hypothesis of 1427, with the place of the aphelion, diminished by 1' 3".2 (that is, by 2' 41".8 less than in the first case), gave 2' 25".8 too small, so as to change the error 3' 23".5, it follows, that to correct the 57".7 of the first hypothesis, it will be requisite to diminish the aphelion by a quantity less by 45".5 than in the first hypothesis, in which the correction was taken 3' 45", the difference is 2' 59".5, and it is this quantity which must be taken from the aphelion of the tables.

It may now be shewn, in the first place, that this excentricity, 1419.84, with the place of the aphelion diminished by 2' 59".5, will represent the first interval. For we have found that 1417 of excentricity with 3' 45" of diminution in the place of the aphelion, or 1427 of excentricity, with 1' 3" of diminution in the aphelion, represented equally the given interval or the difference of mean anomaly of the two first observations. Hence any other excentricity with a proportionate diminution of the aphelion, will represent this given interval, therefore 1419.84 of excentricity, with 2' 59".5 of diminution of the place of the aphelion, will agree with the two first observations.

In the second place, it may be proved, that this supposition will satisfy the second interval, or the mean anomaly between the second and third observations; for in the first hypothesis, 1417, we found 57".7 too much for this difference, and in the second 2' 25".8 too little, according to which proportion, 1419.84 should give the true difference, which answers to the greatest equation of 10^h 41' 19". It is not necessary in practice to carry the calculation to tenths of seconds; as the observed longitudes cannot be obtained nearer than 5".

The excentricity and place of the aphelion being found, nothing remains but to determine one mean longitude of the planet;

ELEMENTS.

planet; to have the three elements required, for this purpose, one of the three mean anomalies may be taken as found above, for example, $11^{\circ} 25' 6'' 43'' 6$, and add the place of the aphelion of the tables, diminished by $2' 59'' 5$, according to the last result, and the mean heliocentric longitude of Mars in his orbit will be $4^{\circ} 26' 27'' 21''$ for the moment of the first observation, which exceeds the tables of Halley $9''$.

The following table of the elements of the planets is taken from the last edition of La Place's "Système du Monde."

Table of the Elements of the planetary Orbits from La Place.

Duration of their several revolutions.

Mercury	87 ^d .969255	87 ^d 23 ^h 15 ^m 44 ^s
Venus	224.700817	224 16 49 11
The Earth	365.256384	1 ^y 0 6 9 8
Mars	686.979579	1 321 23 30 35.6
Jupiter	4332.602208	11 317 14 27 10.7
Saturn	10759.077213	29 174 1 51 11.2
Uranus	30689.000000	84 29 0 0 00

Semi-major axes of their orbits, or their mean distances.

Mercury	0.387100
Venus	0.723332
The Earth	1.000000
Mars	1.523693
Jupiter	5.202792
Saturn	9.549724
Uranus	19.183620

Proportion of the excentricity of the semi-major axes, for the beginning of the year 1750.

Mercury	0.205513
Venus	0.006885
The Earth	0.016814
Mars	0.093083
Jupiter	0.048077
Saturn	0.056223
Uranus	0.046683

The secular variations of this proportion, (the sign — indicates a diminution.)

Mercury	0.000003369
Venus	-0.000062905
The Earth	-0.000045572
Mars	0.000090685
Jupiter	0.000134245
Saturn	-0.000261553
Uranus	-0.000026228

The mean longitudes at the commencement of 1750. These longitudes are reckoned from the mean vernal equinox at the epoch of the 31st of December, 1749, at noon, mean time at Paris:

Mercury	281 ^o .3194	253 ^o 11' 14".8
Venus	31.4963	46 20 48.0
The Earth	311.1218	280 0 34.5
Mars	24.4219	21 58 46.9
Jupiter	4.1201	3 42 29.0
Saturn	257.0438	231 20 21.9
Uranus	353.9010	228 33 53.6

Longitudes of the perihelion at the beginning of 1750.

Mercury	81 ^o .7401	73 ^o 33' 57".9
Venus	141.9759	127 46 41.9
The Earth	309.5750	278 37 15.9

Mars	368 ^o .3005	331 ^o 28' 13".6
Jupiter	11.5012	10 21 3.8
Saturn	97.9466	88 9 6.9
Uranus	185.1262	166 36 48.8

The sidereal and secular motion of the perihelion. (The sign — indicates a retrograde motion.)

Mercury	1735 ^o .50	9' 22" 3
Venus	-699.07	3 46.4
The Earth	3671.03	19 49 6
Mars	4834.57	26 6.4
Jupiter	2030.25	10 57.8
Saturn	4967.64	26 49.5
Uranus	759.85	4 6.1

The inclination of the orbit to the ecliptic at the beginning of 1750.

Mercury	7 ^o .7778	7 ^o 00' 00"
Venus	3.7701	3 23 35
The Earth	0.0000	0 00 00
Mars	2.0556	1 51 00
Jupiter	1.4036	1 19 2
Saturn	2.7762	2 29 54
Uranus	0.8599	0 46 26

The secular variation of the inclination to the true ecliptic.

Mercury	55".09	17".50
Venus	13.80	4.47
The Earth	0.00	0.00
Mars	-4.45	-1.4
Jupiter	-67.40	-21.8
Saturn	-47.87	-15.5
Uranus	9.38	3.0

The sidereal and secular motion of the node upon the true ecliptic.

Mercury	-2332".90	12' 35".8
Venus	-5673.60	30 38.2
The Earth	0000.00	0 00.0
Mars	-7027.41	37 58.0
Jupiter	-4509.50	24 21.0
Saturn	-5781.54	31 13.2
Uranus	-1068.00	57 16.9

Longitude of the ascending node upon the ecliptic at the beginning of 1750.

Mercury	50 ^o .3836	45 ^o 20' 42".8
Venus	82.7093	74 26 18.0
The Earth	0.0000	00 00 00.0
Mars	52.0377	47 38 38.0
Jupiter	108.8062	97 55 32.0
Saturn	123.9327	111 32 21.9
Uranus	80.7015	72 37 52.8

In the history of astronomy, published in the *Connoissance des Temps* for 1809, we find the following short abstract relating to the elements of the planet Vesta.

On the 25th of April, 1807, M. Burckhardt read in the class of sciences a note, in which he gave the first sketch of the orbit of Vesta. According to the first calculations the semi-major axis, or the mean distance, would be 2.6, that is to say, rather more than twice and a half the distance of the earth from the sun; the excentricity 0.16; the place of the perihelion 248^o; that of the node 107^o; finally, the inclination 7^o.

More

More recent investigations gave him 2.36 for the semi-major axis; $25^{\circ} 20'$ for the place of the perihelion; $103^{\circ} 19' 40''$ for the place of the node; $7^{\circ} 7\frac{1}{2}'$ for the inclination; and finally, 0.093 for e 's excentricity.

While M. Borchardt was calculating the elements, which we have just given at Paris, and to bring them to perfection, was occupied in determining the perturbations, without which only approximation for a short interval can be obtained, M. Gauss lost no time in sketching the orbit of a planet to which he had given a name, and which appears to be universally adopted.

He then found for the mean longitude on the 29th of March, at midnight, mean time on the meridian of Bremen $193^{\circ} 8' 5''$; the perihelion $249^{\circ} 7' 41''$; the node $103^{\circ} 8' 39''$; the inclination $7^{\circ} 5' 50''$; the excentricity 0.097503; and finally, the mean distance 2.359604.

A second trial gave him $192^{\circ} 9' 54''$; $249^{\circ} 57' 52''$; $103^{\circ} 18' 54''$; $7^{\circ} 8' 7''$; 0.087223; and the mean diurnal tropical motion $983^{\circ}.797$.

These elements, compared with sixty-eight observations, have only shown very slight errors. We find, from the journal of M. de Zach, September 1807, that according to the new investigations of M. Gauss, these elements have undergone some slight modifications, as follow:

$192^{\circ} 23' 30''$; $249^{\circ} 50' 32''$; $103^{\circ} 18' 28''$; $7^{\circ} 8' 11''$; 0.085505; and 2.355135, with a diurnal motion of $981^{\circ}.8459$.

At the end of these elements we find, in the same work, a comparison made by M. Gauss of its second orbit, with twenty-two observations by M. Bouvard; the errors do not amount to $17''$ in right ascension; they are generally smaller in declination, except on the 21st of April, where it is evident that an error of $1'$ has crept into the Paris observations.

The following are the elements of the other new planets, Ceres, Pallas, and Juno, for the 1st of January, 1805.

	Inclination of the orbit.	Place of the ascending node.	Mean distance.	Excentricity.	Mean distance in millions of miles.	Place of the aphelion.	Mean place of the planet.
Ceres	$10^{\circ} 36'$	$9^{\circ} 21' 7''$	27670	0.170	263	$10^{\circ} 20' 2'$	$13^{\circ} 0^{\circ} 12'$
Pallas	$34^{\circ} 38' 5''$	$22^{\circ} 31'$	27630	0.600	269	$10^{\circ} 1' 3'$	$0^{\circ} 18' 13''$
Juno	$13^{\circ} 45'$	$21^{\circ} 4'$	26640	0.770	253	$7^{\circ} 23' 11''$	$11^{\circ} 12' 33''$

ELEMENTS, in *Chemistry*. It necessarily happens in every department of human science that the spirit of philosophizing or generalizing outruns the careful investigation of facts. A few prominent circumstances are first noticed, the imagination is struck with their resemblance to each other; their characteristic differences are neglected, and, as it is natural to attribute similar effects to the same operating cause, a general principle or theory is invented, and thus originates the first germ of science. The advantage of thus classifying a number of otherwise independent facts is great; the memory is assisted, the imagination is engaged, and in the attack or defence of a brilliant hypothesis the mind is more interested, and more easily induced to persevere than it would be by the gradual and laborious investigation of simple truth.

The science of chemistry, on account of its vast extent, and the number of striking analogies and resemblances that it presents, has been peculiarly fruitful in hypotheses, some of which have been partial and others general. Of the latter kind are those speculations concerning the elementary principles of substances, which occupied so much of the attention of the ancient chemists. The universe itself (and

therefore all chemical substances) was supposed to be formed of the four elements; but, without carrying the hypothetical analysis of bodies to their utmost extent, there appeared to be a number of intermediate principles to which all chemical phenomena were referred by the early investigators of this science. Thus, all inflammable substances were supposed to be compounded of a common inflammable element, called at first sulphur, and afterwards phlogiston, to which their generic characters were owing, united in different bodies to different substances, from which were derived their specific distinctions. Thus also, all salts were supposed to contain a common saline principle; and all metals a mercurial or metalline principle. Modern chemistry, however, does not acknowledge any particular number of elements, but freely admits into this class all substances that have not hitherto been decomposed. An element, therefore, in the present meaning of the term, is merely one of the last results of chemical analysis, and hence the number of elements must be continually fluctuating, according to the progressive advance of experimental science.

ELEMENT, in the science of *Elocution*, is the general name of any simple enunciation found, (see ENUNCIATION.) of which a letter may be set down as the arbitrary or visible sign. Elements differ both from the letters that represent them, and from the names of those letters, in the same respect (though not in both cases, from the same necessity) as a tree, or a man, differs both from the sound of the words, man and tree, and the forms of the letters, of which the words are respectively composed.

Part of this distinction is sufficiently obvious. No one is in any danger of supposing any resemblance between the sound presented to the ear and the picture presented to the eye. It would be well if the other not less important distinction were as strongly impressed, and a consequent practice were adopted, of associating, in the first instance, with the form of the letters, not the name of that letter, but its elemental sound: for what connection, for example, can there possibly be between the names *double you* and *tee-aitch*, and the actual sounds usually assigned to the letters W and Th? [And the same might evidently be said of the Euphion τ , Theta θ , Sigma Σ , &c. of the Greek, and of many of the letters of every known alphabet, of ancient and modern times.] And what inconvenience must not inevitably result from the awkward and impertinent intervention of the complicated names of these letters, between the arbitrary sign and actual sound, which ought to be immediately associated in the infant mind. Some judicious private teachers have of late ventured to reform, in some degree, this abuse, by keeping their pupils unacquainted with the customary names of the letters, till the association between the forms and the elementary sounds became familiar; and a laudable (though perhaps imperfect) attempt has been made by Miss Edgeworth, in her "Rational Primer," to generalize a practice so commendable. Still, however, as in all the instances that have fallen within the observation of the writer of this article, the practice of these commendable innovators has not gone so far as to give to their pupils the *naked sound* of the consonants, (which in every one of them but the three absolute mutes, it is contended, is clearly practicable,) without some portion, initial or terminative, of vowel sound. All that in reality has been effected is to give to the generality of the letters names more simple, and more approximate to the elementary sound, than those that are usually given to the alphabetic characters. It will be shewn hereafter, that something more is necessary, in order to secure all the advantages that might be derived from this innovation in the system of elementary instruction.

ELEMENTS.

Elements, like letters, (though not to the same extent,) differ in their number, in different languages; scarcely any (if any) language availing itself of all the modifications of elementary sound, which the organs of enunciation, by the nice diversities of action and position, are capable of producing. The English elements represented by V and Th, for example, being deficient in some languages, while certain guttural sounds, familiar enough, not only in some parts of the continent, but even to the Highlander and the native of North Wales, are perfectly unknown in the southern parts of England; though their signs are still preserved in our written language. See CONSONANT.

For anatomical definitions of the respective elements, see the respective titles, VOWEL, LIQUID, SEMI-LIQUID, SIBILANT, SEMI-SIBILANT, ASPIRATE, and MUTE; also, LINGUAL, LABIAL, GUTTURAL, and NASAL. The learned reader may consult, among others, upon this subject, Dionysius Halicarnassensis ("De Comp. Verb.") and Dr. John Wallis ("Grammaticæ Lingue Anglicanæ"); and the English reader will do well to read with attention the Grammar of old Ben Jonson, and, with caution, the "Analysis of Articulate Sounds," among the additional notes to Dr. Darwin's "Temple of Nature." Those who are particularly interested in the subject may also consult Dr. Holder's "Elements of Speech," Lond. 1669, a scarce, but valuable tract; and a neglected book, bearing the same title, 1773, by the late John Herries. Among these, and some other writers upon the formation or anatomy of the elements, some differences and contradictions will be found; partly, perhaps, accountable from provincial or other peculiarities in the pronunciation of the writers themselves; but, still more, from non-observance of the varieties existing in the conformation of the mouths and organs of different speakers, and the consequent necessity of corresponding differences of action and position for the formation of the same element. In the theory of the formation of several of the more difficult elements of speech, as in many other respects, he who, from an individual instance, hastily proceeds to draw general conclusions, or lay down general rules, will frequently be found to be only positive in error, while he thinks himself most luminous in the demonstration of practical truth. Mr. Thelwall who, for several years, has been practically employed both in the investigation of these topics, and in the application of his principles to the removal of every species of imperfection in human utterance, has, in his unpublished lectures, introduced a classification and series of definitions, differing in many particulars, as to the positions and actions of the organs, from those of Dr. Darwin; and ascribing to some mistakes in the theory of that celebrated physiologist a part, at least, of the impediment by which his utterance was notoriously obstructed. These definitions, not being elsewhere extant in any printed form, will be inserted in this work under the titles of their respective classes above referred to. According to the doctrines of this professor, (see a species of Elementary Horn Book prefixed to a volume of Selections, &c.) of all the letters of our alphabet, three only, t, k, and p, are to be regarded as *pure consonants*, (according to vulgar definition,) or *mute stops*. "All the others are elements of quantity, and capable of duration and tune (except s = *c siss*, ch, sh, th, and fh, which, though they have quantity, have no tune). They may, therefore, be partially sounded without the addition of any vowel; and the student is recommended to habituate himself to so found them, in the first instance; and then to write them out, in cadences, in combination with all the respective vowels with which they can enter into com-

position, both as initials and as terminatives, and to exercise himself in those combinations in the same way."

To the uninitiated there may be some difficulty in realizing this theory, with respect to some of the elements here maintained to be susceptible of independent sound: but, under proper directions, the difficulty is surmountable, and the experiment will be found practically important, not only in the removal of impediments, but in the improvement of the grace, force, and harmony of utterance.

ELEMENTS, in the *Higher Geometry*, are the infinitely small parts, or differentials, of a right line, curve, surface, or solid. Thus, (*Plate II. Analysis, fig. 27.*) the small space P M m p, formed by the two ordinates, P M, p m, infinitely near each other, and the arc M m of the curve, is the element of the space A P M, P p is the element of the abscissa A P, M m that of the curve A M, &c. See DIFFERENTIAL, FLUXION, &c.

ELEMENTS, in *Physics*, the first principles or ingredients of which all bodies are composed.

The natural operations which commonly occur within the cognizance of our senses, and in a more particular manner the analytical processes of the chemists, shew that certain ingredients, precisely of the same kind, are yielded by compound bodies of different kinds. Thus water is obtained from vegetables, from animal bodies, and from certain minerals; an earthy or unevaporable sublimance is obtained from the same bodies, and so forth. This naturally suggested the idea, that all bodies consisted of certain primitive and homogeneous substances, to which philosophers and chemists gave the name of *elements*, or *elementary bodies*. Therefore the elements are supposed to be the simplest bodies of the universe; which, whilst they themselves are not reducible into more simple components, form, by their combination in different number and various proportion, all the compound bodies that belong to the globe we inhabit.

So far the idea is natural and generally received; but the determination of the number, as well as of the nature, of these elements, has always been, and will probably long continue to be attended with great difficulty. Various opinions have been entertained, and various hypotheses have been advanced, concerning the elements; some of which have been suggested by reasoning entirely upon suppositions, whilst others have, in great measure, relied upon a firmer base; namely, the result of experiments. Of these opinions, and of these results of experimental inquiries, we shall now select the best.

Epicurus thought that all bodies were modifications of one homogeneous primary substance, whose particles were of a particular figure, solid, and in their nature unalterable; and that they only required to be arranged in this or that other manner, in order to compose the various bodies of the universe. But the constant and unalterable properties of a great number of bodies, peculiar to each and dissimilar from others, render this hypothesis highly improbable; for we find that gold, iron, mercury, &c. though dissolved, reduced, hammered, mixed, separated, and so forth, can never be converted into other bodies, but each of them may always be reduced to its original nature; that is, the iron into iron, the gold into gold, &c. which could hardly take place if the identical elementary substance formed them all.

Certain authors make a difference between elements and principles; but it is difficult to form a clear idea of their meaning. *Principle*, they say, as matter, is a kind of incomplete nature, but *element* is a perfect or complete one.

Another question has likewise been much discussed among the philosophers of antiquity: namely, whether the ele-

ments were corruptible or incorruptible; and it is difficult to conceive how the defenders of the former could possibly support a doctrine so very contradictory; for if corruptibility means a decomposition, (and it seems that no other idea can be formed of it,) a corruptible element is the same thing as a decomposable indecomposable substance. If by the word corruptibility they meant something else, we must acknowledge our ignorance of their meaning. It is farther to be remarked, that some of those philosophers admitted one corruptible element, whilst others admitted more than one. Of the former, the principal are Heraclitus, who held fire; Anaximenes, air; Thales Milesius, water; and Hesiod, earth; as the only element. Hesiod is followed by Bernardus, Telesius; and Thales, by many of the chemists.

Among those who admit several corruptible elements, the principal are the Peripatetics; who, after their master Aristotle, contend for four elements; *viz.* fire, air, water, and earth. Aristotle took the notion from Hippocrates; Hippocrates from Pythagoras; and Pythagoras from Ocellus Lucanus, who seems to be the first author of the dogma.

The Cartesians only admit three elements; which they pretend are all that could arise from the first division of matter. See *CARTESIAN Philosophy*.

Paracelsus and his followers attempted to establish four elements, which they called *salt, sulphur, earth, and mercury*. And some chemists, rejecting the last, retained only three, *viz. salt, sulphur, and mercury*; but their expressions are so very indefinite and perplexed, as by no means to convey any distinct and satisfactory idea.

The late discoveries relative to the aerial, or permanently elastic fluids, (which shewed that those fluids consist of certain bases, expanded and rendered elastic principally by their union with heat; also that heat renders ice fluid, water elastic, mercury volatile, &c.) produced a new and singular opinion respecting the elements, which was adopted by several philosophers, and particularly by the count de Tressan, in his Essay on the electric fluid. According to this doctrine, two primitive material substances are supposed to exist in nature; one that incessantly acts; and to which it is essential to be in motion; the other absolutely passive, and whose nature it is to be inert, and move entirely as directed by the former. The active principle has, by some, been supposed to be a certain fluid or element, which, according to its various modifications, they thought, produces *light, or heat, or electricity*. The other principle has not been attempted yet to be defined. We need not endeavour to give a formal refutation of this doctrine, which is evidently too indefinite and insufficient.

Our great Sir Isaac Newton, considering the primary elements of bodies on the atomic system (see *ATOMICAL Philosophy*), says, that all things duly regarded, it seems probable, that God in the beginning formed matter in solid, massive, hard, impenetrable, moveable particles, of such sizes and figures, and with such other properties, and in such proportion to space, as most conduced to the end for which he formed them; and that these primitive particles, being solids, are incomparably harder than any porous bodies compounded of them; even so very hard as never to wear out; no ordinary power being able to divide what God made one in the first creation. While the particles remain entire, they may compose bodies of one and the same nature and texture in all ages; but should they wear away, or break in pieces, the nature of things, depending on them, would be changed; water and earth, composed of old worn particles, and fragments of particles, would not be of the same nature and texture now, with water and earth composed of entire particles in the beginning. And, therefore, that things may be lat-

ing, the changes of corporeal things are to be placed only in the various separations, and new affections and notions, of those permanent particles; compound bodies being apt to break not in the midst of solid particles, but where those particles are laid together, and only touch in a few points. It seems to him likewise, that these particles have not only a *vis inertiae*, with the passive laws of motion: retarding therefrom, but are also moved by certain active principles; such as is gravity, and that which causes fermentation, and the cohesion of bodies. See *COHESION, EARTH, FERMENTATION, GRAVITY, and PRINCIPLE*.

Of all these opinions, that of the four elements, under the names of *fire, air, earth, and water*, has been more generally adopted, and has prevailed for a much longer time; until towards the latter end of the last century, Dr. Huggins, in his work upon Light, attempted to increase their number from four to seven; but the great improvements in chemistry which followed soon after, (having decidedly shewn that water and the atmospheric air are compound bodies,) produced a total change of opinion relative to the elements: in consequence of which the scientific persons of the present day acknowledge for elements not those which are suggested by their fanciful suppositions, but those which they are not able to decompose.

According to this new system, both philosophers and chemists in coalition, (for they are both inquirers into the works of nature;) rejecting the example of their predecessors, endeavour to express themselves in a manner more consonant with truth, and better authorized by the result of experiments. In the first place, they acknowledge that they are ignorant of the real number of elementary substances. Secondly, they consider as elements all those bodies which no known process has been able to decompose; that is, to reduce into simpler bodies; allowing, at the same time, that this want of actual or practical decomposition at present does not imply that a certain substance is absolutely an element; for by a new method of decomposition, that substance which has long been considered as an element, may be found to be a compound body; and, in fact, such discoveries are now frequently made. Also, certain bodies which have at one time been looked upon as distinct from each other, have afterwards been found to be of the very same nature. Therefore, under the denomination of elements we must now understand all those bodies which differ from each other in some essential property, and which have not as yet been reduced into simpler bodies.

The list, which follows, contains all the elementary bodies which were acknowledged as such soon after the commencement of the present century. We shall then add all the material alterations, which the discoveries made during the few years that have since elapsed, have necessarily introduced.

Elementary substances.

Manganefe,			

The ſix four of theſe elements may with propriety be called hypothetical. Theſe are, *light*, or that fluid which renders objects perceivable by our eyes; *caloric*, or that fluid which is ſuppoſed to produce the phenomena of heat, *viz.* to affect us with the ſenſation of heat; the *electric fluid*, which is ſuppoſed to produce the phenomena called *electric*; and the *magnetic fluid*, to which the properties of the magnet are attributed; for, in truth, the phenomena which fall under each of theſe four denominations, are only ſuppoſed to be the effects of a ſingle fluid; reſpecting the nature of which, however, various opinions are entertained. See the articles under their denominations of HEAT, LIGHT, ELECTRICITY, and MAGNETISM.

Several of the above radicals appear, in conſequence of various experiments, to be of the ſame nature; but as this cannot be made to appear without the detail of the experiments, we muſt refer the reader to the articles of their particular names.

A very great alteration has been produced reſpecting the alkalis by the recent and capital discoveries of Mr. Davy, who has found that every one of the three alkalis is a compound body. The pot-aſh conſiſts of a metallic ſubſtance, which he has called *pot-aſium*, and oxygen; the ſoda conſiſts of another metallic ſubſtance, which he has called *ſodium*, and oxygen; ſo that pot-aſh and ſoda are two metallic oxyds. Therefore in conſequence of this diſcovery, the two alkalis, *viz.* pot-aſh and ſoda, muſt be ſtruck out of the liſt, and two new metallic ſubſtances, *viz.* *ſodium* and *pot-aſium*, muſt be placed amongſt the other metals. The components of *ammonia* have not been as yet exactly aſcertained, though no doubt remains of its being a compound ſubſtance.

Some of the earths, and eſpecially the alkaline earths, as they are commonly called, have given ſtrong indications of their being compound bodies, and of a metallic nature; but we muſt refer the reader to the articles of their peculiar names for farther particulars.

A new metallic ſubſtance was lately ſaid to have been diſcovered in tungſten, and is deſcribed under the name of *cerium* by Hiſſinger. Dr. Wollſton has very lately diſcovered, that the two metallic ſubſtances *columbium*, and *tantalum*, are one and the ſame thing; ſo that one of theſe names muſt now be ſtruck out of the liſt of metals.

ELEMENTS are alſo uſed, figuratively, for the grounds and principles of arts and ſciences.

Thus we ſay, letters are the elements of ſpeech: he does not know the firſt elements of grammar.

The ELEMENTS of mathematics have been delivered by ſeveral authors in their courſes, ſyſtems, &c. The firſt work of this kind is that of Peter Herigon, in Latin and French, publiſhed in 1664, in ten tomes; wherein are contained the elements of Euclid, Euclid's Data, Apollonius Pergæus, &c. with the elements of arithmetic, algebra, trigonometry, architecture, geography, navigation, optics, ſpherics, aſtronomy, muſic, perſpective, &c. The work is remarkable for this, that, throughout, a kind of real and univerſal characters is uſed; ſo that the demonſtrations may be underſtood by ſuch as only remember the characters, without any dependence on language or words at all.

Since Herigon, the elements of the ſeveral parts of mathematics have been laid down by others, particularly the Jeſuit Schottus, in his *Curſus Mathematicus*, in 1674; Sir Jonas Moore, in his *New Syſtem of Mathematics*, in 1681; De Chales, in 1674; Ozanam, in his *Cours de Mathématique*, in 1699; and, above all, Chriſt. Wolfius, in his *Elementa Mathematicæ Univerſæ*, in two vols. 4to. the firſt publiſhed in 1713, and the ſecond in 1715; a work held in high eſtimation. There has been another edition of this excellent work publiſhed at Geneva, in five volumes in quarto; the firſt volume in 1732, the ſecond in 1733, the third in 1735, the fourth in 1738, and the fifth in 1741.

The Elements of Euclid are the firſt and beſt ſyſtem of geometry. We have abundance of editions and comments on the fifteen books of Euclid's Elements. Orontius Fincius firſt publiſhed the firſt fix books in 1530, with notes, to explain Euclid's ſenſe. The like did Peſtarius in 1557. Nic. Tartaglia made a comment on all the fifteen books about the ſame time, with the addition of ſome things of his own; and the like did Fran. Fluſtates Candalla, a noble Frenchman, in the year 1578, with conſiderable additions, as to the compariſon and inſcriptions of ſolid bodies; which work was afterwards republiſhed, with a prolix comment, by Clavius, whoſe edition has ſince been reprinted, at various places and times.

Dr. Gregory publiſhed an edition of all Euclid's works, including his Elements, in Greek and Latin, in 1703, fol. But as the whole fifteen books do not ſeem neceſſary, eſpecially for young mathematicians, ſome authors have choſen only the firſt fix, with the eleventh and twelfth at moſt. It would be endleſs to relate the ſeveral editions hereof; there is a French one of De Chales, and a Latin one of And. Tacquet; the beſt edition of the former of which is that of Paris, in 1709, by Ozanam; and of the latter, that of Cambridge, in 1703, by Mr. Whifton. Mr. T. Simpson's Elements of Geometry is an excellent compendium of this kind; and Dr. Simpson of Glasgow publiſhed, in 1756, a Latin edition of the ſix firſt, and eleventh and twelfth books of Euclid, with notes.

ELEM, or ELEM, in *Pharmacy*, a pellucid reſin, of a whitith colour, intermixed with yellowiſh particles, and often much of the colour and conſiſtence of wax; of a pretty briſk bitter, though not diſagreeable taſte; and a ſmell ſomewhat like that of fennel.

It is uſually called gum elemi, though very improperly, inasmuch as it takes fire readily enough, and diſſolves in oleaginous liquors, which are the characters of a reſin, not a gum. It totally diſſolves in rectified ſpirit of wine; and in diſtillation with water, ſixteen ounces of gum yield one ounce of eſſential oil. It flows from inciſions made in the

trunk and large branches of a large and tall tree, of the olive kind, growing in Ethiopia and Arabia Felix. It is also found in Apulia, a province in the kingdom of Naples. See AMYRIS.

Pomet in his History, and Lemery in his Dictionary of Drugs, describe elemi as a white resin, bordering on green, odoriferous, and brought from Ethiopia, in cakes of two or three pounds a-piece, and usually wrapped up in the leaves of the Indian cane.

It is excellent in diseases of the head; and is proper to digest, resolve, and suppurate. It is held a kind of natural balsam; and is sovereign in the cure of all sorts of wounds.

One of the best officinal digestives, commonly called the ointment or liniment of Arcæus, consists of six parts of the elemi, five or six of turpentine, and twelve of laud, or a mixture of laud and suet melted together.

The true gum elemi is that above described; but there are several spurious sorts, some natural, and others factitious, frequently sold for it.

The factitious, or counterfeited, is usually made of resin washed in oil of aspic: though the ill smell, and white colour of this might easily discover the fraud. The natural gums, obtruded from elemi, are,

1. A gum brought from the American islands, in eggs of different weights, covered up with the leaves of a plant unknown in Europe.

The second may be taken for common resin, but for its smell, which is somewhat sweeter, and more aromatic.

The third is of an ash colour, bordering on brown, brought over in large pieces, and very dry and friable.

Pomet does not take any of these for different genuine gums, but rather supposes them to be originally elemi, only impure, and coarse, since melted down, and made up by the fire.

ELENCHUS, in *Antiquity*, a kind of ear-rings set with large pearls.

ELENCHUS, ΕΛΥΧΟΣ, in *Logic*, by the Latins called *argumentum*, and *inquisitio*, is a vicious or fallacious argument, which deceives under the appearance of a truth; the same with what is otherwise called *sophism*.

ELEOCARPUS, in *Botany*. See ELEOCARPUS.

ELEOSACCHARUM. See ELEOSACCHARUM.

ELOSELINUM, in *Botany*, a name by which some authors have called the paludespium or smallage. Ger. Emac. Ind. 2.

ELEPHANT, in *Zoology*. See ELEPHAS.

ELEPHANT, *Elephas*, gives the denomination to an ancient and honourable military order, conferred by the kings of Denmark on none but persons of the highest quality and extraordinary merit.

It is called the "order of the Elephant," from its badge, which is an elephant with a castle on its back, set with diamonds, and hung on a watery sky-coloured ribband, like the George in England.

There are different sentiments as to the origin and institution of this order; the first is that of Mennicus and Hoepingius, who attribute it to Christian IV. who was elected king in 1584. The second, that of Selden and Imhof, who derive it from Frederic II. elected in 1542. Gregorio Leti goes back as far as Frederic I. who reigned about the year 1530. Bernard Robolledus will have king John to be the author, who began to reign about 1478. A. Helmius, Røsserus, and Loefcher, hold it to have had its rise under Christian I. father of Frederic I. Lastly, Voigtius, Becman, and Bircherodius, maintain Canutus VI. to have been the first institutor; and the occasion thereof to

have been the croisades. This prince, according to the chronology of Swainning, reigned towards the close of the twelfth century, from the year 1168 to 1191. This, at least, we are certain of, that the order was subsisting in the year 1494; there being a painting still extant, done that year by count Reindens, a knight of this order. And we have even authentic evidences of the marquis of Mantua's being created knight of the same order by Christian I. in 1474. There are bulls of pope Pius II. and Sextus IV. confirming the statutes of the order, authorizing the holding of assemblies, or chapters, in the chapel of Roschild, and settling the privileges of the knights. Edmondson says, that it was instituted in 1478 by Christian I. king of Denmark, on the marriage of his son John with Christiana, daughter of Ernest, duke of Saxony.

The order was first called the "order of St. Mary," *ordo S. Mariæ*; though it seems to have had the appellation of the Elephant as early as Christian I.: witness the figure of an elephant so often struck on his coins, medals, &c.

The manner of its institution is thus related: king Canutus having sent a fleet against the Saracens in 1189, which took Sitium and Ptolemais, a gentleman among the Danish croisades killed an elephant; in memory of which extraordinary accident the order was erected. This account is rendered the more probable by this; that it is referred to an era, when nothing was more common than to take the spoils of a vanquished enemy for armories or cognizances; and accordingly, some of the principal arms of the like kind now on foot, *e. gr.* the lions of the Low-Countries, had their rise at the time of the croisades, as is shewn by Hentertius and Hoepingius; which circumstances greatly corroborate the opinion of those who ascribe the order to king Canutus.

The collar of the order is of gold, composed of elephants and towers alternately, enameled proper: to the front of the collar is pendent an elephant, with a castle on his back, also a man, all enameled proper: and on the side of the elephant a cross of Danebrog in diamonds. The knights all wear the badge pendent to a sky-blue ribband, which passes scarfwise over the left shoulder to the right hip. See the abbot Justiniani, Hist. de tutti gli Ord. Milit. e Caval. tom. ii. cap. 72.

The chapel of Roschild was founded by Christian I. for the assemblies or chapters of this order to be held in. It was first called the "Chapel of the Three Kings," *Capella Trium Regum*; afterwards Frederick I. gave it the name of the "Royal Chapel."

The order was restored by Frederic II. who created abundance of knights at the ceremony of his coronation, which is the only time when the Danish kings made any knights of the Elephant. Christian V. augmented and enriched it very considerably. In the year 1694, a grand chapter of the order was held at Fredericburg, in the chapel of the knights, wherein six German princes were admitted into the order.

We have a multitude of writings on the subject of this order, whereof that of Janus Bircherodius may serve for all the rest; it is the latest, most ample, and learned. It was published at Copenhagen in 1705, under the title of "Brevarium Equestre, seu de illustissimo, & inclytissimo Ordine Elephantino," &c.

ELEPHANT'S BONES. Many teeth and bones of animals have been found in a fossil state, both in Siberia and on the banks of the Ohio, in North America. The French academicians, on comparing some of these with the bones of real elephants, determined, that they belonged to the false species of animal: but Dr. Hunter has discovered, on a more accurate

accurate examination, that they are very different from those of the elephant, and belong to another animal. The tusks of the true elephant have a slight lateral bend; but those brought from America have a larger twist, or spiral curve, towards the smaller end: the grinders of the latter are made like those of a carnivorous animal, being furnished with a double row of high and conic processes, as if designed to masticate and not to grind its food; whereas those of the elephant are flat, and ribbed transversely on their surface; besides, the thigh bone is of a very disproportionate thickness to that of the elephant, and has some other anatomical variations. And though the American tusks, when cut and polished by the workmen in ivory, did not differ in texture and appearance from the true ivory, Dr. Hunter concludes, that genuine ivory must be the production of two different animals, and not of the elephant alone; and that the animal to which these bones belonged may be the supposed elephant or mammoth of Siberia, and other parts of the world, which is yet unknown. Phil. Transf. vol. lviii. art. 5.

The ingenious Russian naturalist, M. Pallas, was led to conclude, from the circumstance that these bones are equally dispersed in all the northern regions of Europe, that the climate was probably, in the earlier ages, sufficiently warm to be the native countries of the elephant, rhinoceros, and other quadrupeds now found only in the south. But when, during his travels, he visited the spots where the fossil bones were found, and could form a judgment from his own observations, and not from the accounts of others, he renounced his former hypothesis, and, in conformity with the opinion of many modern philosophers, asserted that they must have been brought by the waters, and that nothing but a sudden and general inundation, such as the deluge, could have transported them from their native countries to the regions of the north. In proof of this assertion, he adds, that the bones are generally found separate, as if scattered by the waves, covered with a stratum of mud, evidently formed by the waters, and commonly intermixed with the remains of marine plants; instances of which he himself observed during his progress through Siberia, and which sufficiently prove that these regions of Asia were once overwhelmed with the sea.

