thing awful and terrifying in their effect. Three days after, 15,000 armed men rendezvoused at Dair-el-Kamar, and operations might have been immediately commenced. The troops of the Druzes have neither uniforms, nor discipline, nor order; they are mere peasants with short coats, naked legs, and muskets in their hands, differing from the Turks and Mamlouks, in being all foot; the sheiks and emirs only having horses, which are of little use from the ruggedness of the country. The war of the Druzes is merely a war of poits; for they never risk themselves in the plain, as they would not be able to stand the shock of cavalry, having no bayonets to their muskets. They are excellent marksmen, and accustomed to sudden surprisings; though they are daring even to temerity, and sometimes ferocious; they possess two qualities essential to the excellence of any troops; they strictly obey their leaders, and are endowed with a temperance and vigour of health, unknown to most civilized nations. They can pass three months in the open air, without tents, or any other covering than a sheep skin, and their provisions consist of small loaves baked on the ashes or on a brick, raw onions, cheese, olives, fruits, and a little wine. They have no knowledge of fortification, the management of artillery, or the mode of encampments; in a word, they are ignorant of war, considered as an art.

The Druzes, comparing their own situation with that of the subjects of the Turkish government, acquire an idea of their own superiority, which has an influence on their personal character. Hence they are in their disposition elevated, energetic, and active; and they are considered, through the Levant, as restless, enterprising, hardy, and brave even to temerity. No people have a higher sense of honour than the Druzes, and this has produced a politeness which is visible even among the peasants. They are also distinguished for their hospitality; for any one who presents himself at their door as a suppliant or passenger, is sure of being entertained with lodging and food, in the most generous manner. The poorest peasants have given the last morsel of bread to the hungry traveller; alleging that "God is liberal and great, and all men are brethren." They have, therefore, no inns in this country; and when they have once contracted with their guest the sacred engagement of bread and salt, no subsequent event can induce them to violate it. The Druzes, like the Bedouens, pay great respect to the antiquity of families; but nobility exempts no sheik or emir from paying tribute, in proportion to their respective revenues; and it confers upon them no prerogatives. Every thing among the Druzes is held in freehold; after paying his mird and his rent, every man is master of his property. Fathers have here, as in the Roman law, the power of preferring such of their children as they think proper. Such are their prejudices, that they do not chuse to make alliances out of their own families. They invariably prefer a poor relation to a rich stranger; it is usual with them for a brother to espouse a brother's widow; and, in various respects, they retain the customs of the Hebrews, in common with other inhabitants of Syria, and all the Arab tribes.

The proper and distinguishing character of the Druzes is a sort of republican spirit, which gives them a greater degree of energy than other subjects of the Turkish government, and an indifference for religion, which forms a striking contrast with the zeal of the Mahometans and Christians. In other respects their private life, their customs and prejudices are the same with other orientals. They may marry several wives and repudiate them when they chuse; but this is seldom practised, except by the emir, and a few men of eminence. Occupied with their rural labours, they experience neither artificial wants, nor those in-

ordinate passions which are produced by the idleness of the inhabitants of cities and towns. The veil, worn by their women, is their protection; inasmuch that no one knows the face of any other woman besides his wife, his mother, his sister, and sister-in-law. The women are perfectly domestic; those even of the sheiks make the bread, roast the coffee, wash the linen, cook the victuals, and perform all the offices of the family. The men cultivate their lands and vineyards, and dig canals for watering them. In the evening they assemble in the arca, or court, or house of the chief of the village or family; where, seated in a circle, with legs crossed, pipes in their mouths, and poniards at their belts, they discourse of their various labours, the scarcity or plenty of their harvests, peace or war, the conduct of the emir, or the amount of the taxes; they relate past transactions, discuss present interests, and form conjectures on the future. Their children listen, and at 10 or 12 years of age they talk with a serious air of war and taxes. This is their only education. They are not taught to read either the Psalms, as among the Maronites, nor the Koran, like the Mahometans; and even the sheiks scarcely know how to write a letter. Among the Druzes there is little appearance of the gradation of ranks; all, both sheiks and peasants, treat one another with a familiarity, which is equally remote from rudeness and servility. In a word their manners are those of ancient times, and that rustic life, which marks the origin of every nation; and which proves that the people, among whom they are found, are hitherto only in the infancy of the social state. Volney's Travels in Egypt and Syria. Tott's Memoirs. Rococke's Description of the East, vol. ii.