Elephant caterpillar, a name given by some authors to a species of insect, commonly known in Ireland by the name of Connaught-worm, and supposed to be poisonous to cattle which feed on it. See *Connaught Worm*.

Elephant, era of the, in *Chronology*, an era among the ancient Arabs, which commenced A.D. 578, in the year when the Abessines were vanquished in their expedition against Mecca, and in which Mahomet was born. From this era the Arabs computed their time for 20 years. This was followed by another, called that of the unjust, or impious war; and this was finally succeeded by that of the Hegira.

Elephant fish. See *CHIMÆRA*.

Elephant's-foot, in *Botany*. See *Elephantopus*.

Elephant's-head, in *Botany*, a species of the *rhinanthus*, which see.

Elephant mountain, in *Geography*, a mountain on the S.E. coast of the island of Ceylon; 7½ miles S.E. of Candy.

Elephant's nose, or *elephant's nose*, as it is called by the Dutch, is a species of the *acus* or needle fish, caught in the East Indies, so named from the resemblance of its snout to the trunk of an elephant. It is a very singular species, the lower jaw running out to a very long and sharp-pointed spine: it is round-bodied, and beautifully variegated with spots, and has on each side a green line running from head

to tail. It is caught in salt waters. Ray's *Ichthyogr.* app. p. 4.

Elephant, water. See *Hippopotamus*.

Elephanta, in *Geography*, a small island situated in a large sound, about 5½ miles E. of Bombay, on the coast of Hindoostan, and acquired by the English from the Maharrattas, to whom it belonged. The circumference of the island is about five miles, and the number of its inhabitants, including women and children, about 200, who inhabit a neat village near the landing place; they are employed in cultivating rice and rearing goats for their support; they are under our protection, and pay about 56*l.* annually to the government: the surplus revenue furnishes their simple clothing. Their ancestors, as they say, being improperly treated by the Portuguese, fled hither from the opposite island of Salsette. Its proper name is "Gali Pouri," but the Europeans call it Elephanta, from the statue of an elephant formed of black stone, which stands in this island, in the open plain, near the shore. This island is famous for its subterraneous temple, formed in a hill of stone, about ¾ of a mile from the beach, of which M. Niebuhr made drawings, and which he has particularly described. It is 120 feet long, and the same in breadth, exclusively of the chapels and adjacent chambers. Its height within is nearly 15 feet, and the whole of it is situated in a hill of considerable height, cut out in the solid rock. The pillars supporting the roof are also parts of the rock, which have been left standing by the architect. The walls are ornamented with figures in bas-relief, so prominent that they are joined to the rock only by the back. Many of these figures are of a colossal size, being some 10, some 12, and some even 14 feet high. Although these bas-reliefs cannot be compared, either in design or in execution, with the works of the Grecian sculptors, they are much superior in elegance to the remains of the ancient Egyptian sculpture; and they are finer than those from the ruins of Persepolis. These figures, probably, mark events relating to the mythology and fabulous history of the Indians, for they seem to be representations of gods and heroes. The modern Indians are so ignorant, that they can give no information concerning these curious remains of antiquity. One person, who pretended to be wiser than the rest, assured M. Niebuhr, that one of the largest statues was that of Kaun, one of their ancient fabulous princes, notorious for the cruelties which he perpetrated upon his sister's children. The statue is well-formed, and has eight arms, an emblem of power, which the Indians give to their allegorical figures. None of these figures have beards, but all of them have very scanty whiskers. At present all the young Indians wear whiskers, and as they become more advanced in life, they commonly allow the whole beard to grow. The lips of these figures are thick, and their ears are lengthened out by large pendants; ornaments which almost all wear. Several of them wear a small cord in the fashion of a scarf; a mode now prevalent among the Bramins. One woman has but a single breast; from which it should seem, that the story of the Amazons was not unknown to the old Indians. Several figures, as well masculine as feminine, have one arm leaning on the head of a male or female dwarf, whence we may infer, that these monsters of the human species have been always objects of luxury and magnificence among the great. Several figures have hair on their heads, not of native growth, but resembling a wig, whence we may conclude that this covering for the head is of very ancient invention. The female bosom is perfectly round, which intimates, that the Indian fashion of wearing thin wooden cases

upon the breasts is very ancient. The head-dresses of these female figures is commonly an high-crowned bonnet. Several are naked; the dresses of others more nearly resembles that of the moderns. In several parts of these bas-reliefs appears the famous Cobra de Capello, a sort of serpent, which the human figures treat with great familiarity. These serpents are still very common in the isle of Elephanta, and the inhabitants say that they are friendly to man, and do no harm unless provoked: their bite, however, is reckoned mortal. On each side of the temple is a chapel nine feet high; and the walls of these chapels are covered with bas-relief figures, on a smaller scale than those upon the walls of the temple. The smallest of the chapels, having no sculptured figure but that of the god "Cannis," is still in a state of neat preservation; and the inhabitants repair hitherto to perform their devotions. Before the entrance into this chapel is a pile of shapels stones, bedaubed with red paint, supposed to be representations of the new objects of worship adored by the Indians. Such red stones are not uncommon in other parts of India, and are held in high veneration. The rest of the temple is now become the haunt of serpents and beasts of prey. On a hill at a small distance is another temple; but it is not easy of access. In India are other temples of a similar kind. (See SALSETTE.) As the Greeks, and perhaps also the Egyptians, drew the first elements of their knowledge from India, these monuments of Indian antiquity deserve particular examination; as it might serve to throw new light on those opinions and modes of worship, which were by degrees diffused through other parts of the East, and at last into Europe.

Mr. Goldingham, in the fourth volume of the "Asiatic Researches," has given a particular description of the cave of Elephanta, and of the figures which it exhibits. He estimates the length of the great cave at 135 feet, and its breadth at nearly the same dimensions. The whole information which he could obtain from the inhabitants was, that they conceived it to have been formed by the gods. Some have, without sufficient authority, deduced its origin from the Egyptians, from the Jews, or from Alexander the Great; but it is much more probable that the ancestors of the Hindu race were its fabricators; and this writer is of opinion, that it was a temple dedicated principally to Siva, the destroyer or changer. Upon this principle he has endeavoured to describe the several figures, with their appropriate attributes and accompaniments. It is not so easy, says this writer, to ascertain the era of its fabrication. He has no doubt, however, that it was posterior to the great schism in the Hindu religion, which, according to the Purana, happened at a period coeval with our date of the creation. But without tracing it to this fabulous antiquity, we have accounts of powerful princes who ruled this part of the country at a later period; particularly of one who usurped the government in the 90th year of the Christian era, famed for a passion for architecture. Possibly he might have founded the cave; but no evidence occurs to support any hypothesis beyond conjecture.

ELEPHANTANA, in *Ancient Geography*, a town of the island of Sardinia. Anton. Itin.—Also, an episcopal town of Africa, in Mauritania.

ELEPHANTIASIS, in *Medicine*, *ἰσχυρισμός*, *elephantia*, a loathsome, contagious, and hitherto incurable disease, of the chronic kind; characterized by the appearance of tubercles, producing great deformity of the face and limbs, with a thickened, rough, and wrinkled state of the skin, loss of hair on the chin and body, insensibility of the extremities, ulcerations in the throat, nose, fingers, &c. and other cachectic symptoms.

An extreme degree of confusion has prevailed in the writings of physicians, with regard to this disease, in consequence of the circumstance, that the Arabians have described the same symptoms, under the denomination of *lepra*, or *leprosy*, to which the Greek physicians had assigned the appellation of *elephantiasis*; whence the term *leprosy* has been indiscriminately applied to both diseases. But, in our inquiries concerning the nature of leprosy, we should constantly bear in mind, that the leprosy of the Greeks (*lepra Græcorum*) and the Arabian leprosy (*lepra Arabum*) are altogether different in nature; and that the leprosy of the Arabians is the elephantiasis of the Greeks. The *leprosy*, properly so called, as described by the best Greek writers, is a disease of the skin only, and much less formidable than the elephantiasis; Hippocrates speaks of the former as an affection merely superficial, and to be ranked among the blemishes, rather than among the diseases of the body; (lib. π. π. π. π.) and Galen, (De tumorib. præter nat. cap. 13.) Aetnarius, and Paulus Ægineta, make similar observations. The Arabians have described the different varieties of the leprosy (*lepra Græcorum*) under the generic terms of *morphea* and *albura*, with the specific titles *alba* and *nigra* white and black. See LEPROSY.

What has contributed still further to augment the confusion, in which these diseases have been involved, is, that most of the Arabians have also described a disease, under the title of *elephantiasis*, which is altogether different from both the lepra and elephantiasis of the Greeks, and which does not appear to have been known to the latter. This is a mere enlargement, or thickening of the legs, with a change of the colour and texture of the skin, producing a resemblance, it is said, to the leg of the elephant: it is compared, in its nature and origin, to the enlargement from varicose veins; and was probably similar to the thick leg of Barbadoes, or, in some instances, a symptom of leucy. Thus Avicenna, in his chapter "De Elephantia," observes, that it consists of "an intumescence of the feet, similar to what occurs in the varix of the veins: sometimes, and indeed most frequently, it arises from a melancholic humour, and sometimes from a thick phlegm, and occasionally also from the same causes, which render the veins varicose; it is at first red, and afterwards black; and is relieved by the same circumstances which relieve the varices." (Avicenn. lib. iii. Fen. xxii. Tract. i. cap. 16.) Thus also Rhazis writes respecting the *elephantia*; "est cum pedis crassities augeri videtur, et color obscurat, venæ quoque vites vocatur apparere experint." (Ad Almanfor, lib. ix. cap. 93.) And Avenzoar asserts simply, that "a prænatural swelling happens in the legs, which is called *elephantia*, and this on account of its resemblance in thickness to the legs of the elephant." (Lib. ii. cap. 26.) It ought not here to be omitted, however, that Haly Abbas stands alone among the Arabian writers, upon this subject, in point of correctness; for, under the term *elephantia*, both in his description of the symptom and his observations on the practical treatment of the disease, he has in view the proper elephantiasis of the Greeks; (see his works, Theoricæ, lib. viii. cap. 15. and Practicæ, cap. 4.) and he treats of the leprosy of the Greeks under the head lepra. But he also describes the thick leg, distinguishing it (or at least his translator has so done) by the term *elephas*.

"Quæ vero in cruribus et pedibus sunt *elephas* vocatur, et quæ dicuntur varices venæ. Et elephantius morbus apostema est melancholicum quod in cruribus fit et pedibus; et ejus signum est, quod pedis figura figuræ elephantis similis fit, aqualis, et non diversa." (Theoricæ, lib. viii. cap. 18.) We know not the original terms here employed, but if the translation be correct, the intended distinction is obvious.

ELEPHANTIASIS.

For after noticing the ulcerations of the face and nose, belonging to elephantiasis, properly so called, he says, "but the disorder which takes place in the legs and feet is called *elephas*, (the elephant:)" and he also terms it the "elephant-like disease" (*elephantinus morbus*.) This distinction has been noticed by Sennertus, as a contradiction on the part of Haly Abbas; (see Sen. Opera lib. v. part 1. cap. 45.) where it is obvious that the distinction of the terms, employed by the Arabian, is overlooked. The difference between the leprosy of the Greek and Arabian writers has been so often pointed out by the learned, that it is remarkable how the confusion of the two diseases should have so often prevailed. (See Fuchsi Praxis Medice, lib. ii. cap. 16. Gregor. Horst. Obs. Med. lib. vii. obs. xviii. Epist. Hopenero. Turner, on Dis. of the Skin. chap. i. where part of the epistle of Horstius is translated. Sennertus, loc. cit. cap. 40.)

The elephantiasis of the Greek writers, then, and of Haly Abbas, (as distinct from the *elephas* of that writer) is the subject of our consideration at present. The origin of the name is differently explained by different authors. The Arabians seem to have misapplied the term, from a supposition that it referred alone to a similarity in shape, colour, and other qualities of the skin, in the disease, to that of the elephant; but it appears to have been adopted from a more general analogy of the magnitude and severity of the disease, with the size of the animal. "Est enim visu scedus," says Aretæus, "et in omnibus terribilibus, quemadmodum et *elephas bellua*;" and Aëtius observes, "elephantia quidem ex magnitudine et dæmonitate affectionis nomen accepit." It has been translated, too, by the poet,

"Est lepræ species, elephantiasisque vocatur,
 Quæ cunctis morbis major esse videtur,
 Ut major cunctis *elephas* animantibus exstat."
 Macer, de Virib. herbarum.

Upon the same principle, Aretæus observes, that it has been called the "Herculean disease;" since no disease is more powerful or more fatal. "Magnus quidem potentia morbus; ad mortem enim inferendam est omnium longe siccissimus." Other peculiarities of the disease have given rise to other denominations, to which the Greek writers allude. Thus it was also called *satyriasis* and *satyriasmus*, partly on account of the change of the features, which often occurred, and rendered the countenance somewhat like that given by painters to the Satyr; and partly from the excessive libidinous disposition which accompanied the disease. (See Aëtius.) The lips, according to Galen, become thick, the nose swells laterally, and therefore appears to be depressed, the ears grow thick, the cheeks red, and tumours arise here and there upon the forehead, somewhat resembling horns. (De tumorib. cap. 14.) And Aëtius observes, that, as if by a sort of spasmodic distention of the muscles of the jaws, the face is dilated, and assumes the appearance of laughter, as in the Satyr. Another condition of the countenance, under this disease, gained it the appellation of *leontiasis*, or *leo*, the lion, or lion-face. Aëtius and Aretæus attribute this name to the laxity and wrinkles of the skin of the forehead, which resembles the flexible eye-brows of the lion. But the Arabian writers ascribe it to a different source. Haly Abbas says, the countenance was called *leonine*, because the white of the eyes becomes livid, and the eyes of a round figure; and Avicenna observes, that the term *leonine* was applied to the disease, because it renders the countenance terrible to look at, and somewhat of the form of the lion's visage.

Symptoms of the Elephantiasis.—The symptoms of this in-

curable disease, which is said to be not only most grievous to the individual who suffers it, but intolerable to bystanders, so that even the domestics and attendants of the patient are averse to intercourse with him, are detailed by Aëtius and Aretæus in nearly similar terms. Both these writers lament, that the incipient symptoms are not observable: there is no unusual derangement of the constitution, no obvious external change, which, being seen at once, might suggest a timely application of medicine: the disease preys for a long time unobserved on the constitution, and when its first symptoms begin to shew themselves externally, the malady is not then commencing, but is completely established, and the condition of the patient is hopeless. When the disease is about to appear, the person becomes sluggish and inactive, and is sleepy after slight exertions, the bowels are colic, but the appetite remains unchanged. These symptoms, however, are not very unfrequent in ordinary health. The first external marks of the disease generally appear in the face: the cheeks and chin become thickened and red, but of a livid, not a florid hue: pustular tumours arise, sometimes with a white top, and livid base; and the veins under the tongue become varicose and black. The breathing is now slower and more difficult, the breath fetid, the sluggishness and inability of exertion increase, the appetite is but little altered, but continual eruptions occur, which are offensive even to the patient, the urine is thick, like that of cattle, the bowels extremely constipated, and the venereal appetite great. The hair begins to fall off from every part of the body. From the pubes, the eye-brows, and the chin, and the hair of the head is thinned, and the scalp becomes rough, and chopped, with deep fissures. The pulse is small, slow, feeble, "as if moving through mud." The whole skin becomes thickened and rough, and small livid tubercles appear, more particularly on the face, on the nose, and about the ears: the nose swells and dilates, the lips grow thick and prominent, and livid; and the ears enlarge, and become red with a mixture of blackness, and ulcers form about their base; the eye-brows grow prominent, thick, smooth, and pendulous from their gravity, and of a livid or black colour; the eyes of a dark or brazen hue. This condition of the countenance, which somewhat resembles the visage of the lion, gave origin to the name *leontiasis*. The teeth become black; the voice hoarse, and obscure. At length similar pustules and tubercles appear in the extremities, and every other part of the body; much itching is sometimes occasioned, and scratching affords some relief; many thick and rough *rugæ* are also formed over the whole skin, with deep fissures, which extend, in the feet, from the heel to the middle of the toes. As the disease increases the tumours of the cheeks and chin, of the toes and legs, ulcerate, and the ulcers discharge a fetid sanies, and do not heal; but new ones appear one after another, and extend, until the nose, the toes, fingers, and even the hands and feet fall off. But even this degree of disease, says Aretæus, does not liberate the sufferer from his severe calamity and miserable life, although dismembered limb by limb: for the disease, like the animal from which it derives its name, is characterized by longevity. Yet for weak and pusillanimous does the patient become, that he still clings to life, although he avoids the sight of friends, and receives no enjoyment whatever. The appetite for food is not greatly diminished, but the sense of taste is lost, and neither food nor drink afford him any gratification: an insufferable languor and an unusual sense of weight in the limbs oppresses him, but the sense of feeling in every part of the body is nearly lost; rabiosa inest libido; yet every thing is without pleasure; eating and fasting, motion and rest, cleanliness and filth, are equally indifferent to him. The difficulty of breathing becomes extremely great, amounting

ELEPHANTIASIS.

amounting to a sense of suffocation, as if the patient were strangled: and in this way life is frequently terminated. (See Aretaei de Caus. et Signis Morb. dictum. lib. ii. cap. 13. Aëtiï Terribil. iv. Serm. i. cap. 120.)

The ancients all agree in considering the elephantiasis as a cancer of the whole body, as well as in attributing it to the generation of a melancholic humour, or black bile, of great malignity, which contaminates the whole of the blood, and is diffused throughout the habit. They enumerate various exciting causes of this morbid condition of the body. Among these the use of strong, viscid, and indigestible food is much insisted upon; especially the use of salted meats, of fish, and of *affis' stibis*, from which a thick and sluggish blood was supposed to be generated. Climate is also said, together with this sort of diet, to influence the production of the disease: whence Galen accounts for the frequent occurrence of elephantiasis at Alexandria, where the atmosphere is hot, and often loaded with vapours. Hence also Lucretius observes,

“Elt elephas morbus, qui propter flumina Nilii
Gignitur Ægypto in media, neque præterea ulquam.”

Lib. 6.

Though this assertion of the poet be not strictly true, yet the disease appears to have originated chiefly in warm climates. Pliny considered the elephantiasis as peculiar to Egypt, and observes that it was not brought into Italy until the time of Pompey. (Nat. Hist. lib. xxvi. cap. 1.) And Celsus remarks, that it was but little known in Italy in his time. (De Med. lib. iii. cap. 15.) In later ages it has occurred to a great extent in the south of Europe; and is mentioned by travellers as still existing there as well as in Arabia, Abyssinia, and the adjoining regions: it also occurs in the West-Indies, as we shall have occasion to mention more at large below.

Contagion is another source to which elephantiasis is attributed. It is not to be doubted that contact with the diseased will excite elephantiasis, as in other chronic diseases, in which a morbid poison is generated; accordingly the disorder is mentioned as being frequently communicated by cohabitation, either from an infected female to a sound man, or the contrary, or by the common intercourse of life. In the last case it has been supposed to be communicated by effluvia, as in acute diseases, and the air, in which the patient breathes, is said to be contaminated. (Avicenna, &c.) But, this seems questionable, both because it is inconsistent with the general analogy, and because the contagion does not appear to have been so virulent, or to have extended itself with the same activity, as is observed in contagious diseases in general, which infect at a distance. The disease has been also observed to be hereditary; which has been attributed to the contamination of the feminal fluids, by which the fœtus was engendered in disease. (Haly Abbas, &c.) But, like other hereditary diseases, or, more properly speaking, like other diseases, to which there is a connate predisposition in certain individuals, the elephantiasis is said to have lain dormant for one or more generations, and to have re-appeared in the succeeding ones.

Too much exercise, as well as too much indolence, is said by Aëtius to induce elephantiasis, by contributing, as he supposes, to thicken the blood. A thickened and viscid condition of the humours, indeed, is a leading supposition in the pathology of the ancients in respect to this disease; and a dry and corrupt condition of the liver and spleen is assigned as the principal source of this humoral corruption. Hence castration has been seriously proposed, as a remedy, by which the habit might be rendered more moist and ei-

feminate, and its humidity retained. The author, just quoted, observes, that males are more liable to the disease than females, and those especially about the age of puberty.

With regard to the cure of elephantiasis, it is admitted universally by the Greek, Latin, and Arabian writers, that the disease is incurable, except in the very commencement, when its approach can scarcely even be suspected. Numerous expedients were practiced, however, with a view to relieve it. For although we may stretch our hand to the miserable sufferers in vain, says Aëtius, to leave them unaided were an act of despair and cruelty. “Humanum enim et pœnium benevolentia signum est, in extremis etiam malis ulque ad experimentum procedere, ad difficultatem afflictionis competendam.”

Moderate blood letting from the arm is recommended to be first employed, and, after a few days, purging, by means of glysters, and colocynth. The whey of milk, and asses' milk, with other light diet, is then to be taken; and then purging and vomiting, at intervals, by means of the black hellebore, and scammony, &c. (See Aëtius, loc. citat. cap. 122.) The same writer occupies several chapters in the enumeration of pills, and other internal medicines, proper to be administered; and of liniments and other substances for external application, among which the dung of goats, and other animals, was often recommended. Alun, sulphur, nitre, vinegar, pepper, iris, &c. &c. were the remedies chiefly depended upon, externally. The ashes of burnt twigs, mixed with the fat of beasts, as of the lion, panther, &c., were also prescribed, as liniments. (See Aretaei de Curat. Morb. dictum, lib. ii. cap. 13.) The flesh of the viper was generally recommended as a remedy for the elephantiasis. Aëtius calls it “mirabilis elephantiasis remedium;” and it is said by Aretæus to have been discovered to possess those remedial powers by accident; an infected person, exposed in a wilderness, having, either from hunger, or from a wish to get rid of life, eaten a viper alive, and afterwards recovered. Galen, and many succeeding writers, have recommended the use of vipers, prepared in various ways, as beneficial in lepra, elephantiasis, and other diseases of the skin. But ample experience has proved the inefficacy of this medicine. (See Palmarus de Morb. Contag.) Dr. Willan justly remarks, that we cannot but distrust the accounts of the writers, who have more lately recommended the flesh of vipers, “when we read in them at the same time, that equal advantages accrue to the patient from living on pullets fed with vipers' flesh.” (On Cutaneous Diseases. Part ii. Gen. Lepra. p. 142.)

Such is the account of the loathsome and fatal disorder, the elephantiasis, and the means of cure usually resorted to, as recorded by the ancients. In the later periods of European history, especially in the twelfth and thirteenth centuries, the same disease seems to have prevailed most extensively throughout Christendom, more particularly in the south of Europe; it was not, however, altogether confined to the warmer countries, since it was prevalent in England. It was generally denominated *leprosis*; and from the numerous ulcerations, which were among its symptoms, it was also called *Morbis Sti. Lazari*, the disease of St. Lazarus; and many hospitals, or lazarettos, were erected for this disease alone. According to Matt. Paris there were 2000 of these lazarettos in France, and 19,000 in Europe, in the thirteenth century. (Hist. Engl. ad. ann. 1244.) There were several at the same time in England; the principal or head of these was in Leicestershire; but it is said, that the city of Norwich alone contained five. But of this subject we shall treat more at large under the head of *LEPROSY*. The venereal disease, for some time after it was first observed, in 1493,

was

ELEPHANTIASIS.

was considered as a variety of the elephantiasis, or of the Yaws; and it is conjectured by some writers to have sprung from that source; as the leprosy is said to have gradually disappeared, while Syphilis was disseminated. See Sprengel. *Hist. of Medicine* (Geschichte der Artzneykunde) vol. ii. p. 660.

The elephantiasis seems to be at present nearly extinct in Europe. In the year 1755, a hospital, called St. Lazare, which had been established from time immemorial, is mentioned as existing at Le Martiques, a small town in Provence, in which persons attacked with the leprosy were shut up. The disease, as it occurred at that place and period, is said to have commenced with an elastic swelling in the legs, with insensibility of the skin, gradually extending from the toes to the knee; after which the veins became varicose, the skin hard and scaly, and then tuberculated. All these symptoms then appeared on the face, where the skin grew thick, forming large wrinkles full of scirrhous tubercles, "which make the poor wretches look frightful." The skin, especially about the joints, is next affected in the same way. The patients continued in this condition, with little suffering, for years; the voice then became hoarse, corroding ulcers of the palate, and throat, and internal parts of the nose, ensued, with fetid breath, carious teeth, and a livid hue of the face. The scirrhous tubercles then ulcerated, the bones beneath became carious, and in a few cases the poor creatures lost their fingers and toes. They became hectic, and fell into marasmus, when the smell of their perspiration was intolerable, and "at length after about three or four years of suffering," they died. (See a letter from Dr. Joannis of Aix, in the *Med. Obs. and Inquiries*, vol. i. p. 201.) The great propensity to venery was strongly exemplified in that hospital; and the hereditary nature of the disease, to the fourth generation, (when it seemed to wear out) was also observed. It was remarked too, "that the husband rarely communicates the disease to his wife, born of healthy parents, though she may bring into the world children that in time die of leprosy;" which also concurs with the statements of the ancients. There is at present a lazaretto, near Funchall, in the island of Madeira, in which there were ten patients, labouring under elephantiasis, in the year 1803, according to Dr. Adams. We shall speak of the disease, as it was observed in that hospital, presently.

In the warmer climates, the elephantiasis has been observed, and frequently described by physicians and travellers, during the last (18th) century. Niebuhr has given an imperfect description of a malignant species of leprosy, which was prevalent in Arabia and Persia, at the time of his journey into those countries, and which the natives denominate *Djudsdam*, and *Madjuddam*; but it would appear to be a less severe malady than the elephantiasis, or lepra of the Arabian writers. At Bagdat there were several barracks, in one quarter of the town, into which all the leprosy patients were compelled to retire by the magistrate; but they were allowed to go out every Friday, to beg alms in the markets. It is said, he remarks, tous renfermés qu'ils sont, ils continuent leurs amours; and he mentions the circumstance of a man, shut up in the barrack, who contrived to infect a female, for whom he had a violent desire, by means of linen, and then obtained an order for her imprisonment in the same place. (See *Description de l'Arabie*, tom. iii. p. 119.) Bruce has also described the elephantiasis as he observed it in Abyssinia, which, however, seems to have been principally confined to the legs, and to resemble the *elephas* of Haly Abbas, rather than the true elephantiasis. (*Travels*, book v. chap. 2.)

The importation of this horrible malady into the West
VOL. XII.

Indies, from Africa, appears to have been one of the punishments, which that abominable traffic, the slave trade, has inflicted upon the inhabitants. The symptoms of the disease, as detailed by Dr. Hillary, under the title of leprosy of the Arabians, in his account of the diseases of Barbadoes, accord so accurately with the description given by the ancients, that his history appears more like a transcript of the chapter of Aretæus, or Aëtius, than a record of the observations of a modern inquirer, in another climate. Dr. Hillary describes two forms of the disease, which were also noticed by Haly Abbas, (exclusive of the thick leg, or *elephas*;) in one of which the limbs fall off from the joints; but in the other, the ulcerations go on without this effect. The former Dr. H. calls the "leprosy of the joints." (*Observations on the Air and Diseases of the Island of Barbadoes*, p. 322, & 335.—2d edit.)

Dr. Hillary, however, has described another disease, which is endemic in that island, under the title of elephantiasis, having confounded the distinction between the elephantiasis and *elephas* of Haly Abbas, and between the elephantiasis of the other Arabian writers, and that of the Greeks. The elephantiasis of Dr. Hillary appears to be the elephantiasis of the Arabians generally, and the *elephas* of Haly Abbas. It is a disease confined to the leg, and usually to one leg; which grows to a monstrous size, the veins becoming varicose, and the skin thick and scaly, with fissures and chops upon the surface; but which affects the functions and constitution so little, that patients often live many years, some have lived upwards of twenty, "without being sensible of any other inconvenience of life, but that of carrying along with them such a troublesome load of leg." The seat of this disease is confined to the blood-vessels, cellular substance, and skin, the muscles, tendons, and bones below, being altogether unaffected. A great effusion or collection of a fatty and gelatinous matter, in the cells of the membrane, constitutes the bulk of the diseased limb: the veins and arteries being also considerably enlarged. The disease first appears after a febrile paroxysm, in which great pain is felt in the inguinal glands of the side about to be affected. Hence Dr. Hendy gave it the appellation of the "glandular disease of Barbadoes." Dr. Rollo, in his treatise upon the same subject, has properly noticed the mistake of Dr. Hillary, in applying the term elephantiasis to this disorder. But this error is general: the principal use of the term, in this country, at present, is its application to the *thick leg* of this description, which is often seen in persons who have resided in hot climates.

The true elephantiasis (of the Greeks) appears to have first visited the island of Guadaloupe about the year 1730, having been imported with the negroes from Africa, according to Dr. Peyssonel, who has given a minute detail of its progress and symptoms, which agrees in all the leading points with the descriptions of the ancients. (See *Philosoph. Transactions*, vol. i. part 1, for 1737, art. vii.) We shall here transcribe some observations, relative only to the contagious origin of the disease, as it would be superfluous to repeat the symptoms. "We were well assured," says M. Peyssonel, "from our observations that the distemper is contagious and hereditary; and yet the contagion is not so active, nor poisonous, as that of the plague, small-pox, nor even as the ring-worm, itch, scald, and other cutaneous disorders: for, if that were the case, the American colonies would be utterly destroyed; and these persons so infected, mixed as they are in every habitation, would have already infected all the negroes whom they come near.

"We believe, that this contagion does not take place, but by long frequenting the company of the infected, or by carnal

carnal knowledge. Besides, we have observed, that even such long frequenting, or cohabiting with them, are not always sufficient to communicate the disease; because we have seen women cohabit with their husbands, and husbands with their wives, in the distemper, while one is sound, and the other infected. We see families communicate and live with leprous persons, and yet never be infected; and thus, although experience, and the information of the sick, prove the contagion, we are of opinion, that there must be a particular disposition in people to receive the poison of the leprosy.

"As to what regards the distemper's being hereditary, it is assuredly so. We have seen entire families infected; and almost every child of a leprous father or mother fall infensibly into the leprosy; and yet, in several other families, we have seen some children sound, and others tainted; the father has died of the disease, and the children grew old without any infection: so that, though it is certainly hereditary, yet we believe it is of the same nature with those in families troubled with the consumption, gravel, and other hereditary distempers; which are transmitted from father to son, without being so very regular, as to affect every one of the family." In the female children of infected parents, the disease generally first shewed itself at the commencement of menstruation, and continued slightly till they had had one or two children, when the more severe symptoms began to appear; but there was nothing regular in the period of its occurrence in males.

The latest account of the elephantiasis, occurring in Europe, is that which is given by Dr. Adams, in his "Observations on Morbid Poisons," 2d. edition, published in 1807. The disease was minutely examined by that gentleman, in the lazaretto, near Funchall, in the island of Madeira; and his description of its symptoms resembles that of his predecessors, both ancient and modern, in the general circumstances: there are several particulars, however, in which his account differs from the histories detailed by them. We have seen that the ancients and moderns concur in asserting, that the venereal appetite is exceedingly increased, when the constitution is under the influence of elephantiasis. But the observation of Dr. Adams led him to draw a conclusion directly the reverse of that just stated. For, on examining several young men, upwards of twenty years of age, in whom the disease had commenced at or before the period of puberty, he found that they had no hair on the chin and pubes, that the testes were small, and even scarcely to be felt, and that the scrotum, and all the organs very much resembled those of a boy of six or seven years old. And in those men, who had been attacked by the disease, subsequent to the period of puberty, there appeared generally a wasting of the testicles, and a diminution of the beard and hair of the pubes; and one of them, a married man, assured him that he had lost the venereal desire. Dr. Adams therefore concludes, "that all such boys as are attacked with the disease, before the age of puberty, never acquire the distinguishing marks of that change in the constitution; on the contrary, that the testicles, for the most part, diminish, and, as far as can be collected from their conversation, that they retain the implicity of infancy in whatever relates to the sexes;" and "that such as are affected later in life, gradually lose the power of procreation, as far as can be judged by the changes which take place in the organs." P. 267. 268.

Dr. Adams is disposed to deny altogether the contagious nature of the disease; partly from the consideration, that a country must be depopulated by it, if it were contagious; and partly from the fact, that none of the nurses in the lazaretto have shewn any symptoms of the disease, and that

individual lazars have remained for years at home, without infecting any part of their family. Dr. Thomas Heberden (in a paper published in the Medical Transactions of the Coll. of Physicians) has also contended for the same point. It is obvious, indeed, from all that has been written on the subject of elephantiasis, that, if there be contagion, it is not of a violent nature. It must not be omitted, however, that the wife of the married lazarus, just mentioned, was also diseased, and that Dr. Adams heard of two other couple in a similar condition; and also that the porter of the house had become a lazarus, since his residence in the lazaretto.

In addition to the symptoms generally detailed, in the history of elephantiasis, Dr. Adams has stated, that "in the upper and anterior part of the thigh, nearly in contact with the lower part of the scrotum, there is, in almost every case, a firm (to appearance) glandular swelling, moveable and prominent, or concealed, according as the patient is fat or lean, or in proportion to the progress of the disease. It is remarkable that none of the women are without it. In most of the men these tumours are particularly prominent, extending gradually upwards. In some there are also inguinal buboes. In every case the swellings are indolent, never giving pain, nor becoming discoloured, nor shewing any disposition to suppurate." P. 273. The description, which the same writer gives of the characteristic tubercles of elephantiasis, is also worthy of attention. "Among the unequivocal marks," he observes, "we may consider tubercles about the face, particularly on the external ear, *ala nasi*, eye-brows, or forehead. These tubercles, till an advanced stage of the disease, are not only smooth, but have for the most part a higher complexion than the natural skin, approaching nearer to the sanguineous hue, appearing as if semitransparent, splendid as if the surface were smeared with oil, and, on a closer examination, sometimes exhibiting small blood-vessels ramifying on their surface. At first they rise only a little above the skin, have the natural colour of that membrane, or are even paler. The circumscription is irregular, seldom circular, but beset with lateral projections, which, however, are not angular. The colour and elevation of the tubercles will, in most instances, remain stationary for a considerable time; as they become redder, or in people of a fairer complexion, more transparent, they acquire the splendour before-mentioned. Commonly the centre becomes more elevated, and so on towards the edges. So as to render the tubercle somewhat rougher. They still, however, retain their splendour, till they crack in one part, in consequence of which the tubercle is suffused with a white furfuraceous substance," &c. p. 271.

Dr. Adams says nothing of the mode in which the elephantiasis proves fatal; he observes, indeed, that "they, for the most part, seem to die of other complaints;" he does not mention the foetid breath, and carious teeth; and was unable to discover ulceration in the throat, although he admits that the *uvula* disappears, and the *os vomeris* is lost, and the nose therefore flattened. It is probable, indeed, that the fears of the ancients led them to exaggerate in their description of the humours of the disease, which they were loath to investigate minutely; and somewhat of the same apprehensions might have been felt by Hillary, Peyssonel, and others of the moderns, who have described it as not less loathsome. In the account of Dr. Adams, which is illustrated by a portrait of a lazarus, though it occasions deformity enough, it certainly appears under much less hideous colours.

Method of Treatment.—It were almost absurd to talk of the cure of a disease, which modern, not less than ancient, experience has uniformly denounced as incurable, when once established in the habit; and which has been said to be completely

ELEPHANTIASIS.

pletely established at the time when the unequivocal symptoms of the disease first make their appearance. Both the ancient and modern physicians, however, concur in ascribing the possibility of curing it at its very commencement. Dr. Hillary has given the most ample directions for the plan of procedure both medicinally and dietetically.

"If the disease be taken in time," he observes, "namely, at the beginning, and first appearance of its symptoms, the spots above-mentioned, &c., we have sufficient reasons to believe it may be cured; and I have seen some instances of its being cured.

"Notwithstanding that the seat of the venereal disease is allowed to be chiefly in the expansions of the membrana adiposa vel cellulosa, as well as in this disease; and is principally cured by the use of *mercury*, or different preparations of it; yet it is very remarkable that this disease is so far from being either cured, or relieved by it, that, on the contrary, it is greatly increased, and all its symptoms much aggravated by the use of mercurials. I grant that it seems to abate the distemper for a little time, but it soon returns with almost double force and violence after it: and *antimony*, or the best preparations of it, which are of little service in the former, are found to be the most efficacious medicines in the cure of this disease, if properly given, and the disease be taken in time.

"When the above-mentioned spots first appear, either of a yellowish, or brownish purple colour, in order to distinguish whether they are the true spots of this leprosy, (the lepra Arabum,) or they are spots of another kind, which are not uncommon in this climate, and look like them, but proceed from another cause, and are of no bad consequence; anoint the spots gently with a little oleum tartari per deliquium, and a little after rub it well off, and if the spots disappear, and return not again, they are not leprosy spots; but if they remain, or soon return again after being thus anointed and rubbed, they are the true leprosy spots, though the patient finds himself perfectly well in all other respects, and may continue so for many months. Wherefore it is necessary to attempt the cure before the disease gains further ground, and becomes inveterate.

"To which purpose, if the patient be of a sanguine plethoric constitution, it is advisable to bleed, to ten, twelve, or fourteen ounces; after which an antimonial vomit should be given; and then let them enter on the following course of medicines, and continue it for two or three months." This treatment, it may be remarked, is a copy of that recommended by the ancients, from hypothetical notions of the morbid condition of the humours in elephantiasis, and was probably repeated by Dr. Hillary from similar notions, without good grounds; for as the disease is altogether of a chronic nature, and as it is well ascertained, that, in other chronic cutaneous affections, general bleeding, and emetics are altogether destitute of utility, we may presume that these measures had little influence in establishing the cure, when that was accomplished.

The following are Dr. Hillary's formulae: *R sulphuris antimonii precipitati*, drachmas iii; *mercurii calcinati levigati*, grana xxx; *gummi guaiaci pulveris*, drachmas iii; *balsami guaiaci* quantum sufficit; *olei sassafras*, guttas xx; *misce*, fiat pilulæ 90: Of these pills the patient is directed to take three every night, at bed-time, together with fifty drops of the following tincture, and three ounces of the decoction.

The tincture consists of antimonial wine ℥ii, aromatic tincture ℥iſs; and the decoction is as follows.

R radices sarcoparilla, uncias iii; *corticis sassafras* unciam; *salis divoreici* unciam dimidiam; *misce*, et coque, vase clauso, in aqua puraë libris iſs ad libras iſs, et cola; colaturæ adde

tincturæ antimonii unciam; *aque juniperi compositæ* unciam cum femisse; *sacchari* quantum sufficit, *misce*.

Three ounces of this decoction, with fifty drops of the tincture, are also ordered to be taken every morning.

"This method," Dr. Hillary says, "should be continued two months, or longer, if the spots do not entirely disappear before that time, for it is necessary to continue them for some time after the spots are gone off. And the spots should be rubbed well once or twice a day, with a warm dry flannel cloth, first holden a little over the fumes of burning sulphur, mixed with a little antimony, and daily continued as long as the spots remain. If the disease does not abate, and the spots, torpor, and rumbnels decrease, it is sometimes necessary to repeat the antimonial vomit two or three times during this course, especially when the disease is hereditary or proves obstinate: and in this case it is necessary to repeat the whole course over again two or three months after, however in the next spring or autumn following, or both, if the least symptoms then appear, as we know no disease that is more obstinate or more difficult to cure.

"As to the dietetic part of the cure, it is not only necessary that the patients live temperately, but there are several things which must be placed among the *ledentia* in this disease, from which the patient must abstain. They must religiously abstain from all swine's flesh, and all fat meats, and every thing that is oily, fat, or greasy, either in fauces or other ways, and that not only during the time they are under this course of medicines, but for many years after. They may eat any sort of flesh meats at noon, that are not too fat, too much salted, or too high seasoned, with roots, greens, and plain fauces; but the more plain, simple, and the lighter, and more easily digested they are, the better: they should be also very temperate in the use of wine and all spirituous liquors, and strictly abstain from all kinds of malt liquors, for they are by no means a proper drink in the hot climates, as they are too viscid and glutinous a liquid, they require more labour and action, in order to digest and animalize them, than can be well used here (in the West Indies); and as the heat is great, and we perspire much and soon," &c. "they often do much hurt, as I have often observed, and therefore mention it here. Small punch, moderately acid, is a much more proper beverage for the hot climates. Their diet also mornings and nights should be light and easily digested, and gently attenuating and diluting.

"These rules may seem to be too rigid and severe to some, but they are absolutely necessary, if the patient is obliged to continue in a hot climate, and yet desires to recover his health, and live free from this dreadful dilemma. It is highly probable, that removing into a colder climate may considerably contribute to their recovery, and re-establishing their health, especially as a hot climate is the parent and producer of this disease."

Other writers confirm the statement that mercury, the essential remedy for the venereal disease, which the elephantiasis resembles in some of its symptoms, is useful, if not absolutely pernicious, in the latter. Dr. Joannis, speaking of the difference between the two diseases, remarks, that the leprosy is not so easily communicated as syphilis; "nor will it yield to the same remedies. On the contrary its virulence is increased by them, and they make it break out with more violence. This has been particularly experienced, when, after due preparations, mercurial frictions have been employed." (Med. Obs. and Inquiries, before quoted, p. 210.) And Dr. Peyssonel says, that antivenereal remedies were of no service, and "very often halted the progress of the disease."

Mr. Bruce procured a quantity of the inspissated juice of
5 A 2
cuta,

ciuta, (the conium maculatum of Linnaeus,) prepared by Baron Storck, at Vienna, which he administered diligently to some persons, labouring under the disease, in Abyssinia, but without any success. At Martiques, sulphur, both internally and externally, sudorifics, antiscorbutics, mercurials, sweeteners, diluents, viper-broths and wley, were had recourse to, but they had little or no effect; so that, when Dr. Joannis wrote, they contented themselves with prescribing a mild and moist diet, and left them to wait the last moment which was to free them from their sufferings. In a word, it is obvious that the moderns, with all their powerful additions to the catalogue of the Materia Medica, have not been more successful than the ancients in the cure of elephantiasis, and have been led by experience to follow the plan which they adopted, in respect to the dietetic course, as a slender palliative. Dr. Adams, indeed, affirms, that a generous diet certainly protracts life, and renders it more tolerable, according to the experience of the lazaretto in Madeira; but he admits that all other remedies have proved ineffectual (Loc. cit. p. 281.) It may be observed, however, that an active medicine, which has not long been admitted into practice, has occasionally proved successful in the cure of some partial affections, which have sometimes been deemed cancerous, and sometimes considered as elephantiasis, namely, the lupus, or *noli me tangere*; which corrodes and destroys by ulceration the parts that it attacks. This medicine is the arsenic, a preparation of which was introduced by Dr. Fowler, of York, and which experience has proved to be a safe and valuable remedy, for several diseases. Whether this substance might prove beneficial in the early stages of elephantiasis is a question, which can as yet only be replied to on conjecture, deduced from a slight analogy.

The cure of the *thick leg* of warm climates, which is commonly at present called elephantiasis, is not prosecuted with more success, when it is once established, than the disease of which we have just been speaking. The chief measures of those physicians, who have treated the disorder in those climates in its commencement, have been directed to diminish the febrile paroxysms, by which it is preceded, by emetics, cathartics, diaphoretics, and the usual remedies of fever; and afterwards to strengthen the system by the use of Peruvian bark, the mineral acids, and the cold bath. This method succeeds when the leg is not already grown large; but afterwards, Dr. Hillary observes, "we can only say with Rhazes, that it is incurable; and nothing but amputation can relieve them from such a load of leg; but, alas! this does not relieve the unhappy patient from the disease, unless the fever be taken off also, as above; for this operation has been often performed, but always without removing the disease, for the fever has certainly returned, and the morbid matter has as constantly fallen upon the other leg, and produced the same effects." (Loc. citat. p. 316.)

ELEPHANTINE, *fomctio*, that relates to, or partakes of, the qualities of elephants.

The term is chiefly applied to certain books of the ancient Romans, wherein were recorded the transactions of the emperors, and the proceedings, acts, &c. of the senate. This we learn from Pollio and Vopiscus, in the life of the emperor Tacitus, where he observes, that in the sixth press of the Ulpian library, was kept one of these libri elephantini; wherein, for a long course of time, were written down the decrees and edicts of the senate. In some of these books were registered all the acts and proceedings of the senate, and the magistrates of Rome; in others, the proceedings and events in the provinces, the armies, &c. There were about thirty-five large volumes of them, as many as there were tribes. In them were likewise contained the births, and classes of the

citizens, with the musters, and all things belonging to the census. They are renewed every five years with the censors, and were all anciently kept in the *ararium*, or public treasury, in the temple of Saturn.

Vigenero, and several others, believe these books to have been called elephantine, by reason of their enormous bulk; but Loffel, in the seventeenth chapter of the eleventh book of Aulus Gellius, gives us a different etymology; and assures us, they were called elephantine, because composed of ivory leaves or tablets, which every body knows is a production of the elephant. See DIPTYCHA.

ELEPHANTINE, in *Ancient Geography*, a town and island of Egypt, on the Nile, about a semi-stadium distant from Syene. This island is half a league long by a quarter wide. The town described by Strabo no longer subsists; but a small village is built upon its ruins, near to which is a superb gate of granite, which formed the entrance of one of the porticoes of the temple of "Cnept." A building surrounded by thick walls and rubbish formerly made a part of it; an elevated rampart at the point of the island served to defend it against the inundation. The nilometer formed of a block of marble, so favourably situated in this place, for discovering the first appearance of the increase of the waters, and for regulating the labours of the husbandman, is no more, a part of it being probably buried under the sand and mud of the Nile.

ELEPHANTIS, a promontory of Asia Minor, the Bosphorus of Thrace, towards the northern part of the promontory Caracian.

ELEPHANTOPUS, in *Botany*, so named by Vaillant from *elephas*, an elephant, and *pus*, the foot, because, as he himself informs us in the *Memoires de l'Academie des Sciences* for 1719, of the form and position of the radical leaves in *E. scaber*. The classical meaning of the word, however, is rather ivory-footed. Linn. Gen. 452. Schreb. 589. Willd. Sp. Pl. v. 3. 2389. Juss. 1785. Gært. t. 105. Mart. Mill. Dict. v. 2. Class and order, *Syngenesia Polygamia filigrata*. Nat. Ord. *Compositae*, Linc. *Corymbifera*, Juss.

Gen. Ch. *Common calyx* many flowered, permanent, of three large, broad, acute leaves: *partial four-flowered*, oblong, imbricated; its scales lanceolate-awl-shaped, pointed, erect, four of them equal and longer than the rest. *Cor.* compound, tubular: *florets* all perfect, four, or five, equal, ranged in a simple series; their petal tubular, with a narrow limb, in five deep, nearly equal, divisions. *Stam.* Filaments five, capillary, very short; anthers united into a cylindrical tube. *Pist.* Germen ovate, crowned; style thread-shaped, the length of the stamens; stigmas two, slender, spreading. *Peric.* none, except the permanent calyx. *Seeds* solitary, compressed; down of five bristles. *Recept.* naked.

Obs. Gærtner has rightly corrected the description of Linnaeus and Schreber, that the "florets are ligulate," an error supposed to have arisen from their two external segments being occasionally glued, as it were, together. This mistake involved a much more important one, retained in the *Genera Plantarum*, that "this genus shews there are no limits between the floscular (tubular) and semi-floscular (ligulate) flowers of Tournefort;" which remark now falls to the ground.

Ess. Ch. Partial calyx with four or five tubular florets, all perfect. Receptacle naked. Down bristle-shaped.

Linnaeus describes two species of this genus, *Willdenow* six, all natives of the West Indies, except the first and original one, *E. scaber*, which grows in moist shady sandy places in the East Indies. This is the *Ana-Schovadi* of Rhede's Hort. Malab. v. 10. 13. t. 7, who informs us that this Malabar name is equivalent to "the traces of an elephant's foot,"

as if the leaves had been trodden flat by the steps of that animal; and that its appellation among the Bramins, *Astipada*, has the same signification. This idea was adopted in the generic name by Vaillant. The qualities of the herb are slightly astringent. Its root is woody and perennial. Leaves chiefly radical, depressed, elliptic-oblong, undulated, rough. Stem a span or more in height, corymbose. Flowers pale crimson, most conspicuous for the large heart-shaped rigid leaves of the common calyx. We know nothing remarkable of the remaining species, some of which have spiked flowers. Their general habit is rough and rigid, like the above.

ELEPHAS. See RHINANTHUS.

ELEPHAS, in *Ancient Geography*, a mountain of Ethiopia, above Egypt, near the Avalite gulf. Ptolemy. Arrian calls it a promontory.

ELEPHAS, in *Zoology*, a genus of the *Eruta* order, in the class Mammalia. The Linnæan character of the genus consists in having no fore teeth in either jaw; elongated tusks in the upper jaw only; proboscis very long and prehensile; and the body rather naked.

Of the elephas, or elephant, genus there is in the opinion of Linnæus only one species, and this, from its vast superiority in size to all other quadrupeds he was acquainted with, he denominates maximus. Since the time of Linnæus we are better informed concerning the natural history of the elephant tribe; and it appears at present there are sufficient reasons for believing not only in the existence of two, if not three distinct recent species, but also one, perhaps two, or even more, the remains of which are found only in a state of petrification. Among the number of these it is scarcely to be questioned, in our opinion, that the maximus (or recent elephant) of Linnæus comprehends two distinct kinds, and that the remains of a third, an animal of the antediluvian race, and entirely different from either, is very clearly ascertained. The remainder may require farther consideration.

To the attention bestowed on the pursuits of natural history in France we are in some measure indebted for the ascertainment of the two former, but not entirely so; and it is not to the French naturalists alone that we owe the discovery of the third. It was a fact long since obvious to us, and very probably to many others, that from the structure of the grinders of the elephants brought to Europe for the sake of their ivory, there must be two distinct animals to which these dissimilar teeth belonged. And, whoever has bestowed the least attention to the stupendous remains of the animal popularly called the behemoth, and by naturalists the mammoth, can on no very rational ground dispute that there either does or has existed a third kind of elephant, admitting the latter as one. By the term elephant, as it respects the mammoth, we indeed wish to speak with caution: it possesses some characters which ought, perhaps, to be considered as generically distinct from those of elephas. In this place we nevertheless admit it under that denomination, and that not merely for the purpose of argument, but because we know among the best naturalists of the continent, in the present period, it is so considered; and we shall not incautiously place our solitary opinion against this general conclusion. Its specific characters are obviously distinct from either of the living kinds, and in its general distinctions it certainly approaches nearer to the elephant than any other race of animals known to us. Examples of the teeth of both the first mentioned kinds of elephants, of the elephants' teeth and tusks found at a considerable depth in the ground in various parts of the country, and also the remains of the mammoth we possess in great variety, and from a due consideration of these we believe ourselves enabled to decide the important fact, that there are at least two different

species of the elephant tribe, and the evident testimony of another, which has existed at some remote period of the earth.

A valuable paper on the subject of the two first appears in the Memoirs of the French National Institute by Cuvier. His observations are offered in a conclusive manner, and corroborate our ideas with respect to the two species of living elephants; the mammoth he admits as very distinct from either, but as a species of elephant. His remarks are the result of an examination of various specimens in the National museum. This collection afforded him examples of the skulls of both species of the living elephants, of which we have only seen one, and the difference of these is very remarkable. The two species are named by Cuvier *Capeensis* and *Indicus*, the first inhabiting Africa, about the Cape of Good Hope, the other India. The African sort has the front of the head convex and inclined, the tusks larger, and the perpendicular layers of enamel, which, with the softer ossific matter, compose the grinders, exhibiting on the top, or worn surface, a number of rhomboidal spaces, and which are equally observable in a transverse section of the tooth. The elephant of Asia (*Indicus*) is larger: the front of the skull, instead of being convex, is deeply concave, and the upper part so dilated as to exhibit two pyramidal elevations; and the grinders have the enamel layers disposed in the ossific substance in distinct transverse parallel lines, instead of rhomboidal compartments. The grinder of the mammoth, we may add, has the upper surface divided into eight, ten, or more distinct conic prominences, rising at least an inch above the surface, and disposed transversely in pairs. This last has rather the appearance of the tooth of some carnivorous animal than that of the elephant; and we rather suspect, in contradiction to the current opinion, that its habits were different. See our article МАММОТН.

From the consideration of species, we must descend to varieties, of which there are several in the elephant tribe; some of which may perhaps hereafter be admitted as distinct species, as well as the former. The natural colour of the common, or Indian, elephant is cinereous, from which they sometimes vary to white. The latter colour has been said, in some instances, to arise from illness, or particular maladies to which the animal is liable; an assertion to which the less degree of probability must be attached, as we know the high consideration in which the white elephants are held in India. The elephants of the Cape are of a red, or reddish colour, as we are well assured, and in particular by Levaillant in his second journey through the interior of Africa. But what we consider more remarkable and deserving of further investigation, is that, in his subsequent travels through the same parts, he speaks of a race of elephants which never have tusks, and the head of which is less elongated than the other sorts. This seems to point out the existence of a third living species.

And lastly, while treating on this subject, we must not omit to mention that mysterious animal the fukotyro. This is the animal introduced to the notice of Europe by a description and figure given in the works of Niewhoff, a Dutch traveller, who spent some time in the East Indies, about the year 1563, and pretends to have seen it in the island of Ceylon. To us it appears of the most ambiguous character, and the representation so miserably defective, that we cannot venture any opinion on its genera, except that we believe it is not really what it professes to be, an animal of a new genus. It bears some resemblance to the elephant; and the French writers even call it the dwarf elephant (*elephant-nain*); notwithstanding which it exhibits no appearance of a proboscis; its snout is rather that of

the hog, and, in point of size, it corresponds with the buffalo. The less confidence must be reposed on the authorities of the French writers in classing this uncertain quadruped with the elephants, since it is obvious, they have never seen the animal, and it is seriously to be apprehended, we allow more credit to Niewhoff for the existence of his *kyotyro* than he really merits.

It has been our aim to point out the distinctive characters of the two species of elephant, *capensis* and *indicus*, in order to show that what we have heretofore been taught to consider as a single species, does certainly comprehend two. It would be improper to affirm the existence of more than two living kinds, although we are inclined to think there must be more. Writers often mention the discovery of bones, teeth, and tusks of elephants, found buried at various depths in the earth, and many ingenious remarks and theories on this topic might be related. Few, however, of these writers seem aware of those definitive characters, by which those remains are referable to different species of the quadruped race; and it is only the observations of those attentive to such characters we can repeat with confidence. After this comment it is unnecessary to observe, that those relics which are generally confounded under the denomination of elephants' teeth and bones, are, in our opinion, the remains of more than one kind of animal. The observer should be cautious also in deciding between the recent and fossil bones, or, in other words, between those which have merely undergone a natural decay, from remaining long in the earth, and those which are strictly mineralized; the latter, mentioned, so far as our own observations extend, being indicative of species which are never found in a living state. A more obvious instance of this than the mammoth affords, need not be adduced.

We shall now proceed to the history of the common elephant of India, the largest of all quadrupeds found at this time in a state of nature. The size of this animal, its strength, and sagacity, have rendered it in all ages the admiration of mankind. The height of the elephant, which is often exaggerated by the early writers, appears to be from 10 to 14 feet, and one of the larger size is generally about 16 feet long from the front to the origin of the tail. The circumference of the neck 17 feet, and of the body in its most dilated part about 26 feet. The legs are short and about six feet in circumference, and the tail slender, and about six feet long. These are the dimensions of the largest elephants, and exceed those of the ordinary size by nearly one-third. In proportion to the size of the elephant his eyes are very small, but they are lively, brilliant, and capable of great expression. The mouth appears behind the trunk, which latter hangs between the two large tusks, which are the principal weapons of the elephant's defence. The feet are short, clumsy, and divided into five hoofs, or toes; the tail is terminated by a few large hairs. The teats in the female elephant are two in number, and situated at a small distance behind the fore legs. But the most singular organ of the elephant is the trunk, which is at once the instrument of respiration, and the limb by which the animal supplies itself with food. The trunk of an elephant is about eight feet long, five feet in circumference near the mouth, and eighteen inches near the extremity. It is a pipe of an irregular conic figure, and widened at the end; the superior side of the trunk is convex, and furrowed transversely, and the inferior side is flat, and has two longitudinal rows of small protuberances. The upper part of the trunk corresponds with the extremity of the nose in other quadrupeds, and the inferior as an upper lip, including the nostrils. The trunk is a continued canal, di-

vided into two cavities by a longitudinal partition; these cavities ascend along the fore part of the upper jaw, where they make a turn inwardly and descend into the palate, and then terminate in two separate orifices: they have likewise each a separate orifice at the end of the trunk. At the place where the cavities make a turn, and before they enter into the bones of the head, there is a moveable cartilaginous plate situated in such a manner as enables the animal to shut the canal, and to prevent the water, with which it occasionally fills the trunk, from entering the passage of the nose, where the organs serving for the sensation of smell are placed: the tip is flattish, circular, and furnished with a projecting point, or fleshy moveable hook, of extreme sensibility, and with which he can suck up the smallest objects at pleasure, and which he manages with as much dexterity as a man does his hand, taking up grains of corn, or the smallest pieces of grass, and conveying them to his mouth. When he drinks he thrusts his trunk into the water, and fills it by drawing in his breath and exhauſting the air. When the trunk is thus filled with water, he can either throw it out to a great distance, or drink it, by putting the end of the trunk in his mouth. In each jaw are four large flat grinding teeth, with the upper surfaces flat, and striated or scored. The two large tusks, by some called the horns of the elephant, produce the finest ivory. Those imported into Europe are chiefly such as are found in the woods of Africa. Instances have sometimes occurred in which, on sawing a tooth, a musket bullet has been found completely imbedded in the central part without any visible indication on the outside, the ivory having gradually grown over and enclosed it. The ears are large and long, situated close to the head, and are commonly pendulous, but he can raise them or move them with great facility, and frequently uses them as a fan, to cool himself, or to defend his eyes from dust and insects.

The texture of the skin is uneven, wrinkled, and knotty, full of deep fissures, and resembling the bark of an oak tree; and in the fissures, which are moist, are some bristly hairs.

Buffon supposed the ancients to have been deceived when they tell us that the elephants cover like other quadrupeds, and has brought forward a multitude of arguments to prove its impossibility, from the peculiar situation of the parts of generation in the female. The vagina being placed in the middle of the abdomen seems to have been his principal objection, and hence Buffon asserts that the union of the elephants could not be accomplished in the ordinary way of quadrupeds. De Feynes and Travenier positively assure us that the situation of the sexual organs confirms this fact, and that these animals cannot intermix unless they have more time and convenience, for the purpose than other quadrupeds, and that it is for this reason they never evince their natural passions, unless in the enjoyment of full liberty and retirement. Many anecdotes on this subject are related by travellers, and which in general tend to support the conjectures of Buffon; but from the observation of M. Blefs, who was secretary for the space of twelve years to the Dutch government in Ceylon, M. Buffon was so far convinced both his judgment and the information he obtained had deceived him, that in his supplement he retracts the opinions advanced in the former part of his Natural History. The observations of M. Blefs are to the following effect: "I have perceived (says this writer) that the count de Buffon is deceived with regard to the copulation of the elephants. I know that in several parts of Asia and Africa these animals, especially during the season of love, remain in the most inaccessible places of the forests: but in the island of Ceylon, where I lived twelve years, the land being every where inhabited

habited, they cannot so easily conceal themselves, and having often examined them, I perceived that the female organ is situated nearly under the middle of the belly, which would lead us to think, with M. Buffon, that the males cannot cover the females in the manner of other quadrupeds. However, there is only a slight difference of situation. When the female courts the carresses of the other sex, she prostrates her fore legs upon the ground, and every difficulty is thus removed. I can likewise affirm that the elephants go with young about nine months. In the season of love the males are strongly chained for four or five weeks, and are, during that period, so furious, that their cornacks, or governors, cannot come near them without danger. The domestic female elephant, on these occasions, sometimes make their escape and join the wild ones in the woods. Some days afterwards her cornack goes in quest of her, and calls her by name, till she comes. She submits with complacence, and allows herself to be conducted home, and shut up in the stable. According to the recent observations of Mr. Corfe, related both in the Philosophical Transactions of London, and the Transactions of the Bengal Society, it appears, however, that the elephants both couple and produce young in a state of domestication. In order to determine this experiment, a couple of elephants were put to rut in an inclosed space, where they had abundance of food, and every necessary accommodation. At first they were only sociable, at length they became more familiar, and began to shew signs of fondness, by frequently carressing each other with their trunks, and on the 28th of June, at night, the expectations of their observers were fulfilled. They were seen to cover like the horse, and this was witnessed no less than five times in the course of sixteen hours.

Elephants, even in a savage state, are peaceable and gentle creatures, and are said never to use their weapons but in defence of themselves or companions. Their social dispositions are so strong that they are seldom found alone, but march always in large troops; the oldest and most experienced lead the van; the younger or lame ones keep in the middle, and those of a second rate, as to age, walk in the rear. The females carry their young on their tusks, embracing them at the same time with their trunk. They seldom march in regular order but when they reckon the journey dangerous, such as an expedition to cultivated lands, where they expect to meet with resistance, on other occasions they are less cautious: some of them falling behind, or separating from the rest, but seldom so far as to be without the reach of assistance, by alarming and assembling their companions. It is dangerous to offer them the least injury; for they run straight upon the offender; and although the weight of their body be great, their steps are so large, that they easily outrun the swiftest man, whom they either pierce with their tusks, or seize with their trunk, dart him into the air like a stone, and then trample him under the feet. But they are said never to attack any person unless provoked. However, as they are extremely sensible and delicate with regard to injuries, it is always prudent to keep out of their way. Travellers, in countries they inhabit, kindle large fires, and beat drums during the night, in order to prevent their approach. After being once attacked by men, or falling into an ambush, they are said never to forget the injury, but seek every opportunity for revenge. As they are endowed perhaps with a more exquisite sensation of smell than any other animal, owing to the great extent of their nose, they can scent a man at a great distance, and trace him by his footsteps.

Elephants are peculiarly fond of the banks of rivers, deep valleys, and marshy grounds, especially in the depths of forests. They delight in drawing up water into their trunks, when they do not drink it, and amuse themselves in dashing the

water around: they cannot endure cold, and are equally averse to an excess of heat: in order to avoid the scorching heat of the sun, they retire to the thickest and most shady parts of the forest. The bulk of their bodies is so enormous that they do not often go into deep waters. The ordinary food of the elephant consists of roots, herbs, the tender branches of trees, fruit, and grains, and they abhor animal food. When any of them discovers a fine pasture, he invites his companions to the repast, and as they devour a large quantity of food in a short time, they are always shifting their pasture. When they meet with cultivated grounds they make prodigious desolation, and destroy more plants by treading them down than they use for nourishment, which last is very considerable, and amounts to about 150 pounds of herbage every day. As they constantly graze in large troops they lay waste whole fields in an hour. The Indians and negroes employ every art to prevent them from visiting their cultivated lands, by making great noises and burning large fires round their fields. However, these precautions are not always sufficient to prevent the elephants from visiting them. They chase away the domestic animals, put the inhabitants to flight, and sometimes throw down their habitations. Elephants are hardly susceptible of fear; the only things which can surprize them, or stop their course, are fire works, such as squibs, crackers, &c. the effects of which are so sudden and so quickly repeated, that the elephants frequently turn back, and when one runs, all the rest follow his example.

Although the social disposition in the elephant be remarkable, in the rutting season their docility gives place to the stronger impulse of love. They steal off in couples to the most secret parts of the forest. The elephant, when it comes into the world, is as large as a young boar, and equal to an ox in size when six months old. The young suck the teats of the female with the mouth, and not the trunk, as erroneously represented.

The manner of taking and taming elephants merits attention. In forests, and such places as are frequented by elephants, the Indians choose a spot, and inclose it with strong palisades: they use the largest trees as the principal stakes, to which are fixed smaller ones, in a transverse direction. These cross trees are so fixed as to allow a man to pass easily through. There is likewise a large entrance left for the elephant, over which is suspended a strong barrier, which is let down afterwards as soon as he enters. In order to decoy him into the enclosure, the hunters take along with them a tame female in season, and travel about till they come so near that the cry of the female can reach the male, whom they previously observe in the forest; then the guide of the female makes her give the cry peculiar to the season of love, to which the male instantly replies and approaches. The guide then makes the female proceed towards the artificial inclosure, repeating her cries as she proceeds; she enters the inclosure, the male follows her, and the Indians immediately shut the port behind him. He no sooner discovers that he is ensnared than his passion for the female is converted into rage and fury. The hunters entangle him with strong ropes, and bring two or three tame elephants to pacify him, and in a word, by the application of torture and carresses, reduce him in a few days to obedience.

There are many other methods of catching elephants. Instead of making large inclosures with palisades, like the kings of Siam and other monarchs, the poor Indians are content to adopt a more simple method; they dig deep pits in the roads, frequented by elephants, covering them with branches of trees and turf, into which the elephants are precipitated

ELEPHAS.

by their enormous weight in attempting to pass, and being unable to extricate themselves, are easily taken.

The elephant, when tamed, is the most friendly and obedient of all animals, and is entirely attached to the person who feeds and takes care of him. He readily understands signs and the sounds of his master's voice, and distinguishes the language of passion, command, and satisfaction. He receives his orders with attention, and executes them with alacrity and prudence. He easily learns to lower his body for the convenience of those who mount him. He caresses his friends with his trunk. With this wonderful organ he also lifts burdens, and assists those who are loading him in laying them on his back. When yoked in a cart or waggon, he pulls equally and cheerfully, unless abused, or injudiciously chastised. His guide is generally mounted on his neck, with a small iron rod sharp at one end, and with this he directs his motion by pricking him on the ears and head, but more frequently it is sufficient to direct him by the voice. A tame elephant will do more labour than six horses, and he requires a quantity of food in proportion. They are the principal beasts of burden in many parts of Africa and the East Indies. They carry sacks and bundles of all kinds on their neck, back, and tusks. They never lose or damage any thing committed to their care; and it is said, they will stand on the edge of a river, take bundles off their neck and tusks, and lay them carefully in any part of the boat desired, and try with their trunk whether they are properly situated, and if they be loaded with ease, they go in quest of bones to prop them, and prevent them from rolling.

The elephant is not only the most tractable, but the most intelligent of animals, sensible of benefits, resentful of injuries, and endowed even with a sense of glory. Some extraordinary instances of this, though often related, may bear repetition. In India they were once employed in launching ships; one was directed to force a vessel of large size into the water, the work proved superior to his strength, his master, with a sarcastic tone, desired the keeper to take away this lazy beast and bring another; the poor animal instantly repeated his efforts, fractured his skull, and died on the spot. The celebrated story of the taylor at Delhi is recorded as a remarkable example of the elephant's sagacity. The elephant, passing along the streets, put his trunk into the window of a taylor's shop, where several people were at work, one of whom pricked the end with his needle; the beast passed on, but in the first dirty puddle filled his trunk with water, and on his return discharged it over those who offended him, and spoiled their work. This is related by Ludolph. (Hist. Ethiop.) who also gives the following anecdote. An elephant at Admeer, which often passed through the market, as he went by a certain herb-woman always received from her a mouthful of greens. At length he was seized by one of his periodical fits of rage, broke from his keeper, and running about the market, put the crowd to flight. Among others, was this woman, who in her haste forgot a little child she had brought with her. The animal recollected the spot where his benefactress usually sat, and taking the infant up gently with its trunk, removed it to a place of safety.

Buffon relates, that a soldier at Pondicherry, who was accustomed, whenever he received his portion of provisions, to convey a certain quantity of it to one of these animals, having one day drank rather too freely, and finding himself pursued by the guard, who were going to take him to prison, took refuge under the elephant's body and fell asleep. In vain did the guard try to force him away from this asylum, as the elephant protected him with his trunk. The next morning the soldier, recovering from his drunken fit, shuddered with horror to find himself stretched under the belly

of this huge animal. The elephant, which, without doubt, perceived the man's embarrassment, creased him with his trunk, in order to inspire him with courage, and make him understand that he might now depart in safety.

In the memoirs of the French Academy of Sciences, we are told the following circumstance. A painter was desirous of drawing the elephant which was kept in the menagerie at Versailles in an uncommon attitude, namely, that of holding his trunk raised up in the air with his mouth open. The painter's boy, in order to keep the animal in this posture, threw fruit into his mouth, but as the lad frequently deceived him and made an offer only of throwing him the fruit, he at last grew angry, and as if he had known the painter's intention of drawing him was the cause of the affront, instead of revenging himself on the lad, he turned his resentment on the master, and taking up a quantity of water in his trunk, threw it upon the paper on which the painter was drawing, and spoiled it.

At the Cape of Good Hope it is customary to kill these animals for the sake of their teeth by the chase. Three horsemen well mounted and armed with lances attack an elephant alternately, each relieving the other as they see their companion pressed, till the beast is subdued. Three Dutchmen (brothers,) who had made large fortunes by this business, had determined to retire to Europe and enjoy the fruits of their labours; but resolved before they went; to have a last chase by way of amusement; they met with their game, and began in the usual manner; but unfortunately one of their horses fell down and flung its rider; the enraged elephant instantly seized the unhappy man with its trunk, flung him up to a vast height in the air, and received him on one of its tusks; then turning towards the two other brethren, as if it were with an aspect of revenge and insult, held out to them the impaled wretch writhing on the bloody tooth.

By the ancient Indians, elephants were much used in war. Porus, the Indian monarch, is said to have opposed the passage of Alexander over the Hydaspes with eighty-five elephants. A number of these taken by Alexander were afterwards, as is recorded, sent into Greece, where Pyrrhus employed them some years after against the Romans in the battle of Tarentum. Both the Greeks and Romans soon learnt to get the better of these monstrous animals; they opened their ranks and allowed them to pass through; neither did they attempt to hurt them, but endeavoured to kill their guides. Now that fire-arms are the principal instruments of war, elephants, who are terrified at the noise and flame, instead of being useful in a charge, would tend only to embarrass an army. However, in Cochín and other parts of Malabar, and also in Torquin, Siam, and Pegu, where fire-arms are little understood, they are still used in battle. The guide sits astride upon the neck, and the combatants sit or stand upon the other parts of his body. They are more commonly used in those provinces of India where the use of fire-arms prevails, for fording rivers, and carrying magazines, military chests, or even the field pieces in swampy grounds, where they cannot readily be drawn by horses. In crossing rivers after the keepers have loaded them sufficiently, (and they carry from three to four thousand weight,) they fasten ropes to them, of which the soldiers taking hold, either swim or are drawn across the river. They are also useful in forcing open the gates of a city or garrison, or forcing any entrance, to prevent which, most of the garrisons in India have large spikes stuck in their gates that project to a considerable distance.

Elephants are however retained by princes in India, rather for the purposes of luxury and magnificence than any real utility, and the expence of keeping them is prodigious. The greatest care is taken in the management and decoration

of these animals, which after their daily feeding, bathing, oiling, and rubbing, are often painted about the ears and head with various colours, and their tusks surrounded with rings of gold and silver. When they appear in state to grace processions or other ceremonies, they are clothed in the most sumptuous trappings. It is said to be not an uncommon circumstance, if a nabob is disposed to ruin a private gentleman, to make him a present of an elephant, which he is afterwards obliged to maintain at a greater expence than he can afford; by parting with it, he would certainly fall under the displeasure of the grandee, besides forfeiting all the honour which his countrymen think is conferred upon him by so respectable a present. That the elephant lives to a great age is not unknown; in a state of slavery and labour, some have been said to live from one hundred to one hundred and thirty years; whether, as some writers assert, in its state of wildness, it lives to the age of two hundred years cannot easily be determined; they are also said not to attain their full growth till they are thirty years old, and that their propagative abilities do not fail at the age of one hundred and twenty. In Africa, where elephants are far more numerous than in Asia, the natives hunt them for the sake of their flesh as well as the ivory of their tusks. The trunks they esteem a delicious morsel. So numerous are the herds of elephants in some parts of Africa, that the natives are compelled to live in subterranean dwellings to avoid them. Their tusks, which are found in the woods by the negroes, form an article of immense commerce in Congo and Guinea, and also in Acra, Ante, Benin, Rio de Calbari, and on the Gold Coast.

The ancients held the elephant in high veneration for his sagacity. They pretended that he understood the language of men, and, what was infinitely more to its honour in their ideas, the worship of the gods: they adored the sun and moon, and offered supplication for favours, and gratitude for benefits bestowed. The moderns entertain other notions, and ascribe it to a superiority of intellect over the whole brute creation: for it is not instinct merely, but reason which they allow the elephant to possess. From the observations, however, of our countryman, Mr. Corse, whose residence in India afforded him an opportunity of investigating the subject with exactness, it does not appear that the elephant is altogether entitled to that elevated character with which it has been so frequently honoured; and that neither its docility nor its memory can be allowed a very high rank, when compared with those of some other animals; and that the scrupulous delicacy which, it was pretended, forbid all public demonstration of its natural passions, is a mere fable. A female elephant has been known to forget her young one, after having been separated only for the short space of two days, and to repel its advances: and an elephant, also, which had escaped from its confinement, has again suffered itself to be trepanned, and reconducted to its former state of captivity.