DRUSIAS, in *Ancient Geography*, a town of Palestine, placed by Ptolemy W. of the Jordan.

DRUSILLIANIA, an episcopal town of the proconular Africa.

DRUSIUS, JOHN, in *Biography*, a very learned theologian of the Protestant faith, was born at Oudenard, in Flanders, about the year 1550. The first rudiments of his education he had at Ghent, and from thence he was sent to Louvain to go through a course of philosophy. His father, in 1567, was one of the victims of the savage tribunal established by the duke of Alva in the Netherlands, which stripped him of his estate, and obliged him to seek refuge in England. Young Drusius, notwithstanding the vigilance of his mother, who, being herself a zealous Catholic, took every method of detaining the youth in Flanders, found means to escape and join his father in London. He almost immediately entered himself at Cambridge, and studied with much ardour the classics and philosophy, and was at the same time employed as private tutor to some young men at the same college with himself. In 1571 he returned to the metropolis, and was preparing for a journey to France, with a view of farther improvement, when the news arrived of the dreadful massacre in Paris on St. Bartholomew's day. In the following year he was admitted a member of Merton college, Oxford, took his degree of B. A., and had an establishment appointed him for reading a lecture in the oriental languages. He continued the duties of this office four years, and then feeling a strong desire to visit his native country, he quitted Oxford and went to Louvain, where he applied himself to the study of the civil law. Here his continuance was very short, on account of the troubles excited by bigots in religion, and he returned to his father in London. A sudden turn in the affairs of his country, by the pacification of Ghent, enabled both father and son to return home in security. The latter began now to look for a settlement in some Protestant country on the continent, and was accordingly appointed professor of the oriental languages

in the university of Leyden. In the duties of this office he laboured with ind. fatigable industry, and, during the eight years which bore witness to his assiduity as a lecturer, he published works that established his fame for solid erudition in various departments of literature. In the year 1550 he married, and openly expressed a wish for a more lucrative settlement, in order that his means might correspond to the additional expences in which a family might involve him. The prince of Orange knew his value in the university, and, with his own hand, wrote to the magistrates of Leyden, exhorting them to furnish Drusus with such ample provision as should prevent him from leaving their city. Inattentive, however, to his great merits, they suffered him to accept of the situation of Hebrew professor in the university of Francker. He entered upon the duties of his new office in the year 1585, and retained it with the highest reputation to himself till his death, in 1616. He left behind him, in his numerous works, monuments to his fame, as one of the ablest scripture critics, having written upwards of thirty separate works on the subject. The greatest part of these has been incorporated in the well-known and highly esteemed "Critici Sacri in Vet. et Nov. Test.," first published in this country, and of which we have an abridgment in Pool's "Synopsis Criticorum," a work that is become almost as scarce as it is valuable. Besides these we have many other writings of Drusus, which indisputably prove his deep skill in the Hebrew language, and his extensive acquaintance with the Jewish antiquities, and with whatever is connected with biblical literature. The private character of this excellent scholar was as amiable and unassuming as his learning was profound. He had a son, of the same name with himself, who exhibited an astonishing instance of genius at a very early age; he understood accurately the Hebrew language when he was only eight or nine years old; and, before he was 17, he was presented to James I. of England; before whom, in the midst of his courtiers, he delivered a Latin oration, which obtained the applause and admiration of all who heard it. He died of the stone, before he was 21 years of age, at the house of the dean of Chichester, leaving behind him many memorials of his learning and unassumed piety.

DRUSOMAGUS, in *Ancient Geography*, a town of Vin-delicia, now *Memmingen*.