The account alluded to is given by Mr. Corse in the Philosophical Transactions for the year 1799, and cannot fail to prove highly conclusive and satisfactory to every curious reader. Mr. Corse observes, that both male and female elephants are divided by the natives of Bengal into two casts, namely, the Koomareah and the Mergee. The first consists of the large and full-bodied kind; the second, of the more slender, with longer legs and thinner trunk in proportion: it is also a taller animal, but not so strong as the former. A long trunk is always considered as a great beauty in an elephant; so that the koomareah is preferred, not only on this account, but for his superior strength in carrying burthens, &c. Many indistinct varieties are again produced

from the intermixture of these two breeds. The torrid zone seems to be the natural climate of the elephant, and the most favourable for the production of the largest and hardiest race; and, when this animal migrates beyond the tropics, the species degenerates. On the coasts of Malabar, elephants are taken as far north as the territories of Coorgan Rajah; but these, according to Mr. Corse, are much inferior to the Ceylonese elephant.

"The tusks in some female elephants," says Mr. Corse, "are so small as not to appear beyond the lip; whilst in others, they are almost as large and long as in one variety of the male, called mooknah. The genders are so much alike in both sexes, that one description may serve for both. The largest tusks, and from which the best ivory is supplied, are taken from that kind of male elephant, called dauntelah, from this circumstance, in opposition to mooknah; whose tusks are not larger than those of some females. An elephant is said to be perfect, when his ears are large and rounded, not ragged or indented at the margin; his eyes are of a dark hazel colour, free from specks; the roof of his mouth and his tongue without dark or blackish spots of any considerable size; his trunk large; his tail long, with a tuft of hair reaching nearly to the ground. There must be five nails on each of his fore-feet, and four on each of the hind ones; his head well set on, and carried rather high; the arch or curve of his back rising gradually from the shoulder to the middle, and thence descending to the insertion of the tail; and all his joints firm and strong. In one variety of the elephant, the tusks point downwards, projecting only a little way beyond the trunk. The tusks of the elephant are fixed very deep in the upper jaw; and the root of the upper part, which is hollow and filled with a core, goes as high as the insertion of the trunk, round the margins of the nasal opening to the throat; which opening is just below the protuberance of the forehead. Through this opening the elephant breathes, and by its means he sucks up water into his trunk: between it and the roots of his tusks there is only a thin bony plate. The first or milk tusks of an elephant never grow to any considerable size, but are shed between the first and second year, when not two inches in length. The time at which the tusks cut the gum varies considerably: sometimes a young elephant has his tusks at five months old, and sometimes not till seven. Even in a foetus, which has arrived at its full time, these deciduous tusks are formed. A young elephant shed one of his milk-tusks on the 6th of November, 1760, when but thirteen months old; and the other on the 7th of December, when above four months old. Two months afterwards, the permanent ones cut the gums; and on the 19th of April, 1791, they were an inch long. Another young elephant did not shed his milk-tusks till he was sixteen months old; which proves that the time of this process varies considerably. The permanent tusks of the female are very small, compared with those of the male; and do not take their rise so deep in the jaw. The largest elephant tusk Mr. Corse ever saw in Bengal did not exceed the weight of 72 pounds avoirdupois; at Tipperah, they seldom exceed 50 pounds each. Both these weights are very inferior to that of the tusks brought from other parts to the India House, where some have weighed 150 pounds each. These, Mr. Corse suspects, were from Pegu. The African elephant is said to be smaller than the Asiatic; yet the ivory-dealers in London affirm that the largest tusks come from Africa, and are of a better texture, and less liable to turn yellow than the Indian ones: a circumstance which corroborates the truth of the specific distinction between the Asiatic and African elephants. The increase of the tusks arise from circular layers

of ivory applied internally, from the core on which they are formed, similar to what happens in the horns of some animals. The grinders of elephants may be considered as composed of several distinct laminae or teeth, each covered with its proper enamel; and these teeth are merely joined to each other by an intermediate softer substance, acting as a cement. This structure, even at first glance, must appear very curious, being composed of a number of perpendicular laminae, which may be considered as so many teeth; each covered with a strong enamel, and joined to one another by the common officious matter: this, being much softer than the enamel, wears away faster by the mastication of the food; and in a few months after these teeth cut the gum, the enamel rises considerably higher, so that the surface of each grinder soon acquires a ribbed appearance, as if originally formed with ridges. The number of these teeth, or proportions, of which an elephant's grinder is composed, varies from four to twenty-three, according as the animal advances in age; so that the grinder, or case of teeth, in a full grown elephant is more than sufficient to fill one side of the mouth. The shape of the grinder of the lower jaw differs from those of the upper, which are very convex on the back part; whereas the lower has a bent or curved direction, adapting itself to the shape of the jaw, and is concave on the surface. The grinders, like the tusks, are already formed even in the very young animal. The first set of grinders, or milk-teeth, begin to cut the gum eight or ten days after birth; they are not shed or cast as the milk tusks are, but are gradually worn away during the time those of the second set are coming forward. Mr. Corke could not ascertain the exact time at which the second set of grinders makes its appearance; but when the elephant is two years old, the second set is then completely in use. At about this period the third set begins to cut the gum; and from the end of the second to the beginning of the sixth year, the third set comes gradually forward as the jaw lengthens, not only to fill up this additional space, but also to supply the place of the second set, which is, during the same period, gradually worn away. From the beginning of the sixth to the end of the ninth year, the fourth set of grinders comes forward, to supply the gradual waste of the third set. After this period, other sets are produced; but in what proportion, and in what time, is not yet ascertained: but it is reasonable to conclude that every succeeding grinder takes a year longer than its predecessor to be completed; and consequently that the fifth, sixth, seventh, and eighth sets of grinders will take from five to eight years (and probably much longer) each set, before the posterior lamina has cut the gum.

The curious reader, desirous of farther information on the history of elephants, may consult the following, among other valuable publications on the subject, with advantage: "Descriptio nova Elephantis," &c. P. Gilvius, 1562, 1565, (seorim edita 1614); "Historia Elephantis," J. Prætorius, 1607; "Elephas, das ist, Historischer und Philosophischer Discurs von Elephantem," C. Horn, 1629; "L'Histoire des Elephants," S. de Priezac, 1650; "Elephas Brutum non-brutum," &c. J. Lipsius, 1650; "An Account of taking and taming Elephants in Zeylon," Strachan, Phil. Trans.; "De Elephantis," &c. C. Cuperus, 1719; "Sur un Elephant qui a vecu a Naples plusieurs Années," Mem. Fr. Acad.; "Geschichte des Elephanten," Berl. 1777; "Account of catching wild Elephants at Typura," Corke, Bengal Trans., &c.

ELEPORUS, in *Ancient Geography*, a river of Italy, in Bruttium.

ELERA, a town of Asia, in Batanae, a country of Syria. Ptolemy.

ELERO, in *Geography*, a river of Piedmont, which runs into the Tanaro, near Carri.

ELESCHIEVI, a town of Russian Siberia, in the government of Tobolsk, on the Tschulun; 84 miles E.N.E. of Tomsk.

ELEVATIO, in *Prosody*, the same as *asis*. See *ARIS*.

ELEVATIO, *Arts*, in *Musice*, the lifting up the hand or foot in beating time, serves to mark the unaccented parts of a bar, and is called the *up*, or that tact or portion of a bar which occupies the second or fourth part of a measure. It was the contrary with the ancients. An elevation of voice, in singing, is ascending to the acute.

In the Roman Catholic church, the lifting up the host or body of our Saviour is called *elevatio*, or the elevation, for which there is a particular service.

ELEVATION, the altitude or height of any thing. See *ALTITUDE*.

The word is formed from *elevare*, to raise or lift up.

ELEVATION of a *Siar*, or other point, in the sphere, is an arch of the vertical circle, intercepted between such star, or other point, and the horizon.

Hence, as the meridian is a vertical circle, a meridian altitude or elevation, *i. e.* the elevation of a point in the meridian, is an arch of the meridian, intercepted between that point and the horizon.

ELEVATION of the pole, denotes the altitude of the pole above the horizon of any place, or an arch of the meridian, intercepted between the pole and the horizon.

Thus, in *Plate XII. Astronomy*, fig. 102. A Q being supposed the equator, H R the horizon, H Z P N the meridian, and P the pole; P R is the elevation of the pole.

In which sense elevation stands opposed to depression or depth. See *DEPRESSION*.

The elevation of the pole is always equal to the latitude of the place; that is, the arch of the meridian intercepted between the pole and the horizon, is always equal to the arch of the same meridian, intercepted between the equator and the zenith. Thus, the north pole is elevated $51^{\circ} 32'$ above the horizon of London; and there is the same distance, or number of degrees, between London and the equator; so that London is likewise in $51^{\circ} 32'$ of northern latitude.

To observe the elevation of the pole of any place, see *POLE* and *LATITUDE*.

ELEVATION of the Equator, is an arch of the meridian, less than a quadrant, intercepted between the equator and the horizon of the place.

Thus A Q, as before representing the equator, H R the horizon, P the Pole, and H Z P N the meridian; H A is the elevation of the equator. See *EQUATOR*.

The elevations of the equator, and of the pole, together, are always equal to a quadrant; consequently, the greater the elevation of the pole, the less the elevation of the equator, and *vice versa*.

Thus, in the figure just cited, P A is supposed by the construction a quadrant, and H A + A P + P R a semicircle; consequently, H A + P R is a quadrant.

ELEVATION of the Equator, to find the. Find the elevation of the pole, after the manner hereafter directed, under the article *POLE*.

Subtract the elevation found from a quadrant, or 90° ; what remains is the elevation of the equator. Thus, the elevation of the pole $51^{\circ} 32'$, being subtracted from 90° ; leaves the elevation of the equator $38^{\circ} 28'$.

ELEVATION, in *Architecture*, is the orthographic projection of an edifice, or object, by a system of rays parallel to the horizon. Hence its use in describing the vertical parts

of

of objects, particularly when these objects consist of planes, and when these planes are parallel to the plane of projection. By the use of plans and elevations, we are enabled to communicate our ideas of a design to others, who are thereby enabled to put them in practice.

ELEVATION, in the *Romish Religion*, is applied to that part of the mass wherein the priest kisses or raises the host, with the cup above his head, for the people to adore it, after having first consecrated and adored it himself.

Whilst the priest officiates at mass, a bell is rung at the elevation, to apprise the people to cast their eyes upon their new-formed Saviour and adore him.

St. Lewis decreed, that they should fall on their knees at the elevation, in imitation of certain religious whom he does not name. The Chartreux, and the religious de la Trappe, still observe this ceremony of prostrating themselves at the elevation.

ELEVATION, *Angle of*, in *Mechanics*, is the angle A R B (*Plate XXII. Mechanics fig. 4.*) comprehended between the line of direction of a projectile A R, and the horizontal line A B. See PROJECTILE and ANGLE.

ELEVATION of a Cannon or Mortar piece, is the angle which the chase of the piece, or the axis of the hollow cylinder, makes with the plane of the horizon.

ELEVATOR, in *Anatomy* is a name given to several muscles of the body, which have the office of elevating or drawing upwards the parts into which they are inserted. It has the same import with levator or attollens, and is directly opposite to depressor.

ELEVATOR *Ale Nafi*, is a name given by Cowper to the *Centrefessor narium*, which see.

ELEVATOR *Auris*, is the same with attollens auriculam. See EAR.

ELEVATOR *Humeri*, is an old name for the *Deltoides*, which see.

ELEVATOR *Labiorum communis*, the same with levator anguli. See DEGLUTITION.

ELEVATOR *Labii inferioris*, is described in the article DEGLUTITION, under the name of levator menti.

ELEVATOR *Labii superioris*, is a name given by some authors to that part of the levator labii superioris and alae nasi, which is inserted into the upper lip. See DEGLUTITION.

ELEVATOR *Oculi*, is the superior straight muscle of the eye. See EYE.

ELEVATOR, in *Surgery*, an instrument for raising depressed portions of the skull.

Besides the common elevator, now generally preferred by all the best operators, several others have been invented, as, for instance, the tripod elevator, and another which was first devised by M. I. L. Petit, and afterwards improved by M. Louis.

The common elevator is an exceedingly simple kind of instrument, being in fact a mere lever, the end of which is somewhat bent, and made rough, in order that it may be less apt to slip away from the piece of bone which is to be raised. This instrument may be used by forming a fulcrum for it, either in the hand which holds it, or on the fingers of the other hand; or the operator may make a fixed point for it on the edge of the opening made with the trephine, or of that which the accidental violence has occasioned. In the first case, it has been objected, that the instrument cannot be employed with much force; the hand may give way; or the elevator may slip away from the bone against which it presses, and thus produce a considerable concussion. In the second case, it has been found objectionable, that the part on which the instrument is placed may be forced inward.

Such were the inconveniences which led to the invention of the tripod elevator, one piece of which consists of three branches uniting above into one common trunk. This part of the elevator is pervaded by a long screw, having below a kind of hook, and above a sort of handle for turning it. It is with the hook that the depressed portion of bone is to be elevated. This part of the instrument is to be introduced into the opening made in the cranium, as soon as the elevator has been put in a proper position; and it is to be made to ascend, by turning the screw. Formerly, the tripod elevator was also sometimes used conjointly with a sort of screw, which was first fixed in the piece of bone about to be elevated, and then drawn upward, by placing the hook in a ring, which was attached to its upper part.

The inventors of the tripod elevator were certainly very well acquainted with the imperfections of the common one; and they endeavoured to obviate them, by procuring a firm fulcrum, and a greater degree of power. But it was necessary to change the situation of their elevator, as often as there was occasion to raise a different portion of bone; and the hook, also, being connected with an inflexible piece of steel, the direction of which was always the same as that of the instrument, it became troublesome and difficult to place the hook under the piece of bone, which stood in need of being raised.

On the foregoing accounts, M. J. L. Petit was induced to invent a new elevator. This consisted of a lever, mounted on a handle, and straight throughout its whole length, except just at its very end, which was slightly curved, in order that it might be more conveniently put under the portion of bone which was about to be elevated. The lever under consideration was pierced at various distances from its bent end with several holes, intended for the reception of a little kind of moveable screw-peg, which was fixed on the top of a sort of bridge. This latter part of the instrument consisted of a kind of arch, the ends of which were long and covered with little cushions, while on its centre was placed the little screw-peg already mentioned. M. Petit wished the peg to be joined to the bridge by means of a hinge; and as he often found it necessary to elevate several different pieces of bone in the same case, he thought that the little screw should not be completely fastened in the hole, but that the instrument should be capable of being turned to the right, or left, or to any point of the cranium. However, the structure of the screw only allowed the instrument, on turning this to the right or left, to be applied with its edge obliquely under the bone which one wished to elevate.

M. Louis endeavoured to remove the inconveniences of Petit's elevator, by substituting for the hinge a sort of pivot. This construction rendered the lever capable of being readily moved in every direction, and of being put under any point of bone, which required being elevated, without any necessity for altering the position of the bridge forming the fulcrum.

We have only to repeat, respecting elevators, that all the best modern surgeons give the preference to the common one, which is most simple, and is found to answer every desirable purpose. See TREPAN.

ELEVE, a term purely French, though of late used also in our language. Literally it signifies a disciple or scholar, bred up under any one, being formed from the Italian, *allievo*, an apprentice or novice.

It was first used by the French writers, in speaking of painters; such a painter was an eleve of Da Vinci, of Raphael, &c. From painting it came to be applied to such as studied or learned any other art under a master. In the Royal Academy of Sciences, there were twenty elevés; and

in that of inscriptions, ten elevés. The elevés were to act in concert with the penitents.

The denomination elevé, however, was afterward suppressed, and that of adjoint substituted in its room; because every body did not know the sense affixed to it by the academy; and hence the pensionary academists had not, as formerly, each of them an elevé; but the elevés became adjoints, or associates of the academy. See ACADEMY.

ELEUS, in *Ancient Geography*, an island of Asia Minor, on the coast of Ionia; placed by Thucydides in the vicinity of the town of Miletus.

ELEUSA, an island of Cilicia, according to Pliny; named Sebasta by Ptolemy; situated N. of Rhodes.—Also, an island of Greece, on the coast of Attica, in the Saronic gulf, S. of mount Hymettus, and opposite to a small promontory. Pliny.

ELEUSIN, a town of Greece, in the island of Thera. Ptolemy.

ELEUSINE, in *Botany*, Gærtn. t. I. See CYNOSURUS. sp. 12.

ELEUSINE, in *Ancient Geography*, a village of Egypt, situated near Alexandria and Nicopolis, on the canal of Canopus, according to Strabo.

ELEUSINIA, in *Antiquity*, the mysteries of the goddesses Ceres, or the religious ceremonies performed to her honour; thus called from *Eleusis*, a maritime town of the Athenians, wherein was a temple of that goddess, famous for the celebration of these mysteries. See CEREBALIA.

Some writers call the city where the Eleusinia were celebrated, *Eleusinia* or *Eleusis*: Harpocration confirms this orthography, in deriving its name from *Eleusinus*, a son of Mercury; to which opinion Pausanias likewise adheres, in his Attics. Others who write it *Ελευσις*, *Advent*, suppose it was called because Ceres, after running over the world in search of her daughter, stopped here, and put an end to her pursuit. Diodorus Siculus, lib. v. will have the name *Eleusis* to have been given this city, as a monument to posterity, that corn, and the art of cultivating it, were brought from abroad into Attica.

The Eleusinia were the most solemn and sacred ceremonies in use among the Greeks; for which reason they were called *mysteries*, by way of eminence. They are said to have been instituted by Ceres herself, at *Eleusis*, in memory of the zeal and affection wherewith the Athenians received her.

This is the account Hecates gives in his Panegyric: but Diodorus Siculus assures us, lib. vi. that the Eleusinia were instituted by the Athenians, in gratitude to Ceres, for having instructed them to lead a less barbarous and rustic life: yet the same author, in the first book of his Bibliotheca, relates the thing in another manner.

A great drought, says he, having occasioned a miserable famine throughout all Greece, Egypt, which had that year reaped a most plentiful harvest, bestowed part of the fruits thereof upon the Athenians. It was Erechtheus that brought this extraordinary supply of corn: in commemoration of which benefaction, Erechtheus was created king of Athens, who instructed the Athenians in these mysteries, and the manner of celebrating them.

This account comes near to what we are told by Herodotus and Pausanias, viz. that the Greeks acquired the knowledge of their gods and their religion from the Egyptians.

Theodor. ret, lib. i. Græcænic. Affcct. writes that it was Orpheus, not Erechtheus, who made this establishment, and who instituted for Ceres what the Egyptians practised

for Isis; which sentiment is confirmed by the scholiast on the *Alcestes* of Euripides.

Eleusis, the city where these mysteries were celebrated, was so jealous of the glory thereof, that, when reduced to the last extremity by the Athenians, it would not surrender but on this condition, that the Eleusinia should not be taken away; though these were no religious ceremonies peculiar to the town, but were held common to all Greece.

There were two kinds of Eleusinia, the *greater*, and the *less*; those we have hitherto been speaking of were the *greater*.

The *lesser* were instituted in favour of Hercules; for that hero desiring to be initiated into the form, and the Athenians not being able to gratify his wishes, because the law prohibited any stranger being admitted; being both, however, to give him an absolute denial, they instituted new Eleusinia, in which he assented. These were afterwards celebrated at Agra, near Athens. The *greater* were held in the month of Boedromion, which answered to our August; and the *lesser* in the month Anthesterion, which happened in our January. People were only brought to partake of these ceremonies by degrees; at first, they were to be purified; then admitted to the *lesser* Eleusinia; and at last initiated into the *greater*. Those, who were yet only at the *lesser*, were called *mystæ*; and those admitted to the *greater*, *epoptæ*, or *ephoræ*, i. e. *inspectors*. They were usually to undergo a probation of five years, before they passed from the *lesser* to the *greater*. Sometimes, indeed, they were contented with a single year; immediately after which they were admitted to the most secret religious parts of the ceremony. When any person was initiated, he was introduced by night into the temple, after having his hands washed at the entry, and a crown of myrtle put upon him. Then was opened a little box, containing the laws of Ceres, and the ceremonies of her mysteries; which the initiated person was to read and transcribe. A slight repast succeeded this ceremony; after which the *mystæ* entered into the sanctuary, over which the priest drew the veil, and then all was instantly in darkness. A bright light succeeded, and exhibited to view the statue of Ceres, magnificently adorned; and while they were attentively contemplating it, the light again disappeared, and was succeeded by profound darkness. Peals of thunder, and flashes of lightning, and a thousand monstrous figures that were perceived on all sides in the midst of the sanctuary, filled the initiated with consternation and horror; but the next moment a calm succeeded, and there appeared in broad day-light a pleasant meadow, in which all seemed to dance and partake of mirth. Amidst this jollity and mirth, it is said, the tenets of the mysteries were revealed. Meursius has an express treatise on the Eleusinia, where most of these points are proved.

Secrecy, as Le Clerc after this writer suggests, was enjoined with great strictness, not so much to conceal the abominations charged on these mysteries by the Christian fathers, as because the initiated were thus let into the first history of Ceres and her daughter, which it was necessary to conceal from the public; but if it were known that these two goddesses were merely mortal women, their worship would have become contemptible. Cicero (*Tusc. Quæst. l. i. c. 13.*) favours this opinion. See MYSTERIES.

The matter of these mysteries, as related by Arnobius and Lactantius, was an imitation, or representation, of what mythologists teach of Ceres. They lasted several days; during which, the people ran about with burning torches in their hands; sacrificed abundance of victims, not only to Ceres, but also to Jupiter; made libations from two vessels, one of them to the east, and the other to the west; marched

in pomp to *Eleusis*, making pauses from time to time, wherein they sung hymns, and sacrificed victims; and thus they performed not only in going to *Eleusis*, but in returning back to Athens. For the rest, they were obliged to keep it an inviolable secret; and the law condemned to death any one who should dare divulge their mysteries. Tertullian, in his book against the Valentinians, relates, that the figure shewn in the Eleusinia, and which was so expressly prohibited to be made public, was that of a man's privy parts. Theodoret, Arnobius, and Clemens Alexandrinus, likewise make mention of it; but they say it was the figure of a woman's privities.

The day after the feast, the senate assembled at *Eleusis*, apparently to examine whether every thing had been managed according to order.

ELEUSINUS ΣΙΝΟΣ, in *Ancient Geography*, an ancient name for the Saronic gulf.

ELEUSIS, a town of Attica, on the bank of the Saronic gulf, N. W. of Athens; in which the Eleusinian mysteries were celebrated. See the preceding article.

Dr. Adam Clarke has lately (*viz.* in 1808) published a fac simile of a Greek inscription found on a stone, which was formerly discovered at Eleusis. This inscription, according to the suggestion of the late learned professor Porson, was posterior to the subjugation of Greece by the Romans, as appears by the mixture of the Roman with the Greek names. The stone was seen by M. Spon at Eleusis in 1676, and probably by Mr. George Wheeler, who accompanied him, and who afterwards settled in England. But Dr. Chandler, about 100 years after, could not meet with it, though he made diligent search for it: the stone was, therefore, probably removed before his time. It is not improbable that Wheeler might have brought it with him. By some accident or other it fell into the hands of some person, who, ignorant of its value as a relic of Grecian antiquity, put it down in the back kitchen of a house in North-green, Worship Street, London, where it long served the purpose of a paving stone and chopping block. Here it was discovered in the year 1807.

ELEUTHERA ΚΙΛΙΚΙΑ, a port of Cilicia, situated at the angle which was formed by mount Taurus and mount Amanus, in the vicinity of Cappadocia and of Syria.

ELEUTHERA, a town placed by Ptolemy in the interior of the isle of Crete, and so called from Eleuther, one of the Curetes.

ELEUTHERA, or *Alabaster island*, in *Geography*, one of the Bahama islands, whose climate is healthy and soil fertile. It has a fort and a garrison. N. lat. 25° 14'. W. long. 76° 31'.

ELEUTHERÆ, in *Ancient Geography*, an ancient town of Bœotia, which was afterwards transferred to the Athenians. In this town was a temple dedicated to Bacchus, and also a cavern and a fountain.—Also, a town on the river Ister. Steph. Byz.

ELEUTHERIUS, in *Biography*, bishop of Rome, was a native of Nicopolis, and flourished in the second century. He was first a deacon of the church, and about 177, or perhaps sooner, was elected bishop on the death of Soter. Soon after his elevation, letters were addressed to him by the martyrs of Lyons, then shut up in prison, on the subject of the peculiar tenets of Montanus and his followers; the object of which was to recommend healing and temperate measures in the treatment of that sect. During the episcopate of Eleutherius, the church is said to have enjoyed much peace, notwithstanding the parties which rose up, and which zealously contended for the truth. Among these were persons headed by Florinus and Blautus, both presbyters, who maintained that God was the author of evil as well as good. They

were degraded for this hereby, and cut off from the body of the faithful. Eleutherius died in the year 193, and he is remembered by the additions which he made to the pontifical code, and which reflect credit on his liberality: of these, one enacted that a man should not abstain from any sort of meat that was commonly eaten; and the other, that sentence should not be pronounced against any one accused of crimes, unless he were present to make his defence. According to Bede it was at this period that an embassy was sent by Lucius, king of Britain, to Rome, to request the pope to send over proper persons to explain to him and his people the nature of the Christian faith. Eusebius and other early historians not having noticed this fact, it stands on very doubtful authority. Lardner. Moreri.

ELEUTHERIUS, Ελευθεριος, in *Antiquity*, a Greek word, signifying liberator, or deliverer. It was used by the Greeks as a surname, or epithet of Jupiter, given him on occasion of his having gained them the victory over Mardomus, general of the Persians, and killed, as they say, 300,000 men of his army; and, by that means, delivered them from the danger they were in of being brought under the Persian yoke.

The word is formed from ελευθερος, free.

There were also feasts solemnized on this occasion, in honour of Jupiter Eleutherius, and called *Eleutheria*. They were held every five years, with races of armed chariots, &c. The Scholiast on Pindar, Olymp. Od. 7. says, they were celebrated at Plata, the place where the victory was obtained.

The Samians had another festival of this name, in honour of the god of Love; and slaves, when they obtained their liberty, were wont to keep a stated holiday in remembrance of the happy day in which they were made free. Potter's Archæol. Græc. lib. ii. cap. xx. tom. i. p. 388.

ELEUTHERIOPOLIS, in *Ancient Geography*, a town of Palestine, situated at the distance of 6 miles S. of Diospolis, 20 miles from Jerusalem, and 24 miles from Ascalon, according to Antonine's Itinerary. On the W. and N. it was bounded by a plain, and on the E. by the mountains of Judea. It was an episcopal see under the metropolis of Cæsarea; and after the division of Palestine into two provinces, it belonged to Palestina Prima.

ELEUTHERUS, a river of Phœnicia, whose source was among the northern eminences of mount Libanus, and which, swelling at certain times of the summer by the liquefaction of the snow, might derive its name, (ελευθερος, free,) from this circumstance. Sandy, and others after him, suppose it to be the same with the Casimair, betwixt Sidon and Tyre. Whereas Ptolemy, with whom Dr. Shaw agrees, places it according to the present position of the "Nahr el Berd," 6 miles to the northward of Tripoly. Both these rivers agree in a circumstance mentioned by Pliny, that at a certain season of the year, this river is so full of tortoises, that they were easily taken. This river forms the boundary betwixt Syria and Phœnicia.—Also, a river of Sicily, the source of which is marked in De l'Isle's chart, in mount Cratas, and its mouth E. of Oretlius. Its modern name is "Fiume di Missimeh."

ELF, or **ELVES** LOCKS, in *Antiquity*, locks of hair longer than the rest, or complicated and matted hairs, which are supposed to have been twisted into knots by the latent influence of elves or fairies, to which Shakspear adverts.

—— "This is that very ma,

That plies the manes of horses in the night,
And cakes the elf locks in foul stutfish hairs;
Which once entangled much misfortune bodes."

Midsommer Nigh's Dreams.

A superstitious notion, which originated in the ignorance of

of the dark ages, and is still prevalent amongst the secluded vulgar; who consider it ominous of ill luck to have these pulled or thorn: they are therefore preserved with great care, as being esteemed a favourable appearance. To this custom Apuleius alludes, when he says, "Adjuro per dulcem capilli tui nodulum."

ELFS, or *Elvæ*, called also *Fairies*, the names of deities honoured among the Saxons, with a kind of sacrifice called *Alf blot*.

ELFS *arrovos*, a name given by the people of some parts of Scotland to certain stone weapons which they find, and which have been in use before tools and weapons of iron were used there. It is not only in Scotland that these are found, but in America, and many other places also. They are styled by some *ceravnia*, and *thunder-bolts*, and are supposed to have fallen from the clouds in storms of thunder; others, not less erroneously, suppose them to be natural fossils; but their true origin is from the workmanship of man, out of common flints, and other stones. Woodward's Cat. Foss. ii. p. 52.

ELFCARLEBY, or ELFKARLEBY, in *Geography*, a small town of Sweden, in the government of Uppl, on the Baltic sea, near the place where the river called the Dal Elbe, or Dal Efwæ, discharges itself into that sea.

ELFDAL, or ELFDALEN, a small town of Sweden, in the province of Dalecarlia.

ELFEDSJ, a mountain of Arabia, in the province of Yemen; 12 miles N. E. of Aburaisch.

ELFRIC. See *ELFRIC*.

ELPSBORG, OLD, a town of Sweden, in the province of West Gothland, with a strong castle near the sea; 4 miles S. W. of Gothenburg.

ELPSBORG, *New*, a fortress of Sweden, in West Gothland, on an island at the mouth of the Moldal; 4 miles W. of Gothenburg.

ELGA, a river, which rises 3 miles N. from Penna Major in Portugal, and runs into the Tagus, between Alcau-tara and R. Smarthal, separating the countries of Spain and Portugal, during its whole course of about 30 miles.

ELGATTAN, a town of Africa, in the kingdom of Algiers; 37 miles S. of Bona.

ELGEND, a town of Arabia, in the country of Hadramaut; 60 miles W. of Hadramaut.

ELGERSBURG, a small town of Germany, in the duchy of Saxe Gotha, not far from the Thuringian forest, remarkable for its manufacture of lamp glass.

ELGG, a town and lordship of Switzerland, in the canton of Zurich.

ELGIEHAMA, a town of Africa, in the empire of Morocco, about 2 leagues from mount Atlas.

ELGIN, the capital of the county of Elgin, formerly an episcopal see, but at present a royal burgh, or borough, is situated upon the river Lossie, about seven miles from the point where it falls into the North sea, at the distance of 108 miles from Edinburgh. The name of Elgin, from whence the county has received one of its denominations, the other being Moray, is supposed to be derived from *Helgy*, general of the army of Sigard, the Norwegian earl of the Orkneys, who, about the year 927, conquered that part of Scotland north, comprehending the present counties of Caithness, Ross, Sutherland, and Moray. For the Norwegian history relates that he built a town to the southward of Duffeyrus, and Elgin answers that description as to its site, which is also confirmed by the name. The Norwegians had an harbour at Burgh Duffeyr; several of their princes were named *Helgy*, and the inscription on the common seal of this place is, "sigillum commune civitatis de Helgyn." During the

irruptions to which this part of Scotland was subjected by the northern men, Elgin had a royal fort. It appears to have been first incorporated in the time of Alexander I. about the year 1234. The charter grants a common guild to the burghesses, whence it probably then possessed some foreign commerce; for, in 1383, a large vessel, called *Ear coast*, was the property of the guild. Mr. Pennant describes it as a good town, having many old houses built after the ancient manner, the fronts projecting over piazzas, like those in the city of Chester; and it abounds with ecclesiastical antiquities, which bespeak its former consequence. The noble cathedral, from its ruins, appears to have been once a magnificent pile. A large tower on the north and south side of the building still remains; but the central one, with the lofty spire and the whole roof, are fallen, which, with the mutilated fragments of monumental figures, representing prelates, peers, and knights, in awful dilapidation, bespeak the vanity of all attempts at posthumous perpetuity. At the east end two tiers of lancet-pointed windows remain; but the body is so ruinous as to be not easily defined. The west door is richly decorated with carving, and the choir is beautiful, with a light balustraded gallery running round the whole. Among other distinguished personages, Boethius says, king Duncan I., who was slain by Macbeth at the siege of Inverness, is buried here. This cathedral was built by Andrew de Moray, A. D. 1224, on land granted by Alexander II., whose remains, the same year, were deposited in the choir. The principal tower was erected, and some other additions made to the building by bishop Innes, as appears from an inscription on a column. The country in the vicinity being fertile, extremely pleasant, and provision plentiful, are circumstances that induce many wealthy families to take up their winter abode in Elgin, which may be considered to the highlands what Edinburgh is to the lowlands of Scotland. In 1792 it contained 658 families, and 2020 souls. Pennant's Tour in Scotland, and Sir J. Sinclair's Statistical Account of Scotland.

ELGIN, *County of*. See *MORAYSHIRE*.

ELGIS, a town of Egypt; six miles S. of Abu-Girgè.

ELGUS, in *Ancient Geography*, a small town of Asia Minor, in Lycia.

ELHAM, or ELAM, in *Geography*, a town of Kent, England, was at a former period a place of some note and consequence; for, according to Phillpott, in his history, &c. of the county, "though now the magnificent structures, which in elder times were here, be dismantled, and have only left a mass of deplorable rubbish to direct us where they stood, yet in Domesday Book it is written, that the earl of Ewe, a Norman, and near in alliance to the Conqueror, held it, and left the reputation of an honour unto it, as the reputation of the aid granted at the making of the Black Prince a knight, in the twentieth of Edward III., doth warrant." The grant of the market was made in the thirtieth of Henry III., at the instance of prince Edward, who then owned the manor, and who afterwards alienated it to archbishop Boniface. It is now the property of Sir Henry Oxenden, bart. of Broome. Elham park, of which mention occurs in the records of the time of Henry III., is now, like several other ancient parks in this part of the county, overgrown with wood. The church is a large building, consisting of a nave, aisle, and chancel, with a massive embattled tower, crowned with a small spire. The nave, which is divided from the aisles by pointed arches, opens to the chancel by a very large pointed arch. Elham is sixty-five miles distant from London, contains 27 houses and 144 inhabitants, and has four annual fairs; the market has been long discontinued. Hasted's History of Kent.

EL-HAMMA, a town of Africa, in the country of Tripoly. N. at. 34°. E. long. 10° 40'.

ELI, in *Biography*, high-priest of the Israelites, and judge of that people for 40 years, was a descendant of Itamar, the younger branch of Aaron's house, and united the offices of high-priest and judge about the year 1150 B. C. He is charged with contributing to the degeneracy of the people over whom he presided, however pious and good with respect to his own character, by want of resolution to reprove and punish immorality, and by a culpable inattention to the conduct of his own sons. The negligence of Eli in the discharge of his office entailed calamities both on the Israelites and on his own family. The former were defeated by the Philistines, the two sons of Eli were slain, and the ark, which was a symbol of the divine presence, was captured by the enemy. The afflictive intelligence overpowered the remaining strength of Eli, so that he fell backwards from his seat, and broke his neck, and died in the 98th year of his age.

ELIA, in *Ancient Geography*, a place of Greece, in the Peloponnese; supposed by Polybius to be the most pleasant part of Laconia. Livy says that it lay E. of the mouth of the Eurotas.—Also, a town of Palestine, between Naplous and Alcala, according to Antonine's Itinerary. Some suppose that it was the same with Jerusalem, which the Romans called "Elia."

ELIAC SCHOOL, in the history of *Philosophy*, a school established by Phædo of Elis, and so called from the place of his birth. This school adhered so closely to the doctrine of Socrates, that it is scarcely to be considered as a separate sect. Phædo, its founder, was descended from an illustrious family, but being deprived of his patrimony in early life, he was sold as a slave at Athens. Socrates, however, accidentally observing in his countenance traces of an ingenuous mind, persuaded one of his friends, Alcibiades or Crito, to redeem him. From this time Phædo became a disciple of Socrates, and devoted himself to the diligent study of moral philosophy under his instruction; and he adhered to the last to his master with the most affectionate attachment. He instituted a school at Elis, after the Socratic model, which was continued by Plutarch, an Elian, and afterwards by Menedemus of Eretria, whence it obtained the name of the "Eretrian" school. Menedemus, having removed this school to Eretria, delivered his lectures to his disciples, not seated on circular benches around him, which was the usual mode, but whilst they attended him in whatever posture they pleased, standing, walking, or sitting. Menedemus rose, from the contempt with which he was first received, on account of the vehemence of his mode of disputing, into high esteem, and was intrusted with a public office, to which was annexed an annual stipend of 200 talents. He discharged his trust with fidelity, and accepted only a fourth part of the appointment. He was honoured with several important embassies, by which he essentially served his countrymen; but becoming jealous of his intimacy with Antigonus, who became one of his disciples, they induced him to make his escape to this prince. Thus mortified and disappointed, he precipitated his end by abstaining for several days from food, and died in the 84th year of his age, and about the 124th olympiad. His genius was versatile and his elocution fluent. Severe in inveighing against the vices of others, and pure in his own manners, he commanded universal respect. In his mode of living he was singularly temperate; and his entertainments, consisting chiefly of vegetables, were always enlivened by liberal conversation.