DRUSUS, MARCUS LIVIUS, in *Biography*, a person of considerable distinction at Rome, was descended from an ancient family, and became tribune of the people about the year 91, B. C. At this period there were great dissensions in the state; Drusus hoped to reconcile the contending parties, but his plan was opposed by all those whom he aimed to benefit by it. Conscious, perhaps, of his own good intentions, he did not readily abandon the scheme, and in some instances he made use of means which were by no means justifiable to promote its success. Finding himself growing unpopular, he proposed, as a bait to the multitude, a gratuitous distribution of corn among them: this measure he followed by a still more alarming motion, of giving to the Latins the privileges of Roman citizens. Hence violent conspiracies were formed, which required all his address to ward off for a time, and which, in the end, proved fatal to him. Returning from the forum, where he had been haranguing in favour of the allies, he was attended to his house by a great crowd of people, in the midst of which an assassin, said to be C. Varus, plunged a knife into his body, and made his escape. Drusus fell, and expired a few hours after, exclaiming, with his last breath, "When will the republic again possess a citizen like myself!" By the party whose cause he espoused his death was sincerely deplored, while those on the opposite side regarded it as a timely deli-

verance of the state from one who was only ambitious of being distinguished as a popular leader. Univer. Hist.

DRUSUS, NERO CLAUDIUS, second son of Tiberius Nero, by Livia, afterwards the wife of Augustus, was distinguished on many occasions for his courage and talents in public employments. His conduct against the Rhetians, a fierce people, inhabiting the country of the modern Grisons, over whom he obtained a complete victory, is celebrated by Horace in the fourth ode of the fourth book. This was about the year 15, B. C.; and in two years afterwards, Augustus, who was his patron, committed to him the charge of stopping the incursions of the Germans into Gaul. In this, and in various other instances, he evinced the characteristics of courage and of the highest military prudence and skill; till, at length, his successes were so brilliant and important, that his army, on the field of battle, saluted him Imperator. On his return to Rome he obtained the honour of a triumph, and in the following year, 9, B. C., he was raised to the consulate. Foreign war called him again to Germany: he crossed the Rhine and the Weser, and made some ineffectual attempts to pass the Elbe. Here he erected trophies to attest his conquests, and then began to march homewards: a fall from his horse, however, impeded his progress; and a fever, the consequence of the accident, put an end to his life, in the 30th year of his age. Though cut off in the prime of life, and even in the ardour of youth, he had lived sufficiently long to establish a high reputation as a soldier and magistrate. His public and private character exhibited the strongest marks of honour and integrity. He was lamented by the army and the people, and all classes of the citizens rendered him every token of homage and respect. He left three children; viz., the celebrated Germanicus; Claudius, who was afterwards emperor; and Livilla. Rom. and Univer. Hist.

DRUSUS, CÆSAR, son of the emperor Tiberius, was born B. C. 13. He was introduced by Augustus to offices in the state at a very early age, and at the time of the death of that emperor, he was nominated to the consulship. In the first year of his father's reign; viz. A. D. 14, he was sent out to appease a sedition, which had broken out in the legions in Pannonia, in which he, happily, succeeded. In the year 17, he was sent to command in Illyricum, in order to keep that province free from the war, which was then raging in Germany. For his prudent and successful services he had the honour of an ovation on his return. He was elected consul, a second time, in the year 21, and during the absence of the emperor in Campania, he fulfilled, alone, the functions of the office to the entire satisfaction of the public. In the following year the tribunial authority was conferred upon him, for which he returned thanks by letter, instead of presenting himself in due form before the senate, which was regarded in the light of an insult. Drusus, however, felt his importance in the state, and could not brook a rival, which led him to dread the growing influence of Sejanus, and to take every opportunity of treating him with indignity. Sejanus was too aspiring and ambitious to submit even to the prince, and determined to destroy him. For this purpose, he insinuated himself into the favour of Livilla, the wife of Drusus, and, at length, seduced her affections, and contrived, by her means, to administer poison to her own husband, the foe of her infamous gallant. In early life Drusus was supposed to betray a cruel disposition, by some feats at the gladiatorian games: he was also, in some degree, addicted to wine, and in other instances he gave tokens of a haughty and violent character. It must, however, be mentioned to his credit, that, while the court was divided between him and his cousin Germanicus, the two princes remained in perfect union, and almost

almost indifferent as to the final decision. Rom. and Univers. Hist.