Nothing farther is known concerning the preceptors of the Eliac or Eretrian schools, but that they studiously avoided,

and strenuously opposed, the sophistical fooleries of the Megaric sect, and adhered closely to the simple doctrine, and useful precepts, which they had received from Socrates. Brucker's *Philos.* by Enfield, vol. i.

ELIAS LEVITA, in *Biography*, a celebrated Jewish rabbi, who flourished in the 16th century, was a native of Germany, but spent the greatest part of his life at Rome and at Venice, where he was employed in teaching the Hebrew language. He was distinguished not only by his learning, but by his critical judgment; and accordingly he exploded many of the unfounded traditions of the Jews; and particularly that which referred the introduction of the vowel points to the time of Ezra, rightly ascribing it to a much later period, or about the 6th century of the Christian era. He was the author of several valuable works, that facilitate an acquaintance with the Hebrew language and writings. Among these we may enumerate his "Massoret Hammassoret," and his "Sopher Zickroneth," or collection of Massoretic observations from ancient authors: his "Chaldaic, Talmudic, and Rabbinic Lexicon," published in 1541, fol.;—his Hebrew glossary, entitled "Thesit," published by Fagius in 1542, 8vo.;—and several works on Hebrew grammar, &c.

ELIAS, MATTHEW, or MATTHIAS, a painter of history and portraits, born at Cassel in 1658. His parents were very poor, and he was employed in taking care of cattle, and whilst they were grazing he amused himself by endeavouring to draw figures on the ground. A painter of history, of the name of Corbeen, one day saw him drawing a fortification, with some figures, in his usual mode; and pleased with the youth's ingenuity, requested of the parents of Elias to let him educate him, and teach him the art of painting. Corbeen behaved liberally to him; and Elias repaid it by diligent study, and making very considerable progress in the art, being very grateful for the great kindness he had received from his master. Corbeen appears to have maintained him some time at Paris for his improvement, whence he went to Dunkirk, and there painted an altar-piece, representing the death of St. Babe, which raised his reputation. He designed correctly, and composed his pictures well, but did not succeed so well in colouring. His works cost him much labour to sketch out, and prepare for the easel, which defect of his genius he was conscious of, and endeavoured to conceal, by not allowing any one to see his preparations. His portraits of men are generally more approved than those he painted of women, which want grace and beauty. He died in 1741, aged 83.

ELIAS, *Mount St.* in *Geography*, a mountain near the shore of the N.W. coast of America, N.W. of Admiralty bay, and S.E. of Prince William's sound.

ELIBERIS, or ILLIBERRIS, in *Ancient Geography*, a large and rich town of Gallia Narbonensis; situated S. of Rufino. Constantine the Great re-established this town, and built a castle, which he called after the name of his mother Helena. It is supposed to be the modern *Elna*.—Also, the name of a river, which watered the above-mentioned town, supposed to be *I. Tec*.—Also, a town of Spain, in Bætica, which was a considerable place, and seated on a mountain, called *Sierra d'Elvira*.

ELIBIA, an episcopal town of Africa, in the proconsular province.

ELICA PASHNUM, in *Natural History*, a name given by the people of the East Indies to a kind of red orpiment, found very frequently in that part of the world, and given internally after calcination, in intermitting fevers.

ELICE, or HELICE, in *Botany*, a name by which the ancient Greek writers have sometimes called the willow, though the more general name among them is *asa*. *He-syctica*

fychius gives many instances of the willow being called *hélíce*.

ELICHMAN, JOHN, in *Biography*, an eminent physician, was a native of Silesia, and practised medicine with great reputation in the 17th century. His skill as a linguist was extraordinary, for he was well versed in sixteen languages. He propagated an opinion, which, to those acquainted with the idioms and sounds of the two tongues, must appear extremely excentric; that the German and the Perlian were cognate, or derived from the same origin. He made a Latin translation of the Tablet of Cebes, which, with the Arabic version and the original Greek text, were published in the year 1643, under the inspection of that celebrated critic Salmassius, who prefixed an ample and learned introduction.

ELICHRYSUM, in *Botany*, $\epsilon\lambda\iota\chi\rho\upsilon\sigma\omicron\varsigma$, or $\delta\iota\alpha\chi\rho\upsilon\sigma\omicron\varsigma$, from $\epsilon\lambda\iota\omega\varsigma$, *marshy*, and $\chi\rho\upsilon\sigma\omicron\varsigma$, *gold*, is an ancient Greek appellation for some yellow flower growing in marshy situations. The description of Diolcorides may very well apply to *Gnaphalium orientale*, or rather to *G. Stoechas* of Linnæus; especially as he mentions rough and rugged ground, not marshes, for the place of growth of his $\epsilon\lambda\iota\chi\rho\upsilon\sigma\omicron\varsigma$. What the poets intended by the above name is more difficult to determine; nor does Theophrastus lend us much assistance. Among the moderns Matthioli has taken *Tanacetum annuum* for the plant in question, but without much probability. Tournefort adopted the name for a genus of his own, which includes the two *Gnaphala* above-mentioned, among numerous other species whose flowers are not yellow, neither do scarcely any of them grow in moist places. Linnæus, therefore, who united this genus to the *Gnaphalium* of the same author, retained the latter name, as by far the most suitable of the two. This decision was reversed by Gærtner, because he followed Tournefort in establishing *Santolina maritima* as the only true *Gnaphallium*; and by assuming the specific name *verum*, he seems to imply that this plant is the $\gamma\alpha\upsilon\alpha\beta\alpha\lambda\iota\omicron\varsigma$ of Diolcorides, a point equally difficult to confirm or refute. Finally, Willdenow, at the suggestion of Jusseu, in judiciously separating from the Linnæan *Xeranthemum* such species as, contrary to the generic character, have a naked receptacle, has chosen for them the name *Elichrisum*, by which many of these plants had already been called in various books. Willd. Sp. Pl. v. 3. 1903. (*Xeranthemum*; Linn. Gen. 420. Schreb. 55t. Ait. Hort. Kew. v. 3. 179. Mart. Mill. Dict. v. 4. Jusf. 179.) Clafs and order, *Syn-genesia Polygamia-superflua*. Nat. Ord. *Compositæ nucamentaceæ*, Linn. *Corymbifera*, Jusf.

Gen. Ch. *Common calyx* imbricated; scales numerous, lanceolate, scarious, permanent, the inner ones longer than the disk, coloured, shining, forming a radiant circle round the whole compound flower. *Cor.* compound, unequal; *florets* of the disk very numerous, all perfect, tubular, funnel-shaped, much shorter than the calyx, in five equal spreading marginal segments; those of the circumference fewer, female, tubular, the length of the former, five-cleft, but rather unequal. *Stam.* (in the perfect florets) Filaments five, very short; anthers forming a cylinder about as long as the corolla. *Pist.* (in the same florets) Germen short; style thread-shaped, longer than the stamens; stigma cloven: the female florets differ only in having a simple club-shaped stigma, and no traces of stamens. *Peric.* none, except the calyx scarcely at all altered. *Seed* in both kinds of florets alike, oblong; down capillary or feathery. *Recept.* naked. *Eff. Ch.* Receptacle naked. Down capillary or feathery. Calyx imbricated, its inner scales forming a coloured spreading radius.

Willdenow enumerates twenty-three species of this genus, which include most of the finest everlasting-flowers of the

Cape of Good Hope. Several more, however, require to be added to this list from New Holland, especially *Xeranthemum bracteatum*, Venten. Jard. de la Malmaison, t. 3. Andr. Repof. t. 375, an annual species of great splendour, which, if raised on a hot-bed in the spring, or even in the natural ground, proves very ornamental to the flower-garden in autumn, and may be preferred for a winter nosegay of long duration. This flower outvies the *fulgidum*, Jacq. Ic. Rar. t. 173, Curt. Mag. t. 414, an old inhabitant of the green-house, native of the Cape. More elegant Cape species, perhaps, are the *fusculatum*, Andr. Repof. t. 242, and *sesamoides*, Curt. Mag. t. 425; but especially *proliferum*, Andr. Repof. t. 374. All these last require the shelter of a green-house or conservatory, and regular, but moderate supplies of water in winter.

ELICIT, or ELICITE, in *Ethics*, is applied to an act of the will, immediately produced by, and of the will, and received within the same.

Such are willing, niling, loving, hating, &c. These acts are denominated elicit, because, being before in the power of the will, they are now brought forth into act. But they are so far intrinsic, that some authors consider them as the will itself; and deny they ought to be distinguished from it any more than light is to be distinguished from the sun.

ELIDION PROMONTORIUM, in *Ancient Geography*, a promontory of Thrace, in the fourth part of the promontory "Eliæ," and in the eastern part of the "Rhodiorum portus," on the Bosphorus of Thrace.

ELIDRION, a word used by the early writers in *Medicine*, in several different senses; some using it as the name of mastic, others of raphanitic, and others of crude mercury. Some of the chemical writers have also made it express a certain mixed metal, composed of three parts; one silver, another brass, and the third gold.

ELIENESS, in *Geography*, a cape of Scotland, on the S. coast of the county of Fife, at the mouth of the Frith of Forth. N. lat. 56° 10'. Long. 0° 22' E. of Edinburgh.

ELIENSIS, in *Ancient Geography*, an episcopal town of Africa, in the Byzacene territory.

ELIGENDO VIRIDARIO. See VIRIDARIO.

ELIGIBILITY, in the Romish *Canon Law*. A bull of eligibility, is a bull granted by the pope, to certain persons, to qualify them to be chosen, or invested with an office, or dignity, whereof they were before incapable, by reason of want of age, birth, or the like.

The word is formed of the Latin *eligere*, to chuse; whence the word eligibilis, &c.

In several churches in Germany, a person, who is not of the chapter, cannot be elected bishop, without a bull of eligibility.

ELIGII MORBUS, a name given by some medical writers to a fitula.

ELIGMA, a name given by Nicolaus, Myrepsius, and some other authors, to that form of medicine, now called a linctus or embative.

ELIJAH, or ELIAS, furnished the *Thibbite*, from his native town or territory, in *Biography*, was one of the most distinguished of the Jewish prophets. He commenced the exercise of the prophetic office about 620 years B. C. and his first commission was directed against Ahab, whose impious character and encouragement of idolatry merited reproof. The sovereign, however, was incensed, and the prophet was obliged to withdraw from the threatened effects of his indignation. During his retirement, Providence miraculously afforded him the means of subsistence. In the mean while the country was visited with a famine, as a token of divine displeasure, and at the termination of this distress, which lasted three

three years, the prophet made another attempt, under divine admonition, to reclaim Ahab from the profligacy of his conduct. The first interview produced mutual recrimination; but Elijah determined to evince to the full satisfaction of the assembled Israelites the absolute nullity of those Sidonian deities, in whom they had confided. The contest between the prophet and the priests of Baal is beautifully narrated in the sacred writings: the result, however, was the complete triumph of the former, and the ignominious defeat of the latter, who became victims to the indignation of the people, whom they had deluded into the practice of idolatry, and the violation of the divine law. The dominion of Jehovah, as the only true God, was signally displayed: and Elijah manifested his divine commission, by the succeeding event. The country was relieved under the distress occasioned by a severe drought; for in answer to the prayers of the prophet, and in fulfilment of his promise, rain fell in great abundance. Jezebel, Ahab's wife, was enraged, and Elijah was obliged to withdraw into the kingdom of Judah, and to conceal himself for some time in the wilderness, depending for his support on the extraordinary interpositions of Providence. Elijah was afterwards employed in various commissions, which he executed with a fidelity and fortitude very honourable to his character. His companion in the closing scenes of his life was Elisha, who was selected to be his successor in the prophetic office, and who was permitted to be the witness of his miraculous translation, by which he was exempted from the common lot of mortality. This event took place in the year 896 B. C. (See 1 Kings, xvii. xviii. xix. xxi. 2 Kings, i. ii.) At a subsequent period, the Jews, misinterpreting the prophecy of Malachi (iv. 5.) entertained an opinion that Elijah would again appear on earth as the harbinger of the Messiah. But this prophecy, properly understood, would only have led them to expect a forerunner and herald of the Messiah, possessing the special power of Elijah, and animated by similar resolution and zeal in the cause of public piety and virtue. It is needless to recite the apocryphal tales that have been related by Christians and Mahometans with regard to this justly celebrated prophet; or to mention the supposititious writings that have been ascribed to him. Bayle will supply the curious with specimens of such fables.

ELIM, in *Ancient Geography*, a place on the eastern coast of the Red sea, which was the sixth station of the Israelites.

ELINE, in *Musie*, the name given by the Greeks to the weaver's song. See *SONG*.

ELINI, in *Ancient Geography*, a people of Greece, in Thesprotia. Steph. Byz.

ELINS, in *Geography*, a town of Poland, in the palatinate of Braclaw; 26 miles N. E. of Braclaw.

ELJOBELI, a town of Arabia, in the country of Yemen; 28 miles S. of Abu-Arifch.

ELIOT, JOHN, in *Biography*, known by the title of the apostle of the North American Indians, was a native of England, and born about the year 1604. He was educated at Cambridge, and engaged himself as an assistant to a school, till an opportunity should occur when he might embark in the work of the ministry. Connecting himself with the Puritan party he was obnoxious to all the evils which the Puritans suffered during the reign of Charles I. To enjoy his own opinions uncontrolled he embarked for America, and became a member of an independent church at Boston. He officiated for the pastor of that congregation during his absence in England, and would have been chosen afterwards to the joint office of minister, but he considered himself bound by a promise to reserve his services for some friends who projected a voyage similar to that which he had undertaken.

VOL. XII.

These friends left their native country in the year 1632. and settled at Roxburg, in New England. Here Mr. Eliot became their minister, and passed with his countrymen and friends the greater part of his life in the active discharge of those duties which belong to the pastoral office. In England he had suffered persecution, yet he had not learned to respect the right of private judgment, with respect to others, and, in America, maintained the divine right of congregational church authority, while he denied that of episcopacy or presbyterianism. This was the fault of the times, and persecution, it is more than probable, would have been exercised by every party, had they possessed the power of drawing the sword. Mr. Eliot, in the year 1646, began to devote himself most ardently to the cause of the native Indians, whom he wished to introduce to the advantages of civilization and Christianity. For this purpose, he learned their language, and preached among them with considerable success. He was exposed in this arduous undertaking to many and very serious hazards; but he sustained every evil with fortitude in the persuasion that his labours and sufferings would be productive of much good. He undertook and accomplished the mighty task of translating the bible into the Indian language: this was printed at Cambridge, in New England, in the year 1664, and a short time before Mr. Eliot's death, it was reprinted with corrections by Mr. Cotton, his fellow-labourer in the Indian mission. By the exertions, and influence of this excellent man, many of the wandering Indian tribes were collected into regular societies, and formed into congregations, which were instructed by him, and by others who joined him, in the manner best adapted to their capacities. At Roxburg he established a free grammar school, which has been eminently beneficial to the interests of learning in the New England states: and among the Indians he formed schools in which many were trained to useful knowledge, and some of whom became qualified for a liberal education, which they afterwards received at college. The measures adopted by Mr. Eliot were aided by large contributions from England, with which estates were purchased and placed in the hands of trustees, who were afterwards incorporated under the title of "The society for the propagation of the Gospel in foreign parts." This venerable apostle continued his labours till he arrived at his eighty-fourth year. He died in the latter end of the year 1689, having attained to the great age of eighty-six. Gen. Bog.

ELIOTT, GEORGE AUGUSTUS, lord Heathfield, youngest son of sir Gilbert Elliott of Stubbs, in Roxburghshire, Scotland, was born about the year 1718. He was educated at home by a domestic tutor till he was of an age fit to be sent to the university of Leyden, where he made considerable progress in the ancient and modern languages. At the royal military school of La Fere in Picardy, he made himself master of tactics, and of the several branches of science connected with military life. He next made a tour through those parts of the continent which were best calculated to exhibit to him in practice what he had studied in theory. Prussia was a model for true military discipline, and in her army he served for some time as a volunteer. At the age of 17 he returned to his native country, and was introduced by his father to lieutenant-colonel Peers of the 23d regiment of foot, as a youth anxious to serve his king and country in the profession of arms. He was accordingly entered as a volunteer in that regiment, where he continued something more than a year, when he joined the engineer corps at Woolwich, and pursued the studies of the place with great ardour till he was made adjutant of the second troop of horse grenadiers. With this body he went to Germany, was soon introduced into active service, engaged in several severe actions, and was

wounded at the battle of Dettingen. He rose through the gradations of captain, major, and lieutenant-colonel, and resigned the commission which he held as engineer. After this he was appointed *aide-de-camp* to George II., and became highly distinguished for his zeal and talents in the military service. In the year 1759 he was appointed to raise a regiment of light horse, which was celebrated for activity, discipline, and enterprise, under the name of "Elliott's light horse." This he commanded in Germany, where he acted as a staff officer, and on every occasion he maintained a very high reputation. He was called from the continent to be employed the second in command at the Havana. On the peace of 1763, his regiment was reviewed by the king, when they presented him with the standards they had taken from the enemy. His majesty, in testimony of their high merit, allowed them to be denominated, "The 15th, or King's Royal Regiment of Light Dragoons." In 1775 general Elliott was appointed commander in chief of the forces in Ireland, but his stay in that country was very short, and soon after he was appointed to the command of Gibraltar, where he had full opportunity to display the greatness and energy of his character. His system of life was peculiarly adapted to a service that required great vigilance. He was one of the most abstemious men of his age; his sustenance was a vegetable diet and water. He slept only four hours at a time, and inured himself to habits of order and watchfulness, so that circumstances, painful and difficult to be borne by other men, were to him rendered pleasant by daily practice. With a very moderate number of men, general Elliott foiled all the attempts of a numerous foe; and when the operations of the siege were quickened, and rendered more formidable, he still maintained that superiority of defence which kept danger at a distance. The final very serious attack by the famous floating batteries, says a writer, "only afforded one of the grandest spectacles of destruction that was ever beheld." On his return to England the gratitude of the British senate was as forward as the public voice, in rendering him that homage, which his distinguished conduct deserved. The thanks of both houses of parliament were voted to the general; and his sovereign conferred on him the honour of knight of the Bath, with a pension during his own life, and that of another, whom he should nominate. On the 14th of June, 1787, his majesty advanced him to a peerage, by the title of lord Heathfield, baron Gibraltar, permitting him to take, in addition to his family arms, the arms of the fortress which he had so bravely defended. His lordship died July the 6th, 1790, in the seventy-third year of his age. By his lady, the daughter of sir Francis Drake, he left one son and a daughter.

ELIPAND, archbishop of Toledo, flourished in the eighth century. He was the intimate friend of Felix of Urgella, and maintained, with him, that Jesus Christ was the son of God, not by nature, but by adoption. This opinion caused long and violent disputes, and was condemned by the council of the church held in the Friuli, under Paulinus, patriarch of Aquileia, in the year 791. It was afterwards condemned, together with its author, in an assembly of prelates, which had been convened by Charlemagne at Ratibon. Felix retracted, but Elipand fearlessly avowed his adherence to what he conceived to be the truth: neither the threats of his enemies, nor the persuasions of his friends, could induce him to retract an iota of what he had before vindicated. Some Spanish bishops endeavoured to convince him and Felix, who was again become the convert to his old opinions, of the truth of the reputed orthodox doctrine: they were seconded by a letter of Charlemagne himself, to the two bishops, entreating them to re-

nounce their heresy, and to unite with the other prelates of the Catholic church, in a common creed. Felix again yielded to the remonstrances of his superiors, which excited Elipand to write against him. This was in the year 799, and he died very soon afterwards. Morcri.

ELIQUATION, or LIQUATION, in *Metallurgy*, is an ingenious process of separating silver from copper by means of lead, which appears now, however, to be very little employed; but a short account of it may be here given.

When rough unrefined copper contains silver in the proportion proper for this operation, it is first melted with a large quantity of lead, and the mixed alloy is cast into loaves or conical masses. These are then set in a furnace on an inclined plane of iron, with a small channel grooved out and heated to a degree just below that of the melting point of the alloy, during which the lead melts, or, as it were, sweats out of the loaf, carrying with it the silver, and the copper is left behind as a reddish black spongy mass. This last is properly the process of eliquation. The silver-holding lead is then purified on a cupel, in the way which will be described under the article *STIVER*.

Eliqueson can only be performed with certain proportions of the three metals concerned in the process. According to Cramer (*Docimasia practica: processus* 48), every half ounce of silver requires 17 lbs. (or 544 times its weight) of lead for its extraction from copper by a single eliquation; and on the other hand, the lead should not be more than about four times the weight of the copper, otherwise the mass will prove too fusible, and the whole loaf will melt down at the heat necessary for the extraction of the lead and silver. On the other hand, if the lead is less than about $2\frac{1}{2}$ times the weight of the copper, the loaf of liquation will not yield all the lead in one process, and much of this metal, and along with it part of the silver, will remain after the operation.

The above data (allowing four times as much lead as copper) would therefore give for the due proportions of the alloy 544 parts of lead, 136 of copper, and one of silver. Other metallurgists diminish the lead somewhat, making it to the copper only as 11 to 3.

The whole process of liquation is described at length in a valuable paper by Duhamel, in the *Memoires de l'Acad.* for 1788, from which the following is a short extract.

The lead and crude silver-holding copper, being duly proportioned, are thrown into a high blast furnace, the floor of which is lined with a mixture of clay and charcoal, rammed hard, and laid in an inclined direction, so as to convey the melted metal into a separate receptacle. The crude copper is first broken in small pieces when hot, and assayed, to determine the proportion of silver. Either lead or litharge is used in the mixture; if the latter, it is mixed with charcoal to promote its reduction, and 120 parts of the litharge are taken as equivalent to 100 of lead. The furnace being first heated by itself for some hours, a basket full of the scoria from the first reduction of the copper ore is thrown in, which soon melts, and forms a vitreous glazing, that protects the walls of the furnace from the violent action of the blast. The mixed metals are then thrown in at intervals, and the whole soon melts into a triple alloy, which flows into the receptacle, whence it is tapped out into iron moulds, whereby it assumes the conical shape requisite for the subsequent eliquation. The heat required in this first operation is much less than that at which copper melts, so that the fusion and reduction of the litharge go on speedily, and in a well-managed furnace, seven loaves of liquation, each weighing about 350 lbs., may be cast in an hour.

The next process is the *eliquation*, which is performed in

a furnace constructed for the purpose, usually holding six loaves, set on iron bars, separated from each other by bricks, and having a channel beneath to convey the silver-holding lead into a basin as it melts out. The management of the heat is here of great importance. If the process goes on well, the lead flows out easily, and the loaves gradually sink down, and become honey-combed, without losing any sensible portion of their copper. If the heat is too great, particles of copper are visibly carried down with the lead, which must be immediately prevented by slackening the fire. When the lead has ceased to flow, the loaves are taken out, and when cold have a dark red colour and a crumbly texture. It requires about four hours to eliquate the loaves. The first portion of the lead is always the richest in silver, but whatever care is taken in the process a little of both silver and lead remains, together with part of the iron, arsenic, and other impurities of the copper.

To collect the small remaining portion of silver, a number of the porous loaves remaining after liquation are ranged in a kind of oven to be as nearly to fill it, and are made moderately red-hot by the flame of wood drawing through it, by which a quantity of mixed metal and scorie drop down on the hearth, consisting of lead holding a little silver, of iron, sulphur, arsenic, some copper, and scorie. This mass is washed in a stamping machine, by which the scorie are got rid of, and the metals alone remain, which undergo a further purification. When the dropping from the oven-furnace begins to be red and compact, it is a sign that all that is heterogeneous to the copper, which can be extracted in this way, is got out, and the copper itself begins to melt. The loaves are then taken out, and appear varnished with a thick vitrescent mass, which, on dropping them into cold water, cracks in every direction, and when cold, may be knocked off with a hammer, leaving the copper considerably pure. This process lasts about 30 hours.

The silver, now transferred to the lead, is afterwards refined in the usual manner.

The process of eliquation, though highly ingenious, is expensive and difficult to conduct, and requires a large supply of lead. To perform it economically, it also requires a copper holding a pretty exact proportion of silver, that is, from $\frac{3}{4}$ to $\frac{1}{2}$ this per cent. of silver, neither more nor less, and hence, where there are parcels of copper of greater or less richness in silver, much judgment is exercised in mixing them in such proportions as to allow of eliquation with the least expence.

ELIRE. See CONGE d'Elire.

ELIS, in *Ancient Geography*, a country of Greece, situated to the west of the Peloponnesus, bounded on the north by a part of Achaia, on the east by Arcadia, on the south by Messenia, and on the west by the Ionian sea. The length, from south to north, was about 20 leagues, and its breadth, from west to east, from six to seven. It was watered by a great number of small rivers, which rendered it very fertile. By ancient authors, however, it is chiefly distinguished by its groves of olive-trees; and it was much frequented by the Greeks who attended the Olympic games. Besides its olives, it furnished abundance of hemp, flax, and silk. This country was divided into three parts, *viz.* Triphyla, to the south, the Pisatide, in the middle, and Elide Proper, to the north.

ELIS, was also the name of the capital of the fore-mentioned province, situated in the northern part of it, on the river Peneus. This town, indeed, gave its name to the province, and, according to Strabo, was built soon after the siege of Troy. It was adorned with temples, porticoes, and gymnasia, where the athletes were formed for various

kinds of combat. Pluto, Bacchus, and Venus, had their respective temples in this city. The statue of Venus bore the name of "Cælestis," and it was formed by Phidias of gold and ivory. The feet of the goddess rested upon a tortoise.

ELISHA, in *Biography*, a Hebrew prophet, was the son of Shaphat, and selected by Elijah, from the pursuits of agriculture, to be his successor in the prophetic office. Many instances occur in the abstract of his history, contained in the sacred writings, which evince the miraculous powers with which he was endowed, and which served as testimonies to his prophetic commission. To the scriptures we shall refer the reader for an account of them. Elisha's life and office were continued to a very advanced age, and terminated about the year 830 B. C. See 1 Kings, xix. 2 Kings, ii.—ix. xiii.

ELISI, FILIPPO, an Italian singer of the first class, with a *soprano* voice of great compass; who, though an admirable singer, was still a greater actor: his figure was large and majestic, and his voice clear, well-toned, and full.

He was fond of distant intervals, of 14 or 15 notes, and took them well. Several airs of Jomelli, which he introduced in different operas, were calculated to shew the dexterity and accuracy with which he could form these remote intervals. He sung an "Aria parlante in Arianna e Teseo; fra stupido e pensoso," composed most admirably by Galuppi, in a new and fine style of dramatic music; in which the accompaniments, in two of three small triplets after each note in the bass, had a new and fine effect.

Elish remained here at first only one season, part of 1760 and 1761. But the impression which his performance made on lovers of music and judges of good singing, was not soon forgotten.

ELISION, in *Grammar*, the cutting off, or suppressing a vowel at the end of a word, for the sake of sound or measure.

Elisions, excepting in poetry, are but little known in English; in Latin, French, &c. they are frequent, and consist mostly in suppressions of the final *a*, *e*, and *i*: as in *Philhela amo ante alias. Si ad vitulum spectet, &c.*

In writing, elisions are often marked by an apostrophe; as *egon' quem quæram?* for *egone. Emin' ego te?* for *emine. Venissin' for venissine, &c. Cust' esperance,* for *cette; l'homme,* for *le homme.*

In the pronunciation we make frequent elisions, but do not mark them in writing: thus we write *risque it*, but pronounce *risq' it*. So the French pronounce *un' ame*, but write *une ame*. In effect, they never mark any elisions but at the end of the monosyllables *je, ne, le, te, ce, que, and la*. They never elide in the *o*, nor *u*, nor *i*, but in the conjunction *si*, before *il*; nor *a*, but in *la*.

In poetry, the syllable in which a vowel is elided, is never reckoned; and great care is taken to avoid the clashing of syllables where there is no elision, this making what they call a *hiatus* or *enjain*.

Some reduce the *schlissis* under the head of elisions; as in *monstrum, horrendum, ingens, &c.* See ECTHLYPSIS.

ELISORS, or ELECTORS, in *Law*, are two clerks of the court, or two persons of the county named by the court, and sworn, to whom the *venire* shall be directed, in cases of exception or challenge to the sheriff or coroners for kindred or partiality, for the choice of a jury. These elisors shall indifferently name the jury, and their return is final: no challenge being allowed to their array.

ELISSUS, in *Ancient Geography*, a town of the Peloponnesus, in Arcadia, which was destroyed by the Lacedæmonians.

monians.—Also, a river of the Peloponnesus, in Sicyonia, the same with *Elifon*.

ELIXATION, or LIXIVIATION, is the separation by means of solution, of a simple or compound salt, from any insoluble matter with which it is naturally or casually mixed. Water is the menstruum employed for this purpose, and the method of performing it varies according as the water is used, hot or cold. In the former case, a boiler is nearly filled with water, and when the liquor is sufficiently hot, the substance to be lixiviated is carefully stirred in: the insoluble residue is then withdrawn by means of a rake, or any other convenient instrument, and other portions of the mixture are added, and treated in the same way as the first, till the liquor is sufficiently saturated.

In cold lixiviation (as of alum ore), a cask with a false bottom is filled with the earthy mixture, and water is then poured on till the mixture is covered by it. After remaining in this state for a longer or shorter time, according to circumstances, the plug-hole at the bottom of the cask is opened and the liquor drains through, carrying with it all the soluble parts and leaving the insoluble behind: the water thus saturated is called a lixivium.

ELIXIR, in *Pharmacy*. This term was applied to a large class of liquid medicines, consisting for the most part of resins, aromatics, or other powerful medicines, infused in spirits of wine, and employed for internal use. In fact, elixirs, or nearly resemble the tinctures, in their general composition, that the term elixir is now entirely dropped in the modern pharmacopœias, and the formulæ for some of the most valuable preparations of this class have been transferred, with some alteration and much simplification, either to the class of *tinctures*, or to that of *spirits*. The term elixir, however, is still retained in popular use.

Menage derives the word from the Arabic, *elixir*, properly signifying *fraction*, because elixirs have the force of breaking diseases: others more naturally derive it from the Arabic, *alexire*, an artificial extraction of some essence; others from the Greek, *ελαιος*, oil, and *επιωω*, I draw, q. d. an extract of the oil, which is the essential part of mixts; others from the Greek verb, *αλεγειω*, I help, or *αλυσθη*, because of the great succours we receive from elixirs.

ELIXIR aloes, a name given in the late London Dispensatory to the medicine commonly known by the name of "elixir proprietatis," and now called "tinctura aloes composita," which is there ordered to be made in the following manner: take tincture of myrrh a quart; powder of fœtutine aloes, and fine saffron, of each three ounces; digest them a due time, and then press off the tincture, and filter it for use. The "elixir proprietatis" is a remedy said to have been first invented by Paracelsus. See **TINCTURE**.

ELIXIR myrrhe compositum, is now called "tinctura sabine composita." See **TINCTURE**.

ELIXIR pargoricum, a name given in the late London Dispensatory to the "elixir asthmaicum" of Quincy, which is there ordered to be made thus:

Take flower of benjamin, and strained opium, of each a dram; camphor, two scruples; essential oil of aniseeds, half a dram; rectified spirit of wine, a quart; digest all together a proper time, and then strain off the spirit. This always tickling coughs, relieves difficult breathing, and is useful in many disorders of children, particularly in the whooping-cough. The dose for an adult is from 50 to 100 drops. This is now called "tinctura opii camphorata." See **TINCTURE**.

ELIXIR, sacred. See **TINCTURE of Rhubarb**.

ELIXIR salutis. See **TINCTURE of Sena**.

ELIXIR stomachic, is prepared by boiling two ounces of gentian-root, one ounce of Curacao oranges, and half an ounce of Virginia snake-root, and infusing them for three or four days in two pints of French brandy, and then straining out the elixir. This is an elegant stomachic bitter. A small glass, twice a day, relieves in flatulencies, indigestion, want of appetite, and similar complaints. A large dose also relieves the gout in the stomach.

ELIXIR of vitriol, acid, is prepared by gradually mixing one pint of the aromatic tincture with three ounces of oil of vitriol; and after the fœces have subsided, filtering the elixir through paper in a glass funnel. This is said to be an excellent medicine for hysterical and hypochondriac patients, afflicted with flatulencies, arising from a relaxation or debility of the stomach, and intestines. It is to be taken on an empty stomach, twice or thrice a day, in a glass of wine or water, or of any bitter infusion; and the dose may be from 10 to 40 drops.

ELIXIR, among the *Alchemists*, is used for the philosopher's stone, or the powder of projection; and sometimes for an universal medicine, which will cure all diseases, called, by way of excellence, the *grand elixir*.

Those two things most alchemists take to coincide; so that what will make gold, they think, will cure all diseases. See **PHILOSOPHER'S STONE**.

The notion of a grand elixir is of a long standing.

ELIXIS, a name given by some of the *Old Writers* to that form of medicine now called a *linctus*.

ELIXOIA, in *Ancient Geography*, an island of the Hyperboreans, at the mouth of the river Caranbyca (the Dwina;) now the *Podefemsta* at the mouth of the Dwina.

ELIZABETH, in *Biography*, queen of England, one of the most celebrated sovereigns of this or of any country, was the daughter of Henry VIII. by his queen Anne Boleyn, and born in the year 1533. She was educated in the principles of the Protestant religion, and was distinguished for her attainments in classical literature. By the last will of her father she was nominated third in order of succession, but by the influence of the duke of Northumberland, she was by an act of Edward VI. excluded from the crown, to which nevertheless she attained on the death of her sister Mary. During, however, the reign of that sister, she was treated with the utmost indignity and severity, committed to the Tower, and threatened with still more awful calamities. Her confinement in this fortress was short, for even the judges of Mary could find no plea against her, and she was sent from thence to Woodstock, where, though kept in safe custody, she was treated with much respect. Her sufferings and her principles endeared her to the nation, and she became so extremely popular that it was, in a short time, deemed impolitic to put any restraint upon her. When set at liberty she chose study and retirement, and was very submissive to the will of her sister. Attempts were made to draw her into some heretical declarations, but in every instance she acted with so much prudence and caution as to give her enemies no hold upon her. She complied with the external forms of the established religion, though it was well known, she was inimical to the principles which her sister espoused, and which led her to the most atrocious acts of cruelty.

On the death of Mary, Elizabeth was immediately proclaimed sovereign, to the satisfaction of the great majority of the people; indeed almost all descriptions of persons rejoiced in the change, as that in which the glory of the country, and the safety of individuals seemed so much concerned. Elizabeth was at Hatfield when the heard of her sister's death, and, after a very few days, she repaired to the

ELIZABETH.

he metropolis through immense crowds of the people, who strove with each other who should display the strongest testimonies of their respect and affection. On her entrance into the Tower, her mind was so strongly affected with a comparison of her present prosperity with her former sufferings, that she fell on her knees, and expressed the warmest acknowledgments to Almighty God for the deliverance which had been afforded her from the most cruel persecution; a deliverance, she said, no less miraculous than that which Daniel had received from the den of lions. From this moment, in the true spirit of the Christian religion, she determined to forget all the injuries she had endured, and forgave all who had been inimical to her principles during the reign of Mary.

Proposals of marriage had been formerly made her by the king of Sweden, which she thought fit to decline: a similar offer was now made by Philip of Spain, her late sister's husband, which she likewise rejected, signifying, in both cases, that she was determined to lead a single life. She now turned her thoughts to the reformation of the principles of the reformation, which was effected by the first parliament that met after her accession, and from this period England took the decided station among Protestant countries, which it has ever since maintained.

Elizabeth at this time arrogated to herself that supremacy over the faith and worship of her subjects, which before was supposed to belong exclusively to the court of Rome. In her several plans respecting religion, she proceeded with great caution; she checked the forward zeal of those who were for oversteering, at once, the established religion of the country; she published a proclamation by which she prohibited all preaching without a special licence, and though she dispensed with these orders in favour of some preachers of the Protestant religion, she took care that they should be the most calm and moderate of the party.

By the Catholics, Mary, the young queen of Scotland, who had received her education in France, was regarded as the true sovereign of England; she even assumed the ensigns and title of English royalty, which Elizabeth could never forget nor forgive. Mary, when she found it was in vain to look to the crown of England, in opposition to the reigning queen, wished to be regarded as the presumptive successor to the throne, which was refused. From this time Mary was considered as a rival, and every means was taken to thwart her projects, and disappoint her expectations. The conduct of Mary, which will be more distinctly noticed under her own article, was not only imprudent in the highest degree, but furnished ample scope for the invectives of her enemies. In 1568, she was obliged, from fear of her own subjects, to take refuge in England, and her retreat was so sudden, that she had no opportunity of giving to Elizabeth any previous intimation of her intentions. It was resolved by the English ministry to detain her a perpetual prisoner, and a sort of pretext was given them, by her offer to submit the justice of her cause to the judgment of her sister queen. An accusation was accordingly brought against her by the regent Murray, and commissioners appointed to hear the case. Mary refused to reply to the charges exhibited against her, and demanded to be restored to her kingdom, or to be sent to France, a favour which was as positively denied. The consequence of this measure was a secret negotiation between Mary and the duke of Norfolk, the head of the Catholic party, who proposed marriage to her, and was supported in his views by the kings of France and Spain. The discovery of this project caused the duke to be committed to the Tower. This was followed by other rebellions and insurrections which excited in the mind of Eliza-

beth much uneasiness; and various negotiations were carried on with the Scots for her restoration, but without effect.

Elizabeth was now considered as the head of the Protestant party in Europe, and in this character she made a treaty of alliance with the French Hugonots, and afforded them aid in men and money, and received in return the port of Havre-de-Grace, which was held some time by an English garrison, but was at length obliged to surrender. Between France and Spain there was an avowed league for the extirpation of heresy, and Elizabeth felt herself justified, by way of self defence, to give assistance to the cause of Protestantism, wherever it was in danger of being suppressed by force. She not only gave a favourable reception to the Flemish exiles who took refuge in England, from the tyranny of the duke of Alva, and brought over their arts and industry, but she ventured upon stopping a large loan of money which some Genoese merchants were sending by sea to the duke, and which some Hugonot privateers had seized and brought into the English ports. The Spanish court retaliated, by exciting an insurrection among the English Catholics, at the head of which was the duke of Norfolk, who was afterwards discovered, tried, convicted and beheaded, for his crimes. On the horrible massacre at Paris, in August 1572, Elizabeth put herself and court into deep mourning, and received, with a marked and solemn silence, the French ambassador who was sent to apologize for the bloody deed. But she was too prudent to break entirely with the French court, and suffered negotiations to be carried on for her marriage with the king's brother, the duke of Alençon, the youngest son of Catherine de Medicis, whom, after a long courtship, she rejected, and sent back to the Netherlands in great wrath.

In 1575, Elizabeth, as the head of the Protestants, was offered the possession and sovereignty of the revolted Dutch provinces, on condition of becoming their protectress against the Spaniards. This for the present she rejected, though in about three years after she ventured to sign a treaty of alliance with the united states. In the year 1584, an association was entered into by the subjects of England, comprehending persons of all ranks, with a view of affording her personal protection against her enemies, who were supposed to be chiefly adherents to Mary Queen of Scots. About this period laws of great severity were enacted against the Jesuits and popish priests, a plot having been discovered to assassinate the queen, which was known to be favoured by the papal court. Elizabeth now ventured to set at defiance the hostility of Spain, by entering into a treaty with the revolted Low Countries, by which she engaged to assist them with a considerable force, on condition of having some of their ports put into her hands for security. She might indeed have possessed herself of the sovereignty, but was satisfied with having her favourite, the earl of Leicester, admitted into the council of the states. At the same time she sent a powerful armament against the Spanish settlements in the West Indies, under sir Francis Drake, and entered into a league of mutual defence with James king of Scotland, whose friendship she cultivated, though she kept his mother in prison.

Another conspiracy against the life of Elizabeth was detected in 1586; the persons principally engaged in it unquestionably maintained a correspondence with the unfortunate Mary, though it has been doubted whether she was privy to the intended assassination. The plot was unravelled by her minister Walsingham, who discovered the plan to be carried on till he had detected all the conspirators, and had sufficient evidence under her own hand, to involve the queen of Scots as a participator in the intended offence. Fourteen of the conspirators were convicted and executed, and Mary herself

herself was brought to trial before a grand commission of forty noblemen and privy counsellors, who after the usual forms pronounced and signed a sentence of death against her. But Elizabeth was unwilling to sign the warrant of execution, and was anxious to remove the odium of the deed from herself. Parliament, probably by her desire, demanded the execution of the sentence, as she wished it to be supposed that her compliance was extorted from her by the clamours of the people. She is, however, charged with being privy to an attempt made upon the keepers of the prisoner to induce them to disavow her in a more private manner. This they nobly rejected, and a letter, signed by Walsingham to sir Amias Poulet, on this subject is still extant, to the disgrace of that minister who could condescend to so base an expedient. At length the warrant was made out, and the deed was executed, Feb. 5. 1586-7. As soon as the news was communicated to the queen, she affected an excess of grief and astonishment. She even pretended that the thing had been done contrary to her inclination, and committed to prison Davison, who had been her agent in the business, and had him brought to trial and heavily fined. In no instance, perhaps, was hypocrisy carried to a higher pitch than in this by Elizabeth, which was equally derogatory to her good sense, and to the known firmness of her mind in difficult cases. The dissimulation of the queen was not, however, without its effect; it softened the resentment of the king of Scotland, who, instead of revenging the death of his mother, entered into an amicable correspondence with the court of England.

The next thing which engaged the attention of the queen and her ministers was the famous Armada, which, as we have seen, was intended for the entire conquest of the island. (See ARMADA.) Elizabeth next became the ally of Henry IV. in order to vindicate his title, and establish him firmly on the throne of France, and for some years the English auxiliaries served in France, while several naval expeditions, undertaken by individuals, or by the queen, raised the reputation of England to an extraordinary height. At this period Robert Devereux, earl of Essex, the queen's favourite, highly distinguished himself, but the events of his life have been already described. See DEVEREUX.

In 1601, Elizabeth held a conference with the marquis de Rosni, who is better known in history as the celebrated Sully, for the purpose of establishing, in concurrence with England, a new system of European power, with a view of controlling the vast influence of the house of Austria, and producing a lasting peace. The queen coincided with his projects, and the French minister departed in admiration of the solidity and enlargement of her political views. The queen, having suppressed an insurrection in Ireland, and obliged all the Spanish troops sent to its assistance to quit the island; she turned her thoughts towards relieving the burdens of her subjects; she abolished a number of monopolies, and became extremely popular. But the execution of her favourite, the earl of Essex, gave a fatal blow to her happiness. When she learnt from the countess of Nottingham, that he had solicited her pardon, which had been concealed from her, she at first became furious with rage, and when the violence of anger subsided, she fell into the deepest and most incurable melancholy, rejecting all consolation, and refusing food and sustenance of every kind. She remained for days sullen and immovable, "feeding," says the historian, "her thoughts on her afflictions, and declaring life and existence an insufferable burden to her". Few words she uttered, and they were all expressive of some inward grief, which she cared not to reveal: but sighs and groans were the chief vent which she gave to her dependency, and which, though they discovered her

sorrows, were never able to ease or assuage them. Ten days and nights she lay upon the carpet, leaning on cushions which her maids brought her, and her physicians could not persuade her to allow herself to be put to bed, much less to make trial of any remedies which they preferred to her. Her anxious mind at last had so long preyed on her frail body, that her end was visibly approaching; and the council being assembled, sent the keeper, admiral and secretary, to know her will with regard to her successor. She answered with a faint voice, that, as she had held a regal sceptre, she desired no other than a royal successor. Cecil requesting her to explain herself more particularly, she subjoined, that she would have a king to succeed her, and who should that be, but her nearest kinsman, the king of Scots? Being then advised by the archbishop of Canterbury to fix her thoughts upon God, she replied, that she did so, nor did her mind in the least wander from him. Her voice soon after left her; her senses failed; she fell into a lethargic slumber, which continued some hours, and she expired gently, without farther struggle or convulsion, in the 70th year of her age, and forty-fifth of her reign.

"So dark a cloud overcast the evening of that day which had shone out with a mighty lustre in the eyes of all Europe. There are few great personages in history who have been more exposed to the calumnies of enemies, and the adulation of friends, than queen Elizabeth, and yet there is scarcely any whose reputation has been more certainly determined by the unanimous consent of posterity. The unusual length of her administration, and the strong features of her character, were able to overcome all prejudices; and obliging her detractors to abate much of their invectives, and her admirers somewhat of their panegyrics, have at last, in spite of political factions, and what is more, of religious animosities, produced an uniform judgment with regard to her conduct. Her vigour, her constancy, her magnanimity, her penetration, vigilance, and address, are allowed to merit the highest praises, and appear not to have been surpassed by any person that ever filled a throne: a conduct less rigorous, less imperious, more sincere, more indulgent to her people, would have been requisite to have formed a perfect character. By the force of her mind, she controlled all her more active and stronger qualities, and prevented them from running into excess. Her heroism was exempt from temerity, her frugality from avarice, her friendship from partiality, her active temper from turbulence and a vain ambition; she guarded not herself with equal care or equal success from lesser infirmities: the rivalry of beauty, the desire of admiration, the jealousy of love, and the sallies of anger."

Under the wise conduct of Elizabeth the Protestant religion was firmly established, factions restrained, government strengthened, the power of Spain nobly opposed, and without, oppressed neighbours supported, a navy created, commerce rendered flourishing, and the national glory aggrandized. No sovereign was ever more jealous of power and prerogative; yet she was truly ambitious of obtaining the general affections of her subjects. She made, during her long reign, frequent progresses, and paid many domestic visits, which were partly the result of policy, partly of economy. She wished to be thought a friend to literature, but never displayed the liberality of a patroness. Her manners and language were but little suited to the delicacy of the female character.

"When we contemplate her as a woman," says Mr. Hume, "we are apt to be struck with the highest admiration of her great qualities and extensive capacity, but we are apt also to require some more softness of disposition, some greater

ELIZABETH.

greater lenity of temper, some of those amiable weaknesses by which her sex is distinguished. But the true method of estimating her merit, is to lay aside all these considerations, and consider her merely as a rational being, placed in authority, and entrusted with the government of mankind. We may find it difficult to reconcile our fancy to her as a wife or mistress, but her qualities as a sovereign, though with some considerable exceptions, are the object of undisputed applause and approbation." The laxity of her morals in some particular points has given occasion to reproach, and it is impossible to justify her conduct with regard to the queen of Scots, but she was nevertheless great as a sovereign, though not estimable as a woman. Hume's Hist. of England.

ELIZABETH, empress of Russia, was the daughter of Peter the Great, was born in 1709, and when arrived at years of maturity, was admired for her personal attractions. By the revolution of the year 1741, Ivan, whom the empress Anne had nominated for her successor, was set aside, and Elizabeth renewed in her person the line of Peter the Great upon the throne of Russia. Although her beauty, as well as rank and large dowry, occasioned several offers, none of them were accepted, and she died single. From the period of her accession, she renounced all thoughts of the nuptial state, and adopted her nephew Peter. Her dislike to marriage, however, did not proceed from any disinclination to men; for she freely owned to her confidants, that she was never happy but when in love; if a capricious passion, which was ever changing its object, may be dignified by that name. The same characteristic warmth of temper hurried her no less to the extremes of devotion; she was scrupulously exact in her annual confessions of the wanderings of her heart, in expressing the utmost contrition, and in punctually adhering to the minutest ceremonies and ordinances of the church. With regard to her disposition, she is generally styled the humane Elizabeth; as she made a vow never to inflict any capital punishments during her reign, and she is also said to have shed tears upon the news of victories gained by her troops, from the reflection that they were not obtained without great bloodshed. By an edict passed in her reign, corporal penalties were substituted, except in some cases of high treason, in the room of capital sentences. From this suppression of capital punishment in all instances excepting treason, the humanity of Elizabeth's disposition has been highly extolled, and she has been represented, not only by the lively Voltaire, but even by the sagacious Blackstone, as a pattern of legislative clemency. It should be recollected, however, that the state prisons were filled with wretched sufferers, many of whom, unheard of and unknown, perished in damp and unwholesome dungeons; besides, the state inquisition, or secret committee, appointed to judge persons suspected of high treason, had constant occupation during her reign; many, upon the slightest surmises, were tortured in secret; many underwent the knout, and expired under the infliction of this torture. Two ladies of rank underwent this cruel punishment, had their tongues cut out, and were banished into Siberia. The mind of Elizabeth was perpetually haunted by suspicions of the insecurity of her elevated station, and by the dread of a revolution similar to that which had placed her on the throne. Elizabeth established the Academy of Arts, and annexed it to the Academy of Sciences. (See ACADEMY.)

This empress died in 1761, the 21st year of her reign and the 53d of her age; in December, the same month in which she was born, and in which she was advanced to the throne. Peter III. whom she nominated as her successor, was in

about six months reduced to the necessity of abdicating the empire, in favour of Catharine II. (See CATHARINE.) He died on the 7th day of his confinement at Robicha, a small imperial palace, 20 miles from Peterhof, and his remains were interred in the church of the convent of St. Alexander Nevski at Petersburg. Coxe's Travels in Russia.

ELIZABETH, in *Geography*, a post-town of America in Lancaster county and state of Pennsylvania, containing about 30 houses, a Dutch church, and 546 inhabitants; 18 miles N.W. by W. of Lancaster, and 84 W. by N. of Philadelphia.—Also, a short southern arm of James river, in Virginia; affording an excellent harbour, sufficiently capacious for the accommodation of 300 ships. The channel is from 150 to 230 fathoms wide, and at common flood-tide it has 13 feet water to Norfolk, seated near the mouth of its eastern branch.

ELIZABETH'S Bay, a bay in the straits of Magellan, at the entrance of which are two small reefs, that appear above water. All round the bay there is good landing, though it is much exposed to the westerly winds. The best place for anchoring is Passage point. Sufficient wood may be procured here for the use of ships, and there is good watering at a small river. The island affords celery and cranberries. S. lat. 50° 43'. W. long. 73° 24'. Variation 2 points easterly.

ELIZABETH, *Cape*, a lofty promontory on the N.W. coast of America, S.W. of Prince William's sound. N. lat. 59° 10'. E. long. 207° 45'.—Also, a headland and township of North America, in the county of Cumberland, and state of Maine. The cape lies in N. lat. 43° 33'. W. long. 70° 10'. E. by S. from the centre of the town 9 miles. The town contains 1355 inhabitants. It was incorporated in 1765, and lies 126 miles N.E. of Boston.

ELIZABETH City, a county of Virginia, in America, lying between York and James rivers, having Warwick and York counties on the W. and Chesapeake bay on the E. and N. On its sea-coast are several small islands, the chief of which are Long and Egg islands. The S.E. extremity of the county is Point Comfort. It contains 1256 free inhabitants, and 1522 slaves.

ELIZABETH City, a town of Pasquotank county in N. Carolina, in which is a post-office; 299 miles from Washington.

ELIZABETH'S Island, lies in the straits of Magellan, and affords a supply of fresh water, celery, and some wild fowl. The shores also abound with shell-fish.

ELIZABETH Islands, a group of small islands on the S.E. side of Buzzard's bay, extending south-westerly from the extremity of Barnstable county in the Massachusetts, and bearing N.W. from Martha's vineyard; situated between 41° 24' and 41° 32' N. lat., and between 70° 33' and 70° 56' W. long. They are about 16 in number; and the chief of them are Nashawn, Pasqui, Nashawenna, Pinequefe, and Cattabunk: all these belong to Duke's county.

ELIZABETH-Grand, a town and district of Russia, in the province of Catherinenflaf, seated on the Ingul, falling into the Bog.

ELIZABETH-Town, a post-town and borough of America, in Essex county, New Jersey; pleasantly situated on a small creek which enters into Arthur-Kuk. Its soil is equal to any in the state, of which it is one of the oldest towns, having been purchased of the Indians in 1664, and settled soon after. The compact part of the town contains about 150 houses, 2 brick churches, one for Presbyterians and the other for Episcopalians, and an academy. It lies

15 miles S.W. by W. of New York.—Also, a town of Alleghany county, in Pennsylvania, on the S.E. side of Monongahela river, between Redstone Old Fort and Pittsburg, about 18 miles from each. Many boats are built here for the trade and emigration to Kentucky, and in the vicinity are several saw-mills. It has 1904 inhabitants. Another town of the same name in this county contains 111 inhabitants. N. lat. $40^{\circ} 13'$. W. long. $79^{\circ} 23'$.—Also, a post-town of Maryland, and capital of Washington county, formerly called "Hagarstown," seated in the fertile valley of Conococheague. The houses are 300. Episcopalians, Presbyterians, and German Lutherans have each a church. The court-house and market-house are handsome buildings, and the gaol is a substantial edifice of stone. The trade with the western country is considerable, and there are many mills in the neighbourhood on Antietam creek.—Also, the chief town of Tyrrel county, in Edenton district, North Carolina. It has a gaol, court-house, and a few dwelling-houses, 40 miles from Fayetteville, and 55 from Wilmington.—Also, a post-town and the chief in Bladen county, North Carolina, seated on the N.W. branch of Cape Fear. It has a court-house, gaol, and about 20 houses, 36 miles S. of Fayetteville, and 47 N.W. of Wilmington.—Also, a post-town of Essex county, in New York, situated on the W. shore of lake Champlain, N. of Crown point, containing 900 inhabitants; 529 miles N. by E. from Washington.—Also, a township in the county of Leeds, in Upper Canada; the ninth township in ascending the river St. Lawrence; well watered by the river Tonianta, and three other streams.

ELK, a creek of America, in Northumberland county, Pennsylvania, which, uniting with Penn's creek, falls into the Susquehanna, 5 miles below Sunbury.—Also, a navigable river of the eastern shore of Maryland, which rises in Chester county, Pennsylvania, by two branches, *viz.* Big and Little Elk creeks. At their confluence stands Elkton.—Also, a short navigable river in the state of Tennessee. It rises on the N.W. side of Cumberland mountain; runs S. westerly, and falls into the Tennessee, a little above the Muscle shoals; about 40 miles W.N.W. of the creeks' crossing place.

ELK lake, one of the chain of small lakes which connects the lake of the Woods with lake Superior. N. lat. $48^{\circ} 41'$. W. long. 93° .

ELK, in *Ornithology*, a name by which many have called the cygnus ferus, or wild swan, a species of *Anas*. See DUCK.

ELK, in *Zoology*, a species of the cervus, or stag. See CERVUS *alces*.

ELKARRIE, in *Geography*, a town of Arabia, in the country of Yemen; 24 miles N.E. of Abu-arish.

ELKASSARAN, a town of Arabia, in the country of Yemen; 8 miles E. of Chamir.

ELKE, is mentioned in our *Statutes*, as a kind of yew to make bows. 32 Hen. VIII. cap. 9.

ELKHORN, in *Geography*, a small water of Kentucky river, in America. The Elkhorn lands, situated in a bend of Kentucky river in Fayette county, where this small river rises, are much esteemed.

ELKRIDGE, a small town of America, in Ann Arundel county, Maryland, on the S. bank of Patapco river, and on the W. side of Deep-run; famous for the bright tobacco called "Kate's foot;" 8 miles S.W. of Baltimore, and 19 N.W. of Annapolis. N. lat. $39^{\circ} 12\frac{1}{2}'$.

ELKTON, a post-town of considerable trade, at the head of Chesapeake bay, in Maryland, and the capital of Cecil county; though, says Mr. Weld, it is a dirty disagreeable place. The tide flows up to the town, and it derives great advantages from the carrying trade between Baltimore

and Philadelphia. Upwards of 250,000 bushels of wheat are collected here annually for supplying those markets, or the neighbouring mills. Elkton consists of one street, containing about 90 houses, irregularly built, a court house, and a gaol. On the W. side of the town is an academy. It is 10 miles N.E. of Charlestown, 47 S.W. of Philadelphia, and 66 N.E. of Baltimore.

ELKUVAR, a river of Russia, which runs into the Tobol.

ELL, ULNA, a measure, which obtains, under different denominations, in most countries.

The ell is the standard, or measure, whereby cloths, stuffs, linens, silks, &c. are usually measured, or estimated, answering, in good measure, to the yard of England, the canna of Italy, the vara of Spain, the palm of Sicily, &c.

Servius will have the ell to be the space contained between the two hands when stretched forth; but Suetonius makes it only the cubit.

The ells which occur most frequently in England, are English and Flemish; the ell English contains three feet nine inches, or one yard one quarter, English measure; the ell Flemish contains twenty-seven inches, or three quarters of a yard; so that the ell English is to the Flemish ell as five to three.

M. Ricard, in his *Treatise of Commerce*, reduces the ells thus: an hundred ells of Amsterdam are equal to ninety-eight three quarters of Brabant, Antwerp, and Brussels; to fifty-eight and an half of England and France; to an hundred and twenty of Hamburg, Francfort, Leipzig, and Cologne; an hundred and twenty-five of Breslaw; an hundred and ten of Bergen and Drontheim; and an hundred and seventeen of Stockholm.

ELLEDAT, in *Geography*, a town of Ceylon; 12 miles S. of Candy.

ELLEHOLM, a small and very ancient town of Sweden, in the province of Elkingen; 7 miles from Carlshamn, which formerly had a castle.

ELLENBOGEN, a town of Germany, in the county of Bregentz; 17 miles S.S.E. of Bregentz.

ELLENHOFEN, a town of Germany, in the county of Bregentz; 14 miles E.N.E. of Bregentz.

ELLERENA, a town of North America, in Mexico, and province of Zacatecas; 25 miles W. of Zacatecas.

ELLERENA, a town of Spain, in the province of Estremadura, situated in a low tract abounding with fruits and pastures, at the foot of Sierra Morena, and containing about 7000 inhabitants, distant 17 leagues S.S.E. of Merida, near the border of Andalusia. In the mountains, 4 miles from the town, a silver mine was formerly discovered.

ELLESMEKE, a market town of Shropshire, which lies 16 miles N.N.W. from Shrewsbury, and 176 N.W. from London. It is pleasantly situated on an eminence near the margin of a deep lake, which occupies a space of one hundred and twenty acres, well stocked with fish, and particularly eels, whence the town derives its name. From its form and other circumstances it appears to have been a very ancient place, and lying in the marches of Wales, being distant from the boundary stone three miles, a mound called Wat's dyke six, and about nine from the celebrated Clawdd Offa: it was at an early period very strongly fortified. According to the Chronicle of Chester the castle, with the fertile district around, was given by king John as a dower with his natural daughter Joan, when he bestowed her in marriage on Llewelin, prince of North Wales. After the death of that prince it came into the family of L'Estrange, and John L'Estrange was governor of the castle in the thirty-third year of Henry I. Leland speaks of the castle as

standing in his time, that the town had four well-built streets, and was privileged with two annual fairs; but at that time had no market. The building is now no more, and the site, still surrounded with three walls and fosses, is formed into a bowling green, from whence is a most delightful prospect. The number of houses, as appears by the returns made under the population act, was 1035, inhabited by 5553 persons.

This town formerly gave name to the hundred, which at present is denominated Pim-hill. It gives the title of baron to the family of Egerton. Thomas Egerton, celebrated for his talents and virtues, was made lord keeper of the great seal by queen Elizabeth; and lord high chancellor, baron of Ellesmere, and viscount Brackley, by king James: and a descendant, John William Egerton, is now lord Ellesmere, and earl of Bridgewater. This place has of late been much benefited by a navigation, called the Ellesmere canal, which forms a communication between the river Dee at Chester, and the Severn at Shrewsbury. This was cut under the sanction of an act passed in the thirty-fourth year of the present reign; and, by subsequent acts, has been extended and ramified by collateral branches; which communicate with other parts of Shropshire, and the interior of Wales. The aqueduct, formed by a bridge of numerous arches, over which the canal passes across the wide-flowing river Dee, is considered as a *chef d'œuvre* of modern engineering, and masonry. This system of inland navigation in the counties of Chester, Flint, Denbigh, and Salop, was first suggested by Mr. John Duncombe in 1780; on which the opinion of Mr. Jessop having been taken, and an act obtained, the execution of this grand design was confided to Mr. Thomas Telford, the engineer, under whom the same has been now nearly completed. (See CANAL.) A rail-way branch has been made to Plas-Kynaston collieries since that article was written. A steam-engine at Ellesmere park, erected for the purpose of supplying the Wirral part of the line with salt water from the Mersey, has destroyed the fish in this part of the canal, and is said to have much inconvenienced some farmers on the line, by the want of fresh water for their cattle, although some miles inland, as is also the case on the Droitwich canal, from the salt springs by which the same is supplied. On the opening the famous Port-Cyfylyt aqueduct, an appropriate oration was delivered, and was since printed, see the Gentleman's Magazine, vol. lxxv. p. 1228.

ELLEZELLES, a small town of France, in the department of Jemappe, chief place of a canton in the district of Tournay, with a population of 4008 individuals. The canton contains four communes and 14,430 inhabitants, upon a territorial extent of 70 kilometers.

ELLICHPOUR, a fine city of Hindoostan, the capital of a large province or district of the same name; subject to the Nizam; but paying a "chout," or nominal fourth part of its revenues to Nagpore. It was anciently the chief city of Berar Proper, by which Mr. Rennell distinguishes the province known in Ayin Acbaree by that name; for Berar, in modern acceptation, includes the whole country between Dowlatabad and Orissa; the eastern part of which was neither reduced by Acbar, nor even known, in particulars, to the author of the Ayin Acbaree; 122 miles nearly W. of Nagpore. N. lat. 21° 12'. E. long. 78° 51'.

ELLIGER, OTTOMAR, in *Biography*, called the Old, a painter of fruit and flowers; he was born at Gottenburg in 1633. He studied and imitated with great success the peculiarities of Daniel Segers. Elliger's works are much esteemed upon the continent, but are here very little known. He passed some time at the court of Berlin, invited there on

account of his merit and reputation; it is not known when or where he died.

His son, known by the name of the younger Elliger, studied historic painting. He was born at Hamburg in 1666, and having acquired some facility of handling under his father, he was placed as a disciple with Michael Van Musscher, a skillful painter of conversation pieces: but aiming at something of a higher cast, he took Gerard Laursse for his master, under whom he quickly acquired those principles of composition which he desired, and working upon them, gained considerable reputation.

Several of his largest and best works are at Amst. rdam. The dealer of Mentz sewerd, in a very ample manner, the exertion of his talents upon two designs, one, the "Death of Alexander," the other, the "Nuptials of Pelus and Thetus," which were much admired and applauded. Elliger, however, politely declined the honour of being appointed principal painter to the dealer; and unhappily gave up the latter part of his life to dissipation and drunkenness; which weakened his talents and ruined his reputation. He died in 1732, æg. d. 66.

ELLINGTON, in *Geography*, a township of America, consisting of about 200 families and 1209 inhabitants in Tolland county, Connecticut, distant about 12 miles N.E. of Hartford city, and 6 W. of Tolland.

ELLIOTT, WILLIAM, in *Biography*, an English engraver, of a mild and benevolent mind, who resided in London, and died in the year 1766. He engraved some large plates for the elder Boydell, but his works are not highly celebrated. A large landscape, after Gasper Poulin, several after the Smiths of Chichester, and a portrait of Helena Furmans, (the second wife of Rubens,) are mentioned by Strutt, as among the best of his engravings.

ELLIPOMACROSTYLA, in *Natural History*, the name of a genus of crystals. The word is derived from the Greek ελλειψις, *imperfect*, μακροσ, *long*, and στυλος, *a column*, and expresses an imperfect crystal, with a long column. The perfect figure of crystal being a column terminated by a pyramid at each end; those which want this character are esteemed imperfect; and accordingly bodies of this genus are defined to be imperfect crystals, with single pyramids; one end of their column being affixed to some solid body, and composed of thin and slender hexangular columns, terminated by hexangular pyramids. Of this genus there are several species.

ELLIPOPACHYSTYLA, the name of a genus of crystal. The word is derived from the Greek ελλειψις, *imperfect*, παχος, *thick*, and στυλος, *a column*, and expresses a crystal of the imperfect kind, with a thick column. The bodies of this genus are crystals composed of an hexangular column, considerably thick and short, and affixed irregularly at one end to some solid body, and terminated at the other by an hexangular pyramid. Of this genus there are only two known species.

ELLIPSE, or ELLIPSIS, in *Geometry*, one of the conic sections, is formed by the common section of a plane and a conic surface, when the curve line common to the two surfaces completely surrounds the cone, and the cutting plane is neither parallel to the base of the cone, nor takes a contradictory position. See CONICS, Def. 5th, and Schol. Prop. 34.

The periphery of the ellipse, like the circle, returns into itself, and completely incloses space. In familiar language, this figure is called an oval.

The definitions relating to the ellipse have already been laid down in the article CONICS, where the principal pro-

erties which it possesses in common with the other figures, produced by the intersection of a plane and a conic surface, have been demonstrated. The more characteristic properties, which are peculiar to the ellipse, will at present engage our attention.

1. If two circles be described, (*Plate VII. Conics, fig. 1.*) one upon the greater axis of an ellipse, and one upon the lesser axis, these two circles will touch the periphery of the ellipse only at the extremities of the common diameter; and the circle upon the greater axis will fall entirely without the ellipse, and the other circle entirely within it. This is manifested from Prop. 39, Conics.

The circle upon the greater axis is sometimes called the circumscribed circle; and the circle upon the lesser axis, the inscribed circle of the ellipse.

2. If a point, F, be assumed in either axis of an ellipse, and from that point an ordinate be drawn both to the ellipse and to the circle described upon that axis; then shall the ordinate of the circle, FG, be to the ordinate of the ellipse, FH, as A B, the axis upon which the circle is described, to the other axis D E.

For, (Cor. 2. Prop. 28. Conics)

$$AF \times FB, \text{ or } FG^2 : FH^2 :: AB^2 : DE^2,$$

And therefore $FG : FH :: AB : DE$.

3. Let MN, (*fig. 2.*) intercepted between the axes of an ellipse, be equal to the difference of the two semi-axes, A C and C D; then, if M N be produced, so that $MG = CD$ and $NG = AC$; the point G will be in the periphery of the ellipse.

Draw G O and G F perpendicular to C D and A B, and draw C H parallel to N G, and produce F G to meet it in H: then $CH = NG = AC$: therefore H is in the periphery of a circle described upon the axis A B. The two triangles N G O and H C F are plainly equal in all respects, therefore $NO = HF$.

Now, $NO : OC :: NG : MG$;

That is, $HF : GF :: AC : CD$;

therefore the point G is in the periphery of the ellipse (2).

And if $m n$, intercepted between the axes of an ellipse, be equal to the sum of the semi-axes A C and C D; and the point G be taken, so that $n G = A C$, and $m G = C D$: it may be shewn, by the like reasoning, that the point G is in the periphery of the ellipse.

4. If from a point (*fig. 3.*) without an ellipse two tangents be drawn to the curve, and a straight line to the centre; the last-mentioned line will bisect the chord that joins the two points of contact.

Draw C P and C Q, semi diameters of the ellipse, parallel to the tangents T M and T N; and produce the same tangents to meet a diameter F G, parallel to the chord M N, in D and E. Then T M and T N are proportional to C P and C Q (Cor. 1. Prop. 28. Conics), and also to M D and N E (2. 6. Euc.); therefore M D and N E are proportional to C P and C Q. Therefore,

$$MD^2 : NE^2 :: CP^2 : CQ^2$$

$$\text{Prop. 38. Conics, } \begin{cases} NE^2 : FE \times EG :: CQ^2 : CG^2 \\ DF \times DG : MD^2 :: CG^2 : CP^2. \end{cases}$$

Consequently $DF \times FG = FE \times EG$ (22. 5. Euc.); and by adding CG^2 to both, $DC^2 = CE^2$. Therefore $DC = CE$; and T C will bisect M N.

Cor.—The tangents T M and T N are inversely proportional to the perpendiculars C R and C S, drawn to them from the centre of the ellipse.

Let M C and C N be joined; because $MO = ON$, the triangle T M C = triangle C N T: therefore $T M \times C R$

= $T N \times C S$, for these rectangles are the doubles of the triangles.

5. If a tangent of an ellipse H B (*fig. 4.*) meet a diameter produced, and an ordinate H F be applied to the same diameter from the point of contact: then, the semi-diameter C A will be a mean proportional between C B and C F, the parts between the centre and the tangent, and the centre and the ordinate.

Let A M, a tangent of the curve, meet H P in M; and draw A H and C M cutting A H in O, and H F in N; join A N. The triangles A O M and H O N are equal in all respects; for they are equi-angular, and $HO = AO$ (4); therefore A M H N is a parallelogram (33. 1. E.) Because N A is parallel to B H, therefore,

$$BC : CA :: MC : CN;$$

and because H F is parallel to A M (Cor. 1. Prop. 16. Conics), therefore,

$$AC : CF :: CM : CN.$$

Consequently $BC : CA :: CA : CF$.

Cor.—The rectangle $BF \times FC = AF \times FD$.

For $BC \times CF = BC \times CA - CF^2 = AC^2 - CF^2 = AF \times FD$.

6. If G P (*fig. 5.*) drawn perpendicular to a tangent of the curve at G, cut the axis A B in P, and the axis D E in Q, then will P G be to Q G as the square of the axis D E to the square of the axis A B.

Let the tangent meet the axis A B produced in T, and draw G F perpendicular to A B. Then, (Cor. 2. P. 28. Conics)

$$DE^2 : AB^2 :: GF^2 : AF \times FB;$$

Because P G T is a right-angled triangle,

Therefore, (Cor. 8. 6. E.) $GF^2 = TF \times FP$; also

(Cor. 5.) $AF \times FP = TF \times FC$; therefore

$$DE^2 : AB^2 :: TF \times FP : TF \times FC :: PF : CF.$$

But P G : Q G :: P F : F C.

Therefore P G : Q G :: $DE^2 : AB^2$.

7. If a parallelogram R S T U (*fig. 6.*) be formed by drawing tangents to an ellipse at the extremities of two conjugate diameters M N and P Q: that parallelogram shall be equal to the rectangle under A B and D E, the two axes of the ellipse.

From D, one of the extremities of either axis, draw D L perpendicular to that axis, and let it meet one of the sides of the parallelogram in L; join C L and D M, and draw C H perpendicular to R S. Because D L and L M are tangents, C L will bisect D M (4), and consequently the triangles C L D and C L M will be equal: therefore $CD \times DL = CH \times LM$. Therefore

$$CD : CH :: LM : DL.$$

But (Cor. 1. 28. Conics) $CP : CA :: LM : DL$;

Therefore, $CD : CH :: CP : CA$;

Consequently, $AC \times CD = CP \times CH$.

But $CP \times CH$ is one-fourth part of the parallelogram R S T U, and $AC \times CD$ is one-fourth part of the rectangle $AB \times DE$: therefore, parallelogram R S T U = $AB \times DE$.

8. The sum of the squares of any two conjugate diameters of an ellipse (*fig. 7.*) is equal to the sum of the squares of the two axes.

From M and P, the extremities of two conjugate diameters of an ellipse, draw M T, P S, tangents of the curve cutting the axis B A in T and S: draw M H and P K ordinates to the same axis, and P O an ordinate to the axis D E. Because M N and P Q are conjugate diameters, therefore M T is parallel to P Q, and P S to M N: hence the triangles C M T and C P S are equi-angular, and the perpendiculars

perpendiculars MH and PK will cut the two bases similarly. Therefore,

$$CT : TH :: CS : CK;$$

And (r. 6. E.) $CT \times CH : CH \times TH :: CS \times CK : CK^2$.
But (Cor. 2. 28. Conics) $AC^2 : AH \times HB :: CD^2 : MH^2$;
And (5. & Cor.) $AC^2 = CT \times CH$, and $AH \times HB = CH \times TH$; therefore,

$$CS \times CK : CK^2 :: CD^2 : MH^2;$$

$$\text{And (5.) because } CS \times CK = AC^2,$$

$$AC^2 : CK^2 :: CD^2 : MH^2.$$

Now, if this last proportion be compared with the two following ones, viz.

$$(\text{Cor. 2. 28. Conics.}) \begin{cases} AC^2 : AH \times HB :: CD^2 : MH^2, \\ AC^2 : CK^2, \text{ or } PO^2 :: CD^2 : DO \\ \quad \times OE, \end{cases}$$

we must infer that $CK^2 = AH \times HB$, and $MH^2 = DO \times OE$. Therefore,

$$CK^2 \times OP^2 + MH^2 + HC^2 = AH \times HB + HC^2 + DO \times OE + CO^2.$$

But the first of these sums is $MC^2 + CP^2$, and the second is $AC^2 + CD^2$: therefore, $MC^2 + CP^2 = AC^2 + CD^2$.