DRUSUS, the tower of Straton, or Cæsarea, in *Ancient Geography*, a port of Judea on the sea, formerly in the half-tribe of Manasseh, on this side of Jordan, and called Drusus in honour of the son of Cæsar's wife. See CÆSARÆA.

DRUSWER, in *Geography*, a town of Lithuania, in the palatinate of Wilna; 14 miles W. of Braslaw.

DRUTHMARUS, CHRISTIAN, in *Biography*, a learned French monk in the ninth century, was a native of Aquitaine, but he was ordained priest in the diocese of Amiens. His various works prove that he was an excellent scholar; and very conversant in the sacred writings. He left behind him commentaries on the gospels of St. Matthew, Luke, and John; of the last, two fragments only have reached us. His object, as a critic and illutator of the sacred writings, was to give the natural and plain sense of the original language, and he is thought by able judges to have obtained his wish. His commentary on St. Matthew, and the fragments of the others, were published at Strasburgh in 1514, which were soon after suppressed on account of their tendency, which was decidedly in favour of protestantism. The catholics maintained, that these passages are insidious interpolations, and of no authority whatever.

DRUTISCHKEN, in *Geography*, a town of Prussian Lithuania, on the Rominte; four miles S. S. E. of Gumbinnen.

DRUTZ, a river of Russia, which runs into the Dnieper at Rogatchev, in the government of Mogilev.

DRUYE, a town of France, in the department of the Yonne, and district of St. Fargeau; 16 miles S. of Auxerre.

DRUYN, or DREVIN PETRI, or *Grand Drevoïn*, a town of Africa, on the Ivory coast, at the mouth of the river St. Andre. N. lat. 5°. W. long. 4° 5'.

DRUYSKIDWAR, a town of Lithuania, in the palatinate of Wilna; 8 miles N. E. of Braslaw.

DRUZIPARA, in *Ancient Geography*, a town of Thrace, near the river Agrinas, towards the north-west, and at some distance from Perinthus.

DRY. A dry air, *ceteris paribus*, lessens the weight of the human body, and the contrary quality increases it. See *MOISTURE of the air*.

DRY *Aqueduct*, is an arch made under a canal for a road to pass through.

Dry Baths, Confeſſa, Dock. See the substantives.

Dry Exchange, Cambium siccum, a soft appellation, anciently used to disguise usury, intimating something to pass on both sides; whereas, in truth, nothing passed but on one: in which respect it might be called dry. See *INTEREST*, and *USURY*.

"Cambium siccum," says Lud. Lopes, de Contract. & Negot. "est cambium non habens existentiam cambii, sed apparentiam, ad instar arboris exsiccatæ, &c."

Dry Harbour, in *Geography*, a bay on the N. coast of the island of Jamaica. N. lat. 18° 30'. W. long. 77° 10'.

Dry Mists, Measures. See the substantives.

Dry Meat, in the *Manege*, is used for corn and hay. After taking the horse from grass, or housing him, he is frequently put to dry meat.

Dry Moat, Rent, Storax, Suture, Sparvin. See the substantives.

Dry Needle, or *Dry point*, a tool used in copper-plate engraving, generally for the more delicate parts, such as the lights of clouds, white drapery, the light fur of animals, &c.

VOL. XII.

It is called *dry*, in contradistinction to the *dehling-needle*, and because its use is not followed by the application of aqua fortis.

Dry-needles are formed of steel-wire, which should be of excellent temper, that it may cut the copper freely, without breaking. The wire should be from one to two inches in length, and from the $\frac{3}{16}$ th to the $\frac{1}{8}$ th part of an inch in diameter, according to the required strength of the lines which they may be intended to cut. Being thus formed and tempered, the wire should be carefully inserted in slender handles, which are commonly formed of ebony or box, and whetted to conical points, more or less acute or obtuse, in proportion as the lines or incisions in the copper are required to be broad or deep.

That the point may cut lines exactly of the same breadth and depth on every side, it should be whetted as nearly as possible to a perfect cone: in order to which, it should be very carefully inserted in the handle, and so that a right line being supposed to pass from its extreme point, to the centre of the upper extremity of the handle, might form an ideal axis to the whole; during the process of whetting. In proportion to the truth of this ideal axis, will be the truth of the conical point, and the consequent truth of the workmanship for which it may be employed: and to ensure purposes of so much importance to the engraver, the best tool-makers generally insert a brass socket in the handle very correctly, by means of a watch-maker's lathe and wheel, before the dry-needle itself is introduced.