9. If AG and BK (fig. 8.), two tangents of an ellipse, be both parallel to the semi-diameter CD, and be intersected by a third tangent GK: the square of CD will be equal to the rectangle AG \times BK, which is contained by the parts of the parallel tangents between the points of contact and the third tangent.

Join AB, which will pass through the centre C (Cor. 18. Conics): draw HQ parallel to AB, and HO to CD: produce CD to meet GK in P. Then AC and CD are conjugate diameters (Cor. 24. Conics), and HO is an ordinate to AB, and HQ to CD. Therefore (5),

$$CT : CA :: CA : CO.$$

$$\text{Convertendo, } CT : TA :: CA : AO,$$

$$\text{Alter. \& Comp. } CT : TB :: TA : TO.$$

Therefore, by similar triangles,

$$PC : BK :: AG : HO, \text{ or } CQ.$$

Consequently, $BK \times AG = PC \times CQ$. But,

$$(5) PC \times CQ = CD^2, \text{ therefore } BK \times AG = CD^2.$$

10. Two right lines, Mf and Nf (fig. 9.), drawn from a point in the periphery of an ellipse to the two foci, make equal angles with the tangent MT, drawn from the same point.

Let the tangent MT meet the greater axis produced in T, draw MK perpendicular to the same axis, and produce fM to O. Then,

$$(47. 1. E.) fM^2 - MF^2 = fK^2 - KF^2;$$

that is, $(fM + MF)(fM - MF) = fK^2 - KF^2$.

But $fM + MF = 2AC$ (42. Conics), $fF = 2FC$, and $fK - KF = 2CK$: therefore,

$$AC \times \frac{fM - MF}{2} = FC \times CK.$$

$$\text{Therefore, } AC : CF :: CK : \frac{fM - MF}{2}.$$

$$\text{But (5) } TC : CA :: CA : CK.$$

$$\text{Ex æquo, } TC : CF :: AC, \text{ or } \frac{fM + MF}{2} : \frac{fM - MF}{2}.$$

And, componendo & dividendo,

$TC + CF$, or $Tf : TC - CF$, or $Tf :: fM : MF$; therefore (3. 6. E) TM bisects the outward angle FMO; that is, FM and MF make equal angles with TM.

11. If MP (fig. 10. Plate VIII.) touch an ellipse, and Mf be drawn from the point of contact to either focus, then CP, drawn from the centre parallel to Mf, and limited by MP,

will be equal to AC, half the transverse axis of the ellipse.

Draw MF to the other focus, and also FR and CS parallel to MP. Because $FC = Cf$, therefore $fS = SR$. And because fM and FM make equal angles with MP (9), it is plain that the triangle MRF will be isosceles, and $FM = MR$. But $2SM = fM + MR = fM + MF = 2AC$ (42. Conics): therefore $SM = AC$. And, because CSMP is a parallelogram, therefore $CP = SM = AC$.
Cor. 1. If FP be joined, it will be perpendicular to MP.

Let CP meet FM in H; then MF will be bisected in H. Because CP is parallel to Mf, therefore the angle HPM is equal to the angle HMP: therefore $PH = HM = HF$: therefore P is in the circumference of a circle described upon the diameter MF; and the angle MPF, in a semi-circle, is a right angle.

Cor. 2. If FP and fQ be drawn perpendicular to a tangent of an ellipse from the two foci, the points P and Q are in the circumference of the circle described upon the transverse axis as a diameter.

12. The rectangle under FP and fQ, any two perpendiculars drawn to a tangent of the curve from the foci, is equal to the square of the latus axis CD.

For the points P and Q are in the circumference of a circle described upon the greater axis AB: therefore, if PF be produced to meet that circle again in O, the segment QPO, which contains a right angle, will be a semi-circle: therefore QC and CO are in one right line, and the two triangles QCF and OCF will be equal, and Qf will be equal to FO. Therefore $Qf \times FP = OF \times FP = AF \times FP = AC^2 - CF^2 = CD^2$. (Def. 23. Conics.)

13. A straight line Tf (fig. 11.), drawn from the intersection of two tangents of an ellipse to one of the foci, will make equal angles with two right lines Mf and Nf, drawn from the points of contact to the same focus.

Draw MF and NF to the other focus, and produce fM and fN till MG be equal MF, and NH to NF: draw TG, TF, TH. Because TM makes equal angles with MG and MF (10), it is plain that $TG = TF$ (4. 1. E.): and, for a like reason, $TH = TF$: therefore $TG = TH$. But $fM + MF = fN + NF$ (42. Conics); that is, $fG = fH$. Hence, it is plain, that the two triangles TGF and THF are equal in all respects (S. 1. E.), and the angle TfG is equal to the angle TfH.

Cor. 1. The two lines Tf and Tf, drawn to the foci, divide the angle MTN, contained by the tangents, into equal parts.

$$\text{For, } GTF - fTF = 2MTF - fTF = GTF,$$

$$\text{And, } HTF + fTF = 2NTF + fTF = HTF;$$

$$\text{Therefore, } 2MTF - fTF = 2NTF + fTF;$$

$$\text{And hence, } MTF = NTF$$

$$MTF = NTF.$$

Cor. 2. If two tangents of an ellipse (fig. 12.), drawn from the extremities of a chord passing through one focus F, intersect in T; then TF is perpendicular to the chord MN. For the angles TFM and TFN (fig. 11.) are, in all cases, equal; and when MF and FN are in one right line, each of them becomes a right angle.

14. If a tangent of an ellipse, as DE (fig. 13.), intersect two perpendiculars drawn from the extremities of the transverse axis, in the points D and E; then two right lines, drawn from these points to one of the foci F, will contain a right angle.

Draw FM to the point in which DE touches the ellipse; then, because AE and BD are tangents of the curve, FE

will bisect the angle AFM (13), and FD will bisect the angle DFM; whence the proposition is manifest.

15. If MN (fig. 14.) be any chord drawn through the focus of an ellipse, and PQ, likewise drawn through the focus, be ordinarily applied to the transverse axis AB: then, four times the rectangle MF × FN will be equal to the rectangle MN × PQ.

Draw MS and NR perpendicular to AB, and NG, MK, PH, perpendicular to the directrix that corresponds to the focus F. Then (43. Conics),

$$PF : PH, \text{ or } FL :: NF : NG, \text{ or } LR.$$

$$(17. 5. E.) \quad PF : PH :: NF - PF : FR.$$

In like manner, PF : PH :: PF - FM : FS.

$$11. 5. E. \text{ and alternating, } NF - PF : PF - FM :: FR : FS :: NF : FM;$$

$$\text{Therefore, } (NF - PF) \times FM = (PF - FM) \times FN : \\ \text{And } 2NF \times FM = PF \times MN;$$

$$\text{Therefore, } 4NF \times FM = PQ \times MN.$$

16. Let ABCD be a quadrilateral figure inscribed in an ellipse, and from M any point in the curve, let PQ and RS (figs. 15, and 16.) be drawn parallel to two adjacent sides AB and AD; and let the first of these lines meet the opposite sides of the figure in P and Q, and the second, the two other opposite sides in R and S: then the ratio of the rectangle MP × MQ to the rectangle MR × MS will be equal to the ratio of the square of the diameter of the ellipse drawn parallel to AB to the square of the diameter drawn parallel to AD.

When the two sides AD and BC (fig. 15.) of the quadrilateral are parallel, let the right line, which bisects AD and BC, cut RS in K, and let RS meet the ellipse again in O: because MO, AD, and BC, are all parallel, it is plain that the right line which bisects AD and BC will be a diameter of the ellipse, and will bisect the remaining line MO: but the same line which bisects AD and BC will also bisect RS parallel to AD and BC, and terminated by the right lines which limit AD and BC: hence, it is plain, that RO = MS. Therefore the ratio of the rectangle RM × MS to MP × MQ is equal to the ratio of RM × MO to RA × AD; that is (28. Conics), to the square of the diameter of the ellipse drawn parallel to AD to the square of the diameter parallel to AB.

When BC is not parallel to AD (fig. 16.) let it, produced if necessary, meet AD and RS in T and U; let RS meet the curve again in O, and join BO, QS. Then, by similar triangles,

$$BT : TA :: BU : UR,$$

$$CT : TD :: CU : US.$$

$$\text{Therefore, } BT \times CT : TA \times TD :: BU \times UC : UR \times US, \\ \text{but (28. Conics), } BT \times CT : TA \times TD :: BU \times UC : \\ MU \times UO;$$

$$\text{Therefore, } MU \times UO = RU \times US; \text{ and}$$

$$US : UO :: UM : UR :: UQ : UB.$$

Therefore (2. 6. E.) SQ and BO are parallel; consequently the triangles QMS and BRO are equi-angular, and,

$$SM : OR :: MQ : RB;$$

$$\text{Therefore, } SM \times MR : OR \times RM :: MQ \times MP : \\ RB \times RA.$$

Alternando,

$$SM \times MR : MQ \times MP :: OR \times RM : RB \times RA.$$

But (28. Conics) the ratio of OR × RM to RB × RA is equal to the ratio of the square of the semi-diameter of the ellipse parallel to AD to the square of the semi-diameter parallel to AB: whence the proposition is manifest.

Cor. 1. The ratio of SM × MR to MP × MQ is

constantly the same, wherever the point M is assumed in the periphery of the ellipse.

Cor. 2. If, from any point M (fig. 17. Plate IX.) assumed in the periphery of an ellipse, four right lines, MH, MK, MG, and ML, be drawn so as to make given angles with the four sides of a quadrilateral inscribed in an ellipse; then the ratio of MK × MG, the rectangle contained by two of the lines drawn to the opposite sides of the quadrilateral, to MH × ML, the rectangle of the lines drawn to the other two opposite sides, will be constantly the same, wherever the point is assumed in the periphery.

For, having drawn the lines MPQ and RMS, as in the proposition; the four lines MK, MG, MH, and ML will have given ratios to the four lines MP, MQ, MR, and MS, each to each: and hence the ratio of MK × MG to MH × ML, is compounded of the ratio of MP × MQ to MR × MS and given ratios: whence the corollary is manifest.

Of the description of an ellipse in plano.

1. When the transverse axis (fig. 18.) and the two foci of an ellipse are given, any number of points in the curve may be thus found: Take any point O in the transverse axis A B, and from F and f, the two foci, as centres, with radii respectively equal to AO and BO, let arcs of circles be described to intersect in M and m; and these two points will be in the periphery of the ellipse (42. Conics): and, by assuming different points in the transverse axis, as many points as shall be thought necessary may be found in the periphery of the figure.

When the two axes are given, the foci may be readily found (Cor. Def. 23. Conics); and then the curve may be described by this method.

2. Divide the semi-conjugate axis CE, (fig. 19.) and the two halves of the transverse axis AC and CB, into the same number of equal parts, in the points, 1, 2, 3, &c.: with the radius CE describe a quadrant of a circle, and draw 1 r, 2 r, 3 r, &c. ordinates of the circle; also draw 1 L, 2 L, 3 L, &c. perpendicular to AB, and respectively equal to 1 r, 2 r, 3 r, &c.: then will all the points L, L, &c. be in the periphery of an ellipse, of which A B and E D are two axes. The reason of this construction is manifest from (1).

3. An ellipse (fig. 18.) may also be described in various ways, by a point which is made to move by proper mechanical contrivances. And, first, if the ends of a thread, which is exactly equal in length to the transverse axis A B, be fixed in the foci F and f; and a describing pencil be carried quite round, till it return to the place it set out from, in such a manner as to keep the thread always stretched out; then the curve, so described, will be the periphery of an ellipse, as is manifest from P. 42. Conics.

4. If two rulers, as FH and fK, (fig. 20.) each equal in length to the transverse axis A B, have their extremities fixed in the foci so as to be moveable round these points; and if the other extremities of the rulers be connected by a third ruler H K, which is equal in length to Ff, the distance of the two foci, so as to be moveable about the points H and K: then if the ruler H K be moved round the centres F and f, the intersection of the rulers fK and FH will describe the periphery of an ellipse, of which A B is the transverse axis, and F and f the two foci.

For join FK: it is plain that the triangles FHK and fFK are equal in all respects, for the three sides of the one are equal to the three sides of the other, each to each: therefore the angle MFK is equal to the angle FKM: therefore

therefore $FM = MK$. Therefore $FM + Mf = fK = AB$: consequently M is in the periphery of an ellipse, of which AB is the transverse axis, and F and f the foci.

5. If $P M$ (figs. 21, and 22.) be taken in a straight ruler equal to the semi-transverse axis, and $M Q$ equal to the semi-conjugate axis; and if $P Q$, which is equal to the sum or difference of the two semi-axes, be so moved that its extremity Q may slide along BA , and its extremity P along the line CD ; then the point M will describe the periphery of the ellipse which has AC and CD for its semi-axes. This is manifest from (3). Elliptical compasses are an instrument constructed as in fig. 21.

6. If a ruler CO , (figs. 23, and 24.) equal to half the sum or half the difference of the semi-axes of an ellipse, be moveable about the centre of the ellipse C ; and another ruler OP , of an equal length, be connected with it so as to be moveable about the point O ; and if OM be taken in OP , so as to be equal to half the difference of the same semi-axes in the first case, and to half their sum in the other case: then if the ruler CO be moved round about the centre C , while the point P is made to slide along the transverse axis AB ; the point M will describe the periphery of the ellipse.

In CO , or in CO produced, take OK and OL each equal to OM ; join ML and MK , and let MK , produced if necessary, cut the transverse axis AB in H : because the two lines CO and OM are, the one, equal to half the sum, and the other, to half the difference of the semi-axes AC and CD ; it is plain that $CK = CA$, and $CL = CD$: and because $OP = OC$ and $OM = OL$, therefore ML is parallel to AB : but the angle KML , in a semi-circle is a right angle, and therefore KH is perpendicular to AB . Now,

$$CK : CL :: AC : CD :: KH : HM;$$

and, because K is in the periphery of the circle described upon the transverse axis, therefore M is in the periphery of the ellipse (2).

Of the area of an ellipse.

1. The area of a circle described upon the transverse axis of an ellipse, is to the area of the ellipse, as the transverse axis is to the conjugate axis.

Let a polygon (fig. 25.) of an even number of sides, be inscribed in the circle upon the transverse axis, so as to have two of the angles that are diametrically opposite situated in A and B ; and from all the other angular points of the polygon let perpendiculars, FO , GC , &c. be drawn to AB , and let a polygon be formed within the ellipse by joining all the points where the perpendiculars cut the periphery: because the ordinates FO , GC , &c. of the circle, have a constant ratio to the correspondent ordinates NO , DC , &c. of the ellipse, namely, the ratio of AC to CD ; therefore the several triangles FBO , FOC , FGC , &c. that compose the polygon in the circle will have the same constant ratio of AC to CD , to the several triangles NBO , NOC , and DNC , &c. that compose the polygon in the ellipse, each to each (1. 6. E.); consequently the polygon inscribed in the circle will have to the polygon inscribed in the ellipse the ratio of AC to CD (24. 5. E.)

And because a polygon of an even number of sides may be inscribed in the circle, which shall be greater than any space less than the circle, it is clear that no space less than the circle can have to the ellipse the same ratio that AC has to CD : for if so, then a polygon greater than the ellipse might be inscribed in it.

And, again, no space greater than the circle can have to the ellipse the same ratio that AC has to CD : for then the circle would have to a space less than the ellipse, the same ratio that AC has to CD : but a polygon may be inscribed in the ellipse that shall be greater than any space less than the ellipse; and, then from what has been shewn, the corresponding polygon in the circle would be greater than the circle itself.

Therefore the circle upon the diameter AB is to the ellipse as AC is to CD .

Cor. The area of the ellipse is equal to the area of a circle described with a radius equal to a mean proportional between the semi-axes AC and CD .

For the circle upon the diameter AB has to the circle, whose radius is equal to a mean proportional between AC and CD , the same proportion that AC has to CD .

By this proposition the quadrature of the ellipse is made to depend upon the quadrature of the circle. And this is true not only of the whole elliptic area, but of any segment of it. For, by the like reasoning, it may be shewn that any segment of the circumscribing circle, as MBF , has to the corresponding segment of the ellipse KBN , the same proportion that AC has to CD ; that is, the same proportion that the whole circle has to the whole ellipse.

Of the rectification of the ellipse.

The length of a circular arc and the area of the sector which stands upon it, increase in the same proportion: and hence the mensuration of circular areas, and the finding of the lengths of the bounding arcs, are problems for nearly connected, that the solution of the one is a consequence of that of the other. But the arc of an ellipse is a curve line of unequal and continually varied flexure, and increases after a very different rate from the area which it bounds. And the finding of the lengths of such arcs has been found to be a problem of a higher and more difficult class than the mensuration of the correspondent spaces. There are few problems on which more has been written than on the rectification of the ellipse. The complete solution of it has required the successive labours of many ingenious mathematicians, and has been the occasion for inventing some of the nicest artifices in the whole compass of analysis. The subject is too abstruse to be discussed in this place, and we shall be content with giving a useful formula for the computation of an elliptic arc.

Let AC , (fig. 26.) the semi-transverse axis of an ellipse, be = 1 ; CD , the semi-conjugate, = b ; $1 - b^2 = e^2$; $CF = x$, $FE = y$: then

$$AC^2 : CD^2 :: AF \times FP : FE^2;$$

that is, $1 : b^2 :: 1 - x^2 : y^2$:

and hence $y = b \sqrt{1 - x^2}$. Also, let E denote the length of the elliptic arc DE , between the conjugate axis and the ordinate: then, $\dot{E} = x \sqrt{1 + \frac{b^2 x^2}{1 - x^2}} = \frac{x \sqrt{1 - e^2 x^2}}{\sqrt{1 - x^2}}$.

To find the fluent, we may assume $E = A^0 + \int \frac{x}{\sqrt{1 - x^2}}$

$$+ \{ A^{(1)} x + A^{(2)} x^3 + A^{(3)} x^5 + \&c. \} \sqrt{1 - x^2};$$

then by taking the fluxion of this expression, and equating it to the former value of \dot{E} reduced into a series, we shall easily obtain the following equations for determining the assumed co-efficients, $A^{(1)}$, $A^{(2)}$, $A^{(3)}$, &c. viz.

$$\begin{aligned}
 1 &= A^{(1)} + A^{(2)} \\
 -\frac{1}{2}e^2 &= 3A^{(2)} - 2A^{(3)} \\
 -\frac{1 \cdot 1}{2 \cdot 4}e^4 &= 5A^{(3)} - 4A^{(4)} \\
 -\frac{1 \cdot 1 \cdot 3}{2 \cdot 4 \cdot 6}e^6 &= 7A^{(4)} - 6A^{(5)} \\
 &\text{\&c.} \qquad \qquad \qquad \text{\&c.}
 \end{aligned}$$

And by combining these equations so as to exterminate $A^{(1)}$, $A^{(2)}$, $A^{(3)}$, &c. we get,

$$A^{(4)} = 1 - \frac{1}{2}e^2 + \frac{1 \cdot 1}{2 \cdot 4}e^4 - \frac{1 \cdot 1 \cdot 3}{2 \cdot 4 \cdot 6}e^6 + \frac{1 \cdot 1 \cdot 3}{2 \cdot 4 \cdot 6}e^4 - \frac{1 \cdot 1 \cdot 3 \cdot 5}{2 \cdot 4 \cdot 6}e^6, \text{\&c.}$$

By means of this series $A^{(4)}$ may be computed, and then the remaining co-efficients of the assumed series will be found by the following easy formulas :

$$\begin{aligned}
 A^{(1)} &= 1 - A^{(2)} \\
 A^{(2)} &= \frac{2}{3}A^{(1)} - \frac{1}{2}e^2 \\
 A^{(3)} &= \frac{4}{5}A^{(2)} - \frac{1 \cdot 1}{2 \cdot 4}e^4 \\
 A^{(4)} &= \frac{6}{7}A^{(3)} - \frac{1 \cdot 1 \cdot 3}{2 \cdot 4 \cdot 6}e^6 \\
 &\text{\&c.} \qquad \qquad \qquad \text{\&c.}
 \end{aligned}$$

When $x = 1$, or when E becomes a quadrant of the ellipse, the expression will be reduced to its first term

$$A^{(1)} \times \int \frac{x}{\sqrt{1-x^2}} = A^{(1)} \times \frac{\pi}{2}, \quad \pi \text{ denoting } 3.14159, \text{\&c.}$$

the periphery of a circle whose diameter is 1 : and hence the quadrant of the ellipse is equal to

$$\frac{\pi}{2} \times \left\{ 1 - \frac{1}{2}e^2 + \frac{1 \cdot 1}{2 \cdot 4}e^4 - \frac{1 \cdot 1 \cdot 3}{2 \cdot 4 \cdot 6}e^6 + \frac{1 \cdot 1 \cdot 3}{2 \cdot 4 \cdot 6}e^4 - \frac{1 \cdot 1 \cdot 3 \cdot 5}{2 \cdot 4 \cdot 6}e^6, \text{\&c.} \right\}$$

On the subject of the rectification of the ellipse, see the Edin. Transactions, vol. iv. and v. London Transf. 1804. Landon's Memoirs. Le Genre, Mem. de l'Acad. 1786. Le Genre Mem. sur les Transcendentes Elliptiques. Euleri opuscula, Berlin, 1750. See QUADRATURE, and RECTIFICATION.

ELLIPSIS, in *Grammar and Rhetoric*, is a verbal figure, or a figure of syntax, wherein something is suppressed, or left out, in a discourse, and supposed or understood; or it is a defect or omission of some part of a sentence, which must be supplied in order to render the construction complete and fully to express the sense. See on this subject the Port Royal Latin Grammar, vol. ii p. 168, &c. See ZEUGMA.

This figure is often used in proverbial speeches, as when we say; "many men, many minds," that is, "have many minds;" also, "the more danger, the more honour," that is, "gains more honour." This figure also occurs, when, being under the transport of a violent passion, a man is not at leisure to speak every thing out at length, the tongue being so flow to keep pace with the rapid motions of the mind, so that on these occasions we only bring forth broken interrupted words and expressions, which represent the violence of a passion better than any consistent discourse. When used in this sense, it is more generally called *apophepsis*, which see. See also ASYNDETON.

F. Boffu considers the ellipsis as a mode of disguising sentences, by suppressing the word which should make the particular application, and leaving the whole in a kind of ingenious ambiguity. Thus, the Trojans, in Virgil, being reduced by Turnus to the last extremity, and ready to be destroyed, by Æneas coming to assist them; upon which the poet says, "Spes addita fuscitat iras." Which expression signifies either, in particular, that the hope they conceive retrieves and aug-

ments their courage; or in general, that the hope of assistance at hand naturally raises courage, and gives people new strength.

If the poet had added a word, and said, "Ollis spes addita fuscitat iras," the passage had been expressly restrained to the first sense, and had ceased to be a sentence, and commenced only the application of a sentence: the suppression of that word makes it a sentence in form.

This, that excellent critic looks on as one of the finesses of the Latin tongue, wherein it had vastly the advantage of the modern tongues. *Traité du Poème Epique*, p. 460, &c.

ELLIPSIS has a place in Walther's Lexicon as a musical term, to express a passage when broken, and rendered imperfect by a rest; but though some note is left out in moments of rage and perturbation, it is understood, or the time would be broken.

ELLIPSOID *Figure of the Earth, in Geology.* The terrestrial globe, having been found by the measurement of degrees in different latitudes, by the rates of the vibration of a pendulum in different parts, &c. to agree nearly with an ellipsoid, having the polar axis for its conjugate diameter, which Sir Isaac Newton had shewn to be the form which a fluid mass revolving on an axis would assume; Mr. Whitehurst, Mr. Kirwan, and other geological writers, have thence inferred, that the solid matters of the globe were once in a fluid state. It is worthy, however, of consideration, that the present appearances and the Newtonian theory may be perfectly reconciled, without having recourse to a soft or liquefied state of the hard substances which now appear in the earth; the inconceivable number of fragments into which the earth is now divided by its faults or fissures, appear to give it a facility for obeying the impulses of gravity and centrifugal force towards an equilibrium, almost as great as in a fluid, taking the immensity of the mass into consideration; and it is only by the just equilibrium of all its present parts, aqueous and solid, that the continents and islands now preserve an elevation above the aqueous spheroid, which they evidently once had not; as their aquatic mineral remains testify.

The term spheroid is sometimes used when speaking of the earth's figure, synonymously with ellipsoid; but M. Bouguer having applied the term spheroid to a solid generated from a curve of the fourth order, which he conceived would agree better with the terrestrial measurements than known than an ellipsoid, it will be well hereafter to preserve these distinctions, and not use the term ellipsoid, but for the figure generated by a true Apollonian ellipsis, reserving the term spheroid for any other kind of solid, generated by the rotation of an oval curve, or nearly approaching thereto.

ELLIPTIC, or ELLIPTICAL, something that belongs to an ellipse.

ELLIPTIC Arch, in *Architecture*, a part of the curve of an ellipse employed in an arch. It has this advantage over a circle when employed in bridge building, that it not only saves materials, but gives more room under the arch at the hanches, and therefore, in a navigable river or canal, vessels will pass more easily under it than under a circle.

ELLIPTIC Arc. See CATENARIA.

ELLIPTIC Motion. THEORY of the elliptic motion of the planets round the sun. (*Plate XII. Astronomy, fig. 103.*)

Definitions.—The eccentricity of the orbit is the distance CS of the centre from the focus. The radius vector is the

line drawn from the centre of the sun to the centre of the planet. If M represent the place of the planet for a given instant, S M is its radius vector.

The line of apses is the greater axis of the ellipse, and it marks the aphelion and perihelion of the planet. The apheion A, or superior apside, is the point in which the planet is at its greatest distance from the sun. The perihelion P, or lower apside, the point in which it is the nearest.

The anomaly is in general the distance of a planet from its apheion, but some modern astronomers have adopted the method of reckoning the anomaly from the perihelion; for since this must be done in the case of comets, it appears more uniform and consistent to make a general rule serve for all. However, as this is a matter totally indifferent to the theory, we shall for the present suppose the anomaly reckoned from the apheion.

There are several ways of considering this distance.

The true anomaly is the angle formed at the focus of the ellipse, by the radius vector and the line of apses, as A S M.

The excentric anomaly is the angle formed at the centre of the ellipse, by the greater axis and the radius of a circumscribing circle, drawn to the extremity of an ordinate passing through the place of the planet, as N C A. The mean anomaly is the distance from the apheion supposed proportional to the time, so that a planet which should employ six months to go from A to P, would at the end of one month have 30° of mean anomaly. If a line C X be taken to mark the mean anomaly, and this line be supposed to revolve uniformly round the centre C, the line C X will at first be more advanced than the line C N, because A N increases slower towards the apheion, the real motion of the planet being less than the mean motion, and this distance X N will increase, as long as the real motion is slower than the mean motion.

The difference between the true anomaly and the mean anomaly forms the equation of the centre.

Since the mean anomaly is proportional to the time, and is a portion of the time of a whole revolution, it may be measured by any quantity that has a uniform increase; thus, not only A X, the angle A C X, and the sector A C X, may be taken to represent the mean anomaly, but even the elliptic sector or area A S M formed by the radius vector S M, the portion of the greater axis S A, and the elliptic arc A M. Because the areas described are proportional to the times.

Kepler, having found that the planets described ellipses, with areas proportional to the times, it only remained to conclude the true place for a given time.

When the whole time of a revolution of a planet is known, for example, that of the earth equal to 12 months, and it is required to assign its place in its orbit at the end of one month, the problem consists in determining the sector A S M such, that it will be $\frac{1}{12}$ th of the whole surface of the ellipse; this sector is the mean anomaly, and may be expressed in degrees by dividing 360° by 12. It is in degrees, minutes, and seconds that the anomalies are always found in astronomical tables.

When the mean anomaly is known, or the surface of the sector A M S, a question arises, how to find the true anomaly, or the angle A S M of this sector. Kepler perceived the difficulty of this problem, "having given the mean anomaly to find the true," even in a circle, for the difficulty is the same as in an ellipse, and he invited the mathematicians of his time to endeavour to find a solution. This problem still continues to be called the "Problem of Kepler," who thus expresses himself on the subject.

Hæc est mea sententia; quæ quominus videbitur geometricæ pulchritudinis, hoc magis adiutor geometras ut mihi

solvant hoc problema. Datâ arcâ partis semicirculi, datoque puncto diametri, invenire arcum et angulum ad illum punctum: cujus anguli creribus et quo arcu data area comprehenditur; vel arcum semicirculi ex quocumque puncto diametri in data ratione secare. Mihi sufficit credere solvi a priore non posse propter arcum et sinus *1717, p. 112.*

This problem has never yet been solved in any other manner than by approximation. But in practice the investigation is very much simplified by reversing the question, and supposing known the true anomaly to find the mean. This method is shorter and often more exact than the direct method; it was very successfully employed by La Caille in determining the motion of the sun; and is founded on two theorems, which only suppose known some properties of trigonometry and the conic sections.

Lemma.—In an ellipse A M P, about which is circumscribed the circle A N P, C X being the line of mean anomaly, M the true place of the planet, R M N an ordinate passing through the planet, the circular sector A N S A shall always be equal to the circular sector A C X, which represents the mean anomaly.

Demonstration.—Let T be the whole time of a revolution, and t the time employed by the planet in going from A to M, then, because the areas are proportional to the times, we have t : T :: sector A M S : to the whole surface of the ellipse. In the same manner, since A C X is the mean anomaly, t : T :: A C X : surface of the circle. But by the property of the ellipse A M S : A N S :: the surface of the ellipse : the surface of the circle. We have thus two proportions, with three terms in common, from which it may be inferred that A C X and A N S are equal to each other.

The square root of the perihelion distance is to the square root of the apheion distance as the tangent of half the true anomaly is to the tangent of half the excentric anomaly.

Demonstration.—In the triangle R S M (by the property of right-angled triangles,) the tangent of half the angle R S M is equal to the opposite side R M, divided by the sum of the two other sides S R, S M. Hence in the right-angled triangles M S R, N C R, we have this proportion:

$$\text{tang. } \frac{1}{2} \text{ M S R} : \text{tang. } \frac{1}{2} \text{ N C R} :: \frac{\text{RM}}{\text{SR} + \text{SM}} : \frac{\text{RN}}{\text{CR} + \text{CN}}$$

Instead of the ratio R M : R N, substitute C D to C A, which is equal to it by the property of the ellipse, and instead of S R + S M its value P R . $\frac{\text{SA}}{\text{CA}}$, and likewise P R

instead of C R + C N, then the above proportion will be changed into the following.

$$\text{Tang. } \frac{1}{2} \text{ M S R} : \text{tang. } \frac{1}{2} \text{ N C R} :: \frac{\text{CD} \cdot \text{CA}}{\text{PR} \cdot \text{SA}} : \frac{\text{CA}}{\text{PR}}$$

∴ C D : S A. If a be the semi-diameter of the ellipse, e the excentricity C S, then tang. $\frac{1}{2}$ M S R : $\frac{1}{2}$ N C R ∴ C D : S A ∴ $\sqrt{a^2 - e^2} : a + e$; dividing the two last terms by $\sqrt{a + e}$; tang. $\frac{1}{2}$ M S R : tang. $\frac{1}{2}$ N C R ∴

$\sqrt{a - e} : \sqrt{a + e} ; \sqrt{\text{PS}} : \sqrt{\text{SA}}$, or the square root of the perihelion distance is to the square root of the apheion distance as the tangent of half the true anomaly is to the tangent of half the excentric anomaly.

The difference between the excentric anomaly and the mean anomaly is equal to the product of the excentricity by the sine of the excentric anomaly.

Demonstration.—The circular sector A N S A is equal to the sector of the mean anomaly A C X, if the common portion A C N be taken from both, the sector N C X will be equal to the triangle C N S. The area of the circular sector

ELLIPTIC.

NCX is equal to the product of CN by half the arc NX. The area of the triangle CNS is equal to the product of CN by half the height ST, which is a perpendicular let fall from the focus S upon the base CN, continued beyond the centre C; thus the two areas being equal, and having one of the multipliers CN common to both, the other multipliers are also equal; therefore the arc NX is equal to the straight line ST. But in the triangle STC, T being a right angle, ST is equal CS. fin. TCS, according to the common expression of rectilinear trigonometry; therefore NX = CS. fin. TCS = CS. fin. ACN; therefore the difference NX between the excentric anomaly AN, and the mean anomaly AX, is equal to the product of the excentricity CS by the sine of the excentric anomaly ACN.

In order that the lines NX, ST, CS, may be compared with each other, they must be expressed in parts of the same denomination.

The mean anomaly is expressed in degrees, minutes, and seconds; therefore ST, and the excentricity CS, must be expressed in seconds. To obtain it, it is sufficient to know, that the radius AC of any circle whatever, ANX, is equal to about 57°, or to the arc of 206264".8; thus the arc equivalent to the excentricity CS may be obtained by stating this proportion: the mean distance, or the radius AC, is to the excentricity CS as the arc equal to the radius is to the arc equivalent to CS, or to the number of seconds which the excentricity contains. Therefore this number is $\frac{206264".8 \text{ CS}}{AC}$.

If we state AC:CS::1:e, that is to say, if e is the excentricity in parts of the mean distance, e will be equal $\frac{CS}{AC}$; and to express the excentricity in seconds, it would be sufficient to multiply the number 206264".8 by e, the logarithm of which is 5.3144251332. This is also the arithmetical of the log. fin. of 1", so that 206264".8 = $\frac{1''}{\text{fin. } 1''}$, and the fin. 1" = $\frac{1''}{206264".8}$. Whenever Mayer wishes to express a quantity in seconds, he divides it by the sine of 1". If, on the contrary, he wishes to express a number of seconds, in decimals of the radius, he multiplies it by the sine of 1". In fact, the sine and the arc of 1" are apparently equal. We may say 1" : a number of seconds is to the same number expressed in similar parts to those of the sine 1", that is to say, in decimals of the radius, and the fourth term of this proportion is fin. 1". This method may be retained more easily, and fin. 1" takes up less room in a formula. Sometimes 57" is written instead of 206264".8.

It is the same in all quantities which are found in calculations expressed in parts of radius; where it is required to have them in seconds, they are multiplied by 206264", where the constant log. 5.3144251332 is added to their log.

It is the contrary if their arcs are in seconds, and they are required in decimals of the radius.

Before we proceed to give an example of the above theorems, we shall insert the following table for each planet, which contains the two constant logarithms computed for the proportions of the two theorems.

The first for the excentric anomaly, is half of the difference between the logarithm of the aphelion distance and that of the perihelion distance: this added to the logarithm of the tangent of half the true anomaly gives the logarithm of the tangent of half the excentric anomaly.

The second logarithm serves to find the mean anomaly; it is the sum of the logarithm of the excentricity and of the log. of 57°, &c. an arc equal radius. This constant logarithm

added to the sine of the excentric anomaly gives the logarithm of the difference between the excentric and mean anomalies. In the same table is annexed the logarithm of the minor axis, which serves to find the distance. It is the half sum of the logarithms of the aphelion and perihelion distances.

Planets.			
Mercury	0.0905430	4.6272651	9.5784504
Venus	0.0029905	3.1522975	9.8593275
The Sun	0.0072927	3.5394899	9.9999387
Mars	0.0405448	4.2833172	0.1810076
Jupiter	0.0208955	3.9993597	0.7157339
Saturn	0.0244430	4.0643300	0.9788040
The Moon	0.0239255	4.0550625	9.9993412
Herschel	0.0206824	3.9910124	1.2801270

Example.—Suppose the true anomaly of Mars to be 1° 50' 40", and that it be required to convert it into mean anomaly, the logarithm of the aphelion distance, according to the tables of De la Lande, is 5.221552; the log. of the perihelion distance 5.140403; the half difference of their logarithms 0.0405448, this is the constant logarithm for the first analogy, as in the above table.

The distances which answer to the two logarithms of the tables, are 1665530 and 1381856, the half sum of these two distances is 1523693, this is the semi-axis of the ellipse, or the mean distance of Mars from the Sun, the half of the difference between these distances is 141837, or the excentricity. This excentricity must be converted into a fraction, the mean distance of Mars being taken as unity; thus,

152369 : 1 :: 14183 : 0.0930877, which is a decimal fraction of the distance of Mars, and its logarithm is 8.9688921. To reduce it into seconds, it must be multiplied by the arc equal radius, which gives 19200, whose logarithm is 4.2833172.

Log. of excentricity 14183.7	-	-	4.1517895
Subt. log. of semi-axis 152369	-	-	5.1828974
Difference	-	-	8.6688921
Add log. of 57° or arc = rad.	-	-	5.3144251
Sum of the constant log. of the 2d proportion	-	-	4.2833172
Constant log. for the 1st.	-	-	0.0405448
Log. tang. of $\frac{1}{2}$ true anom. 15° 41' 20"	-	-	9.4302374

Log. tang. of $\frac{1}{2}$ excent. anom. 16° 28' 13".8 9.4707822

Therefore the excent. anom. is 3256.176. 4.2833172

Conf. log. for the 2d proportion - 9.7354193

Log. fin. excent. anom. 37° 56' 27".6 - 4.0187365

Log. of 10440".9, or - 2.54 0.9 - 4.0187365

Add. excent. anom. - 32.56 27.6

Mean anomaly = 35.50 28.5

If the true anomaly surpasses 180° or six signs, take its supplement to 360°, and after having found the mean anomaly, take its supplement to 360°, that the mean anomaly may be always reckoned according to the signs.

In this manner we may find the mean anomaly having given the true, but it is usually the true anomaly we wish to find. The mean anomaly being given, we must then proceed thus;

By inspection of the tables, it may be seen nearly what equation of the centre corresponds to the degree of anomaly which is given. This is to be applied to the mean anomaly, to have the

the true, and this true anomaly is to be converted back again into mean, by the preceding rules. If the mean anomaly which results is the same as that given, it shews that the equation employed is correct; if the mean anomaly is found too great, then the supposed true anomaly must be diminished, and thus by these two suppositions, by a simple proportion, a mean anomaly may be found which exactly accords with the given one, the difference between this and the true anomaly employed to find it is the exact equation sought.

The radius vector, or the distance of the planet from the sun, is found by means of the true anomaly, and the excentric anomaly by making the following proportion.

Sin. of true anom. : sin. excent. anom. :: $\frac{1}{2}$ minor axis : radius vector.

Demonstration.—Draw the line NQ parallel to the radius vector MS; then by similar triangles SM : QN :: RM : RN :: CD : CK or CN; hence SM : CD :: QN : CN :: sin. QN : sin. CQN :: sin. RCN : sin. RSM, and sin. RSM : sin. RCN :: CD : SM, which is the distance required.

It is to facilitate the use of this theorem that in the above table is inserted the logarithm of the minor axis for the principal planets. By the property of the ellipse CD, or $\sqrt{SD^2 - CS^2} = \sqrt{CP^2 - CS^2} = \sqrt{CP + CS} \times \sqrt{CP - CS}$; that is, CD is equal to the product of the square roots of the aphelion and perihelion distances.

Example.—The true anomaly being 30° 8' 40", the excentric anomaly 32° 56' 27".6, it is required to find the radius vector or distance of Mars from the sun. Add together the log. of the aphelion distance and the log. of the perihelion distance, take the half of their sum, which is equal to the log. of the semi-axis = 0.1810076
 Add log. sin. excent. anom. 32° 56' 27".6 = 9.7354193
 9.9164269
 Subt. log. sin. true anom. - - - - - 9.7008609

 Remainder is the log. of the radius vector 0.64273 - - - - - } = 0.2155660

ELLIPTIC SPACE, is the area contained within the circumference, or curve of the ellipsis.

It is demonstrated: 1. That the elliptic space is to a circle described on the transverse axis, as the conjugate diameter is to the transverse axis.

2. That the elliptic space is a mean proportional between two circles described on the transverse and conjugate axes. See ELLIPSIS.

- ELLIPTIC *Conoid*, is the same with the spheroid.
- ELLIPTIC *Specula*, or *Mirrors*. See MIRROR.
- ELLIPTIC *Winding-stairs*. See STAIRS.
- ELLIPTIC *Wind-mill*. See WIND-MILL.
- ELLIPTIC *Compasses*, an instrument made usually in brass, for the drawing any ellipsis or oval, by one revolution of an index. See ELLIPSIS and COMPASS.

ELLIPTIC *Dial*, is an instrument usually of brass, with a joint or fold together, and the gnomon to fall flat, for the sake of the pocket.

By it are found the meridian, hour of the day, rising and setting of the sun, &c. See DIAL.

ELLIPTICUM FOLIUM, in *Botany*. See LEAF.

ELLIPTOIDES, an infinite ellipsis, i. e. an ellipsis denoted by the equation $y^m + z^n = b x^m \times a - x^n$, wherein $m > 1$ or $n > 1$. See ELLIPSIS.

Of this there are several kinds or degrees; as the cubical VOL. XII.

ellipsoid, wherein $y^2 = b x^2 \times a - x$. A biquadratic or surfoidellipsoid ellipsoid, or that of the third order, wherein $y^4 = b x^2 \times a - x^2$.

If any other ordinate be called v , and the correspondent absciss z ; there will be

$$a y^{m+n} = b z^m \times a - z^n$$

Consequently,

$$a y^{m+n} : a v^{m+n} :: b z^m \times a - z^n : b z^m \times a - z^n$$

That is, $y : v :: x^m \times a - x^n : z^m \times a - z^n$.

ELLIS, JOHN, in *Biography*, an eminent naturalist, the celebrated assertor of the animal nature of Corallines, was born, we believe, in London, about the year 1710, but our opinion is founded chiefly on conjectural evidence. By a book now before us, in his hand-writing when a boy, it appears that he began the study of vulgar fractions Oct. 1. 1723, and pursued it afterwards to a considerable extent. He is presumed to have been engaged in merchandize, and possibly in some public office, or place under government, but of his precise occupation or station in life, we have no exact information. He soon imbibed a general taste for natural history, and having numerous friends and correspondents in various parts of the world, especially America and the West Indies, he was indefatigable in procuring seeds and specimens of plants, as well as insects, shells, corals, and every kind of natural curiosity. He laboured to discover and to teach the best methods of collecting and preserving such objects, as well as to procure receipts for varnishes, cements, colours, or any thing else which might be useful to him as a practical naturalist. Microscopical enquiries soon engaged his attention, and he improved the microscope then in use, so as to render it more convenient for his purpose. He was the friend of Peter Collinson, of the Rev. Dr. Hales, and of Dr. Alexander Garden, with whom he agreed no less in taste for natural science, than in excellence of moral and religious character through life.

The studies and amusements of Ellis have indeed had many votaries, whose numbers, for a century past, have been rapidly increasing in this and other countries. But how few among these vast numbers have, like him, had the lot of making a grand and original physiological discovery, which removes a numerous and intricate tribe of beings from one kingdom of nature to another, and so clearly elucidates their whole economy that no subsequent doubts can arise, at the same time diffusing collateral light, in various directions, through other ranks of creation! The progress of the discovery of the animal nature of corals and corallines, to which we allude, is well detailed by our author in the introduction to his Natural History of Corallines, published at London in 1755, in quarto, with 37 plates of the various species. The idea appears to have occurred to him in the autumn of 1751, and spring of 1752, when in disposing specimens of various marine productions, hitherto deemed plants, upon paper, he soon learned, by their difference of texture, to discriminate such as he suspected to be more of an animal than vegetable nature. He presented a collection of these newly-discovered animals to the Royal Society, of which he was already become a fellow, and his opinions were confirmed by those of several learned naturalists there assembled. This original collection still remains in four glazed frames, over the chimney-piece of an apartment in the British Museum. In August 1752, Mr. Ellis undertook the necessary examination of these productions in a living state in the life of Shepey, accompanied by a draughtsman. Here he first saw the various living animals,

of which the corallines were but the shells or cases, and we may easily conceive the pleasure with which he watched their various movements in quest of food, or in the enjoyment of animal life, all so strikingly decisive of the truth of his preconceived theory. In June 1754, the celebrated botanist and artist Mr. Ehret accompanied him in an excursion to the Sussex coast; and the pencil of this able man was well employed in the service of his discoveries as they arose. The fruits of this excursion were communicated to the Royal Society, in the 49th volume of whose Transactions the remarks of Mr. Ellis on the subject in question are found, in one letter to the Rev. Dr. Birch, and three others to Mr. Peter Collinson. A fourth letter to the last-mentioned naturalist is printed in the 49th volume of the same publication, containing an account of a "curious fleshy coral-like substance." This is now named *Alcyonium Schlofferi*. Another excursion in August 1754, along the northern coast of Kent, in company with Oeder the celebrated Danish botanist, furnished Mr. Ellis with several new ideas on the subject of his researches, especially the mode of propagation of these animals. He also learned to preserve the polytypes in an expanded state, by suddenly immersing the specimens in proof spirit, by which the vital principle was extinguished before they could withdraw into their cells. By these repeated observations upon our British corallines, and comparing them with some of the exotic more solid or horny corals, this acute philosopher was enabled to prove that even these last are formed upon the same principle. Nothing can be more certain than that their stems, however solid, are originally congeries of tubes, filled up and obliterated by the subsequent deposition of horny matter, as the polytypes advance upwards, and branch off into various new colonies. The same may be observed of the more stony productions properly called corals. These are likewise aggregate animals, whose shells while soft cohere laterally into one common mass; whereas univalve shell-fish are solitary individuals, whose shells as they enclose are convoluted upon themselves. In the famous Wentletrap, *Turbo scalaris*, these convolutions do not touch each other, except by the intervention of thin transverse plates; the same thing is remarkable in the straight tubes of the coral named *Tubipora musica*.

The doctrine of Mr. Ellis however did not escape controversy. Dr. Job Baister, a learned Dutch naturalist, communicated to our Royal Society some doubts upon the subject, which are printed in the 50th volume of the Philosophical Transactions, where also Ellis's reply may be seen. The great Russian naturalist Dr. Pallas was likewise among his opponents, as well as that indefatigable writer Sir John Hill; but the scruples of the latter were afterwards so far removed, that he tried to extend the discovery of Ellis to *Fungi*, wanting to prove them also of an animal nature; in which he was unquestionably as much mistaken as in his previous disbelief of the animal nature of corallines. To detail the arguments on either side would now be superfluous. We shall conclude the subject by remarking, that notwithstanding the discoveries of Ellis, Linnæus has, even in the last edition of his *Systema Nature*, retained so much of the old error as to define Zoophytes "compound animals, which bear flowers, their vegetating stem passing by metamorphosis into a flowering animal." In a note he explains his opinion that the animals do not, like those of stony corals, form their cases or shells, but are themselves formed by those shells, which he conceives to be truly of a vegetable nature. He allows indeed the flowers to be real animals, with organs of generation and of motion. This error is corrected by Gmel-

lin, who justly unites the *Lithophyta* and *Zoophyta* of Linnæus into one order under the latter denomination, and defines them "compound animals, flowering like plants;" such at least is his meaning, though *animalium* is printed for *plantarum* more.

In botany Ellis distinguished himself by an account of two new genera, the *Halefia* and *Gardenia*, printed in the Phil. Transf. vol. 51. The former was named after his learned friend the Rev. Dr. Hales, and is an American flowering shrub or tree of great elegance, which bears our climate well; the latter is a fine Indian shrub, well known in our flowers, named after Dr. Garden, long resident in Carolina. He published also a separate pamphlet on the Venus's Fly-trap; see *DIONÆA muscipula*; and was the author of a fourth new genus, *Gordonia*, named after Mr. Gordon of Mile-end. Every genus therefore which he established has remained unhaken, and we may venture to predict will ever continue so, while botany continues a science. The *Gordonia* was described in the 60th vol. of the Phil. Transf. along with a new species of *Illicium*, or Starry Anise, from West Florida. In the 57th vol. of the Transf. Mr. Ellis describes some *Confervee*, hitherto unknown. One of his most favourite botanical objects was to ascertain the true Varnishtree of Japan, which he contends, in opposition to Miller, to be distinct from the American *Toxicodendron*. The controversy may be seen in the 49th and 50th volumes of the Phil. Transf. The point seems not yet well determined, but the American plant is certainly *Rhus Vernix* of Linnæus. Our author published separately an historical account of Coffee, with remarks on its culture and use, and a plate of the shrub; also a description of the Mangostan and Breadfruit, with four plates. These are quarto pamphlets, and the latter contains many useful "directions to voyagers, for bringing over these and other vegetable productions." This last subject frequently engaged Mr. Ellis's attention, and makes a separate quarto pamphlet published in 1770. In the 51st and 58th volumes of the Phil. Transf. are papers of his, on the preservation of seeds. Nor were these all the scientific pursuits of his indefatigable mind. He wrote also in the Transf. various other papers on Corals, Sea Pens, and other animals of the same tribe, as well as on the Cochineal Insect; on the *Coluber Cerasus*, or Horned Viper of Egypt; on that singular animal, found by his friend Garden in Carolina, the *Siren lacertina* of Linnæus, now esteemed a *Murana*; on the structure of the Windpipes in several birds and in the Land Tortoise; and even on the method of making Sal Ammoniac in Egypt. It appears moreover, by many specimens of his collecting, that he was an assiduous observer of the internal structure or anatomy of vegetables, on which no doubt he had conferred with Dr. Hales, whose experiments and observations he seems often to have had in view.

It would have been extraordinary if the numerous communications of Mr. Ellis to the Royal Society had failed of the peculiar reward, so richly merited, which that learned body has in its power to bestow. Accordingly Sir Godfrey Copley's medal was, on the 30th of Nov. 1768, delivered to him by Sir John Pringle, then President; and it being usual to single out some one or two papers in particular for such a compliment, one "on the animal nature of the genus of Zoophytes called *Corallina*," in a letter to Linnæus, and another "on the *Alimia foetida*," in a letter to the earl of Hillsborough, both printed in the 57th vol. of the Transf. were selected for this purpose.

Of the private occurrences of the life of this distinguished man we have not much information. In a manuscript letter

to the Rev. Mr. Burlace dated March 3d, 1764, the following passage is remarkable. "You too greatly over-value my little progress in natural knowledge. Had I been regularly bred to it I might have made some progress in it worth notice, but I assure you the small advance I have made in it was only to amuse a mind distressed by a series of misfortunes, and I thank God it has had that great and good effect, so as to render this part of my life the most happy of the whole, by my being taken notice of by men of worth and honour." Thus modestly wrote a man whose discoveries form an epocha in natural science, and whose felt a Christian philologist, whose heart expanded to all his fellow-creatures! He was at this time much acquainted with the excellent Dr. Solander, who laboured with him at the study of exotic Zoophytes, as well as of the British Sea-weeds. On the former subject a splendid posthumous work in quarto appeared in 1786, under the direction of the author's daughter, who dedicated it to Sir Joseph Banks. This book is illustrated by 63 beautiful engravings, some of them inferior to none in natural history. Whether Mr. Ellis had been unsuccessful in trade, or from any other cause not perfectly at ease in his circumstances, we know not, but he wrote as follows to a friend in Feb. 1764. "I thank God the agency for West Florida, which my lord Chancellor (Northington) has got me, makes me easy and happy, and I hope will prove of use to natural history. My business does not oblige me to leave London." It appears that in 1757 he resided in Laurencelane; in 1771 in or near Gray's-inn; and that he had occasionally a summer residence at Fulham. In a letter to another friend, dated Gray's-inn, Jan. 2, 1771, is the following passage. "By lord Northington's goodness I have been made agent of West Florida, and lately have got the agency of Dominica. This comfortable income has enabled me to pursue with spirit my favourite study of natural history." After a series of declining health, Mr. Ellis died on the 15th of October 1776, being, as we presume, about 66 years of age, though the time of his birth is not mentioned either in the advertisement prefixed to his posthumous work, or in the Gentleman's Magazine for 1776, where he is said to have died on the 5th of October. His person was tall, his features expressive and strongly marked. Of the time of his marriage, or any particulars concerning his wife, we have no account. One only daughter, named Martha, survived him, to whom he left a handsome competency, and for whom he had the strongest parental affection, which she most abundantly merited and returned. This excellent lady, who inherited her father's taste and character, more especially his piety and sensibility of mind, with a considerable likeness to his person, was the second wife of Alexander Watt, esq. of Northaw, Hts. She bore her husband several sons, now for the most part engaged in the naval service of their country, and one only daughter, who survived her mother but a few years. Mrs. Watt died in childbed at Northaw in the spring of 1795. Her will, written entirely in her own hand, and a letter to her husband, found after her decease, are worthy of the pen of a Richardson and the character of a Clarissa. She honored the writer of this article with her friendship, and enriched him with all her father's original scientific correspondence and other papers, as well as some specimens illustrative of his writings. The bulk of Mr. Ellis's museum was however sold by auction in London in June 1791. Ellis's MSS. and printed works. S.

ELLIS, in *Geograph.* a river of America, in the state of Maine, being a branch of Great Aroostock river.

ELLISIA, in *Botan.* named by Linnæus in honour of John Ellis, esq. F. R. S. Author of several botanical dissertations and discoveries. Linn. Gen. 97. Scrob. 109.

Gen. Ch. Cal. Perianth inferior, in five deep, lanceolate, spreading, permanent segments. Cor. of one petal, funnel-shaped; tube nearly cylindrical, much smaller than the calyx, marked internally with 15 streaks; limb in five obtuse segments. Nectary two small teeth at the base of each filament. Stam. Filaments five, awl-shaped, short; anthers roundish. Pist. Germen superior, roundish, bristly; style thread-shaped, short; stigma two, oblong, erect. Peric. Capsule coriaceous, roundish with a transverse striature, downy, of two cells and two valves, deciduous. Seeds two in each cell, one above the other, globose, dotted. Corrected from the MSS. of Linnæus communicated by Dr. Smith.

Eff. Ch. Corolla funnel-shaped, much narrower than the calyx. Capsule coriaceous, superior, of two cells and two valves. Seeds two in each cell, dotted, one above the other.

E. *Nyctelaa*, Linn. Mant. 336. Nov. Act. Upsal. v. 1. 97. t. 5. f. 5. (Polemonium Nyctelæa; Linn. Sp. Pl. ed. 2. 231. Scorpium humilis virginiana, solis rotundis; Morris. v. 3. 451. Sect. 11. t. 28. f. 3.) This, the only known species, is a native of Virginia, and is more singular in fructification, than beautiful or remarkable in appearance. It is preserved in some curious botanical gardens, but is hardly enough to bear our climate without any care. Root annual. Stem decumbent, much branched, leafy, brittle. Leaves alternate, stalked, pinnatifid, roughish. Flowers small, pale blue, on simple solitary stalks opposite to the leaves.

ELLISVILLE, in *Geography*, a post-town of America, in Cumberland county, Pennsylvania, 156 miles from Washington.

ELLOPIA, in *Ancient Geography*, a name formerly given to the island of Euboea, from Elops the son of Ion, who settled in this island.—Also, an inland town of this island, which, according to Strabo, stood at the foot of mount Telemium. The inhabitants of this place were compelled, after the battle of Leuctra, by the tyrant Philistides, to leave their native country, and settle at Ithæa.—Also, a country of Greece, in the vicinity of Dodona.—Also, a town of Greece, toward Dolopia.

ELLOPIUM, a town of Greece, in Ætolia, according to Polybius.

ELLORA. See ELORA.

ELLORE, in *Geography*, one of the northern circles of Hindoostan, N.E. of Condapilly, and N.W. of the bay of Bengal. See CIRCAR.—Also, the capital of this circar, 32 miles N. of Masulipatam. N. lat. 16° 43'. E. long. 81° 11'.

ELLOTIA, Ελλωτια, among the Greeks, a festival in memory of Europa, Agenor's daughter; who was called Ελλωτια by the people of Crete.

ELLSWORTH, in *Geography*, a township of America, in Hancock county and state of Maine, on both sides of Union river; incorporated in 1800.

ELLWOOD, THOMAS, in *Biography*, was born at the village of Crowell, near Thame, in Oxfordshire, in the year 1639, where he received his education, which, owing to the narrow circumstances of his father, was very limited. When he had attained the age of 21, he was accidentally thrown among the quakers, and received indelible impressions, in favour of their sentiments, from the preaching of Edward Burroughs. This alteration in his religious principles gave great offence to his father, who could not brook the change of manners, language, and dress, assumed by his son, and who behaved towards him with an unbecoming severity, often inflicting on him blows, and a kind of domestic imprisonment.

prisonment. At length the young man was permitted to pay a visit to a friend; and, on his return, passed most of his time in the kitchen and among the servants, in order that his father might not be offended with his wearing a hat in his presence. He soon after became a writer, and a zealous preacher among the friends. His first work was entitled, "An Alarm to the Priests, or a Message from Heaven to warn them." In the same year, 1660, when this was published, Ellwood was arrested and imprisoned at Oxford, on account of an intercepted letter, which was interpreted by the government to be of a political and libellous nature. His imprisonment was short, and not attended with any circumstances of peculiar rigour.

Ellwood was now looked up to as a distinguished preacher, and felt the want of more learning than he had acquired in early life, and applied all his leisure time in improving himself. He, by means of his friend Isaac Penington, procured the employment of reader to the great Milton, which obliged him to read many Latin books, so that the language soon became familiar to him; and as Milton easily knew, by the tone of his voice, whether he understood his author, he would, in difficult cases, stop him, and explain those parts which he did not seem to comprehend. This confinement did not agree with his health; and he was in a short time obliged to leave London. In 1665, Ellwood procured apartments for his master at Chalfont, and was the occasion of his writing *Paradise Regained*, by asking him, what he who had said so much on *Paradise Lost*, could say of *Paradise Found*? Ellwood was again imprisoned in Bridewell and Newgate, for being found at a meeting of the friends in London; but was discharged, after a short time, without the form of a trial. He was next selected by his friend Isaac Penington, as the tutor to his children, an employment in which he continued till the year 1669; but, during his residence in this family, both he and his patron were arrested at Amersham, while attending a funeral at the quakers' burying ground, and committed to Aylsbury gaol, where they were kept till the ensuing assizes, when they, with other prisoners of the same description, were ordered to be fined *6s. 8d.* each, and discharged. This sum they refused to pay, and were committed for one month longer. Scarcely had Ellwood escaped from this prison, when he was committed to the house of correction at Wycombe, where he was confined a quarter of a year. At the latter end of the same year he was married, and settled at Hungerhill, near Amersham, Bucks, where he became a zealous adherent to the rising society of the friends; and was extremely useful, after the passing of the "Conventicle Act," in suppressing the infamous trade of spies and informers. In one instance, he was able to prove an alibi with regard to a friend; and then indicted and convicted the informers of perjury.

Ellwood now became an author, and published many works, which were highly esteemed by the friends of his party. For one, *viz.* "A Caution to Constables and others concerned in the Execution of the Conventicle Act," he was cited to appear before the magistrates, who were empowered to commit him to prison till the next assizes, but who took his word for appearing when called on, and never troubled him more on that head. In 1694, he published a posthumous work of George Fox, which contained a voluminous journal of the events of his life; and in 1705, he gave the public the first part of "Sacred History, or the historical Part of the Holy Scriptures of the Old Testament," which he continued, in the year 1709, by a volume of the history of the New Testament. This was the principal work of our author, who died of the palsy, on the 11th

of March, 1713, in his 74th year. He was a man of considerable abilities, possessed much natural wit, and some learning. His integrity was unquestionable; and his zeal in what he thought right could be damped by no obstacles, nor by any sufferings to which he was exposed. Gen. Biog.

ELLYCHNIOTOS, in the medical writings of the *Ancients*, the name of a sort of tent used by the surgeons, and made of cotton or lint, rolled up into the form of the wick of a lamp or candle. See the next article.

ELLYCHNIUM, a name given, by the ancients, to that sort of matter, whatever it was, which served them in common use for the wicks of their lamps, and had, besides this, its use in surgery. Galen expressly directs the use of the softest ellychium, such as that of Tarsus, instead of sponge, in chyrurgical cases. But we are far from being ascertained, at present, of what this ellychium of Tarsus was. The commentators have guessed differently as to the meaning of the word; and Cornarius supposed it to signify a sort of spongy and light fungus, which, when properly wrought up, might be made to serve for the wicks of lamps, being very inflammable, as we well know many of the funguses to be, particularly that sort which the people of some countries call *spanck*, and use instead of tinder, to catch fire from the sparks of flint and steel; and when in its natural lax state, might, by its open spongy texture, be very well suited to imbibe any medicinal fluid, and retain it a long time, while applied to any diseased part. Other have guessed it to be the xylon, or cotton of the ancients; but, from Galen's proposing it to be used instead of sponge, it seems much more probable to have been what Cornarius supposes. Galen, lib. xiii. and xiv. Cornar. Comment. in 3. *Kar.* 707.

ELLYS, ANTHONY, in *Biography*, a learned rector of the church of England, was born about the year 1693. He studied at Clare-hall, Cambridge, where he took his degrees. He obtained several valuable livings; and was, in the year 1728, created doctor of divinity, when king George II. paid a visit to the university of Cambridge. After this he took an active part against the repeal of the test and corporation acts, and wrote one of the best works on that side of the question, entitled, "A Plea for the Sacramental Test, as a just Security to the Church established, &c." He next published an answer to *Hule's Essay on Miracles*. This was published in 4to. in the year 1752; and almost immediately afterwards, Dr. Elly was promoted to the see of St. David's. He died at Glaston, in the year 1761, aged 68 years. After his death in 1763, was published the first part of a work entitled, "Tracts on the Liberty, spiritual and temporal, of Protestants in England;" and in 1765, the second part was given to the public. The design of the former is partly to vindicate the establishment of the church of England against the objections of the protestant dissenters; but principally to examine and confute the tenets of the church of Rome. The second part relates to civil liberty, in which the author vindicates the principles of the whigs; and in the discussion he has collected a large fund of historical, constitutional, and legal knowledge. The work was drawn nigh under the patronage of government; and on account of its labour which it cost him, he was rewarded with the bishopric of St. David's, though, for reasons not now known it was not published till after his death. The bishop likewise published some single sermons. His character is given by the editors of his posthumous works, as not or eminent for his fine parts, extensive knowledge, and solid judgment; but for a heart so overflowing with benevolence and candour, as never even to conceive terms of acrimony towards the opinions or persons

persons of those who differed from him: and he always thought a person, though on the right side of a question, with principles of perfection, to be a worse man than he that was on the wrong. *Biog. Brit.*

ELM, in *Agriculture*, the name of a very common deciduous tree, of which there are different species and varieties. See ULMUS.

The common or English elm, and most of the other sorts, succeed well in soils of a stiff, loamy, retentive quality, which are in some measure inclined to moisture, growing in some cases to considerable height and size of bole. They are occasionally planted both as hedge-row timber and in mixed plantations, though their wide spreading branches render them in some degree improper for the latter situations. In the former cases, the banks should be well cleaned and wrought over, and the trees be planted out about the latter end of September, being well secured by proper stakes from the effects of the winds. Their heads should likewise be considerably reduced before they are set out, but without injuring the leading shoots, or the branches being too closely pruned.

These trees are well suited for being planted out in the view of affording shelter, or as a screen for breaking off the violence of the winds, as they are capable of being trained up in the form of a hedge, being kept constantly closely cut in, to make them grow thick and close, as well as to a great height. Near tillage land they are, however, very objectionable, as their roots run very extensively near the surface of the ground, and of course obstruct the operations of the plough.

In the planting of this sort of trees, great care should be taken not to bury their roots too deep, especially when the soil is of the clayey or loamy kinds. The plants should not be too large when planted out, as they do not succeed so well. The plants may be raised by suckers, and from seeds in some of the forts.

As timber, the common elm is probably to be preferred to most of the other sorts; but some of the other kinds grow equally large in soils which suit them. This is the case with that which is called the witch-elm. The worst sort in point of timber is that which is usually denominated the Dutch elm.

ELM, in *Botany*. See ULMUS.

ELM, in *Geography*, a small town of Switzerland, in the canton of Glaris; 6 miles S. of Glaris.

ELM-Bark, in *Pharmacy*. The bark of the elm has been strongly recommended, and is occasionally used in obstinate cutaneous complaints. It is given in the form of decoction (decoctum corticis ulmi) of moderate strength; that is, about an ounce to a pint of water, and in the dose of at least a pint daily. This decoction is mucilaginous and slightly astringent.

ELM-Wood, *Petrified*, in *Natural History*. It is related by Mr. Stedcl, that he found pieces of elm-wood, which had been left about seven years in a fountain near Ulm, and had become petrified or converted into stone. (6 Roz. Svo. 3d part, p. 18.) The alleged conversion of wood into silicious stony masses, in modern times, has been doubted by most modern writers; and indeed it appears doubtful, whether any of the numerous silicious stones, that are found with a ligneous texture, can be identified with any recent or known woods, but like the animal remains which often accompany them in a petrified or altered state, when scientifically examined and compared with recent species, they are found all to belong to a prior race of organized beings now totally extinct. See *Petrified Wood*.

ELMA, in *Geography*, a town of Russia, in the govern-

ment of Archangel, at the conflux of the river Elma with the Petchora; 312 miles E. of Archangel.

EL-MACIN, in *Biography*, an Egyptian, who succeeded his father as secretary to the council of war, under the sultans of Egypt, in the year 1238, is chiefly known as author of a chronicle of the Mahometan caliphs, written in Arabic, which commences with Mahomet, and goes down to the reign of Moïtader-Billah, who died in the year 1138. He relates year by year, but in few words, what concerns the Saracen empire, intermixing with it a portion of the history of the Christians of the East. He is supposed, from his manner of writing, to have been a Christian; yet enjoyed places of trust and distinction under the Mahometan princes. His history was translated out of the Arabic into Latin, by Erpenius, and printed in both languages at Leyden, in folio, in the year 1625. Bayle.

ELMAHAD, in *Geography*, a town of Arabia, in the country of Yemen; 8 miles N.N.W. of Zebid.

ELME, SAINT, a strong castle of the island of Malta, on a rock close to the town of La Valette, which protects the two harbours.—Also, an old castle of France, near Colioure, in the department of the Eastern Pyrenées.

EL-MEDEA, call'd also *Africa* (*Turris Hannibalis*), a sea-port town of Africa, in that part of the country of Tunis which was the ancient Bzaciun or winter circuit, situated upon a peninsula, 5 miles to the south of Cape Demas. It appears to have been formerly a place of great strength and importance. The port, which was an area nearly of 100 yards square, lies within the walls of the city, with its mouth opening towards Cap ouïna; but it is not now capable of receiving the smallest vessel. Leo says, that it was founded (or possibly rebuilt) by Mahdi, the first patriarch of Kaerwan, and therefore assumed his name; but the delicacy of the ruins afford reason for suspecting, that the founder was not an Arabian. Thuanus has mistaken this place for Aphroditum, which Dr. Shaw suggests, in his "Travels," to have been more probably at Farafese, a small village and port in the plains of Hamam-et.

ELMEDINA, or ALMEDINE, a town of Africa, in the empire of Morocco, on the edge of mount Atlas.—Also, another of the same name, near the sea-coast.

ELMEN, or ALT SALZA, a town of Germany, in the circle of Lower Saxony, and principality of Magdeburg; 10 miles S.S.E. of Magdeburg.

ELMENAÜ. See ULMENAU.

ELMHAM, NORTH, once a city, is now an inconsiderable village in the county of Norfolk, England, about 4 miles north of East Dereham. It was given by the Saxon prince Sigebert to Felix, who converted the East Anglians to Christianity, and was the first bishop of that part of the heptarchy. At the time the province of East Anglia was divided into two dioceses, this place became a seat of the bishop presiding over the northern portion. During this partition, ten bishops successively resided here; but in the time of Wybrd the 11th, the sees were again united, and fourteen others subsequently fate, till the see was removed from this place to the city of Norwich, by Herbert de Losinga, in the time of William Rufus, A. D. 1094. The bishops of Norwich continued occasionally to reside here; and a fine castle, moated round, was erected by bishop Spencer, in the time of Richard II. The ruins of this palace still remain; and the site of the ancient cathedral, built by bishop Herbert, is still visible. Near it subterraneous hollows have been discovered, and old wells, which have been filled up. In an enclosure near Broom clove, half a mile from the village, the ground was perceived to sink circularly in three different places; in one of which the hole

was 12 feet broad, and 20 feet deep. But vestiges of higher antiquity have been traced: for in this clove were found numerous urns, including divers brass instruments, Roman coins, and a silver seal ring or annular signet, ornamented with an eagle holding a thunderbolt. Henry VIII. granted the manor to Thomas lord Cromwell, who was the first lay proprietor. The present possessor is Richard Miles, esq. in right of his mother, the eldest daughter of Richard Warner, esq. who built a handsome mansion here in 1729, which seat is called North Elmham Park.

ELMINA, or LA MINA, a town of Africa, in the kingdom of Fetu or Fetou, so called by the Portuguese, but by the natives Oudea, which is very long but narrow; the houses being built of a stone, hewn out of a neighbouring rock. In the year 1684, this town was so populous and so powerful, and the inhabitants so brave, that they were the terror of the whole coast. Since that period it has been depopulated by the ravages of the small-pox, and by the tyrannical government and wars of Commendo. This town is seated on the river Benja, in a low, flat peninsula, formed by the ocean on the south, the river on the north, Commendo on the west, and the famous citadel of St. George or Elmina on the east. Towards Commendo it is fortified by a strong wall of large stone, a deep ditch, and some pieces of cannon. The wall begins at the sea-side, and stretches along to the banks of the river, which separates the town from the fort on mount St. Jago. The Dutch call this fort Conradsburgh, which they built for the security of Elmina, in a situation that commands both the town and their chief factory. The inhabitants are robust and warlike, but more civilized than other negroes, on account of their familiar acquaintance with the Europeans. Their usual occupations are fishing, trading, and making palm-wine and oil. Their commerce extends along the coast, as far as Whidah. In the town are many artificers, who work in metals in a manner little inferior to that of the best European mechanics. They cast and carve in gold and silver; they make buttons, plain or filligree rings, chains, sword-hilts, and other ornaments; nor are they ignorant of the method of cutting, grinding, and polishing crystal and glass. The town contains about 200 houses, occupied chiefly by mechanics. It is divided into three districts, each of which is governed by a chief, called by the negroes kasso; with a number of subordinate officers. These three chiefs, with their councils, form the regency and legislative part of this small republic; since the Portuguese rendered it independent of the kings of Fetu and Commendo, who possess the sovereignty of the whole country besides. The inhabitants have thus found means to render themselves formidable to all their neighbours, and to acquire an independence that is not

possessed any where else on the Gold Coast. The river Benja, which glides by the walls of the town, furnishes a fine bay salt, produced in the same manner as in different parts of Europe. The citadel of Elmina stands on a rock, bounded on one side by the ocean, defended by strong bastions, and surrounded by a high stone wall, in the centre of the Gold Coast, so as to be commodiously situated for the purposes of trade and the security of the trader. The works of this fort were begun by the Portuguese, and completed by the Dutch; and it is said to be larger, more convenient, and beautiful than Cape Coast, though less pleasant in respect of situation. The fort of Conradsburgh stands on mount St. Jago, on the frontier of the kingdom of Fetu. Below mount St. Jago the company have a fine garden, enclosed by high stone walls, and beautifully laid out in parterres and rows of orange, lemon, palm, and cocoa-trees; and furnishing all sorts of fruits, roots, and pulse, peculiar to that country, as well as the natural growth of Europe. In the centre stands a magnificent dome or temple, surrounded by lofty trees, which afford the most delightful cooling shade and fragrance.

ELMORE, a township of America, in Orleans county, and state of Vermont, containing 45 inhabitants.

ELMOROSTA, a name given by the Moors to a dish they are very fond of. It is made of pieces of beef, or of camel's flesh, stewed with butter, honey, and water; some add rob of wine to it, and others garlic; but there are always added onions, saffron, and salt. Phil. Trans. No. 253.

ELMSHORN, in *Geography*, a small town of Denmark, in that part of Holstein called the county of Rantzau, situated on the river Aue, which runs into the Elbe, and by means of which the inhabitants carry on a good trade, chiefly in turf and charcoal. The population does not amount to more than 1000 individuals. It is on the road from Hufum to Hamburg, 26 miles N. of the latter place.

ELNBOGEN, a town of Bohemia, and capital of a circle or district, within the circle of Saatz, called "the circle of Elnbogen," or "Loket;" situated on a rock, surrounded with mountains, near the Egra; 62 miles W. of Prague, and 32 S.W. of Saatz.

ELNE, a small town of France, in the department of the Eastern Pyrenées, on the river Tech, not far from the Mediterranean sea; 6 miles S. of Perpignan.

ELNE, a river of England, in the county of Cumberland, which runs into the Irish sea; 4 miles N. of Workington.

ELNIA, a town of Russia, in the government of Smolenk; 32 miles E.S.E. of Smolenk. N. lat. 54° 25'. E. long. 33° 19'.

ELOANX, a name given by some writers to auripigmentum, or orpiment.