The dry-needle is usually whetted to a point, with a little oil, on a bone of the finest kind: by the French engravers latitudinally on the flat surface of the stone, and by most of the English engravers, longitudinally, in a groove of an inconsiderable depth, which is formed in the bone for that purpose.

When the dry-needle is thus prepared, it is used by different artists, with various degrees of freedom or exactitude; the degrees of strength of the incisions in the copper, being effected by mere dint of pressure as the needle is held between the fingers and thumb.

It should be mentioned, that in using this tool, still more than in using the graver, the copper is forced up on either side the incisions, as earth land is forced up in ploughing a furrow. The copper thus forced up, is termed by engravers *the burr*, which is removed either by a scraper, (see *SCRAPER*.) or by a piece of soft charcoal with a flat surface, used either with oil or with water.

Allamet, Le Bas, and several other of the French engravers, occasionally used *oval* instead of *circular* wire for their dry-needles; and Worlidge, who engraved his small portraits and prints from antique gems almost entirely with this tool, used *triangular* points, clearing off the burr which he raised with charcoal; though, as may be seen in his prints, not always clearing it off to the surface of the copper-plate.

DRYADES, DRYADS, in the *Heathen Theology*, the nymphs of the woods; a sort of imaginary deities, which the ancients believed to inhabit the woods and groves, and to hide themselves under the bark of the oak, called by the Greeks *δρυς*.

The dryades differed from the bamadryades, in that these latter were attached to some particular tree, with which they were born, and with which they died; whereas the dryades were the goddesses of the trees and woods in general, and lived at large, in the middle thereof. For, though *δρυς* properly signifies an oak, it was also used for tree in general.

We likewise find mention made, in divers authors, of a kind of prophetesses, or witches, among the Gauls, called dryades, or rather druides. See *DRUIDS*.

DRYÆNA, or **CHRYSOPOLIS**, in *Ancient Geography*, a town of Asia, in Cilicia. Steph. Byz.

DRYANDER, JOHN, in *Biography*, but whose real name was Eichmens, was born at Wetteran in Hesse, but received his education in France, and took his degree of doctor at Mayence. He went thence to Marburg, where he was engaged in teaching anatomy for twenty-four years, viz. from the year 1536, to 1560, when he died. His works are, "Anatomiz pars prior, in qua membra ad caput spectantia, recensentur, et delineantur," Marburg, 4to. 1537. He first observed several distinctions, before unnoticed, between the medullary and cortical part of the brain, and he saw the olfactory nerves, which he miscalls the optic nerves. In 1541, he gave "Anatomiam Mundini ad vetustissimum aliquot manuscriptorum codicum fidem collatam," 4to. with notes, in which he frequently corrects the errors of his author, and for which he is deservedly placed by Haller among the restorers, and improvers of anatomy. He is also mentioned with honour in the Bib. Anat. of Douglas. Haller Bib. Anat.

DRYANDRA, in *Botany*, (so named by Thunberg in honour of his much-valued friend, Jonas Dryander, M. A. the pupil and friend of the great Linnæus and of his son, long resident in this country, and now a vice-president of the Linnæan Society.) Thunb. Japon. 13. Murray in Linn. Syst. Veg. ed. 14. 612. Schreb. 708. Juss. 359. Mart. Mill. Dict. v. 2. Clafs and order, *Diocia Monadelphica*. Nat. Ord. *Euphorbia*. Juss.

Gen. Ch. Male, *Cal.* Perianth of two ovate, acute, equal leaves, shorter than the corolla. *Cor.* Petals five, obovate-oblong, reflexed, somewhat spreading, rather above half an inch long. *Stam.* Filaments nine, united below into one set, unequal, half the length of the petals; anthers minute. *Pist.* none.

Female, *Cal.* and *Pist.* not observed. *Cor.* Petals five. *Peric.* Drupa pear-shaped, angular, furr-wed. *Nut* of three or four cells. *Seeds* solitary, oval.

Ess. Ch. Male, *Calyx* two-leaved. Petals five. Stamens nine. Female, Petals five. Drupa. Nut with three or four cells. *Seeds* solitary.

D. cordata. Thunb. Jap. 267. t. 27. (Abrasin; Kæmpf. Amoen. 789. Ic. t. 23.) Dodiëkn or Abrasin of the Japanese. Native of the island of Nipon, the country of Fankonia, and other places in Japan, flowering in May and June. It forms a small tree, luxuriantly branched; its wood is compared by Kæmpfer to that of the willow, and the pith is light and very abundant. *Branches* round, with a rugged, dotted bark. *Leaves* about the ends of the branches, spreading, alternate, on footstalks, heart-shaped, acute, entire, smooth, paler beneath, five-ribbed, veiny, broad, three or four inches long. In Kæmpfer's figure they are undulated and sometimes lobed, and bear two stalked glands at the base, or one between the lobes, which he also describes in his *Amoenitates*. Flowers in corymbose, aggregate, nearly terminal panicles, white according to Kæmpfer, Thunberg says yellow. The seeds are compared to those of the *Ricinus* or *Panna Christi*, and afford oil for lamps. It is nearly allied to *Jatropha*, or at least to some species incorrectly ranged by Linnæus under that genus.

DRYAS, elegantly so named by Linnæus, from the Dryades, or sylvan goddesses, to whom the oak, $\Delta\rho\upsilon\varsigma$, which its leaves resemble, was sacred. Linn. Gen. 256. Schreb. 343. Willd. Sp. Pl. v. 2. 1118. Sm. Fl. Brit. 555. Mart. Mill. Dict. v. 2. Juss. 338. Gært. t. 74. Clafs and order, *Isolandria Polygynia*. Nat. Ord. *Seneciose*, Linn. *Rosaceæ*, Juss.

Gen. Ch. *Cal.* Perianth of one leaf, inferior, in eight

deep segments, which are spreading, linear, obtuse, equal, rather shorter than the corolla. *Cor.* Petals eight, oblong, emarginate, spreading, inserted into the calyx. *Stam.* Filaments numerous, capillary, short, inserted into the calyx; anthers small. *Pist.* Germens numerous, crowded, small; styles capillary, inserted into the sides of the germens; stigmas simple. *Peric.* none. *Seeds* numerous, roundish, compressed, each crowned with its long, woolly, permanent style.

Schreber remarks, that the segments of the calyx, and consequently the number of petals, vary from six to ten. This is true, but it happens very seldom.

Ess. Ch. *Calyx* inferior, in eight equal segments. Petals eight. *Seeds* with feathery tails. *Receptacle* depressed.

D. obovata, Linn. Sp. Pl. 717. Fl. Lapp. ed. 2. 181. Sm. Engl. Bot. t. 451. (*Chamaedrys* tertia, five montana; Clus. Hist. v. 1. 351.) is the original, and as Willdenow justly observes, only genuine species, its generic character depending not only on the number of petals, and corresponding number of the segments of the calyx, but on the equality and uniformity of the latter. By this rule the other species are removed to *Geum*. It is found on most of the high Alpine beaths of Europe, forming wide entangled depressed tufts or patches, flowering from the middle of June till late in August. The stems are woody, branched, leafy, a few inches in height. *Leaves* evergreen, crowded, stalked, ovate, blunt, strongly serrated; dark shining green above, snow-white, veiny, downy and concave beneath. *Stipules* united with the footstalk, as in roses. *Flowers* solitary, white, large, and handsome, each on a long, erect, solitary, terminal, reddish, glandular stalk. *Calyx* also glandular and brownish. *Anthers* yellow. It is one of the most elegant of Alpine plants, and may be cultivated in a gravelly soil, mixed with loam and some bog-earth, under a north wall in our gardens, but it requires a pure air, and some cover during the cold windy weather usual in our tardy spring. S.

DRYAS, in *Ancient Geography, a river of Greece, in the Thessaly, 20 stadia S. of the river Sperchius, and about the same distance N. of Alopus.*

DRYAS, in *Zoology*, a species of *Myoxus* which see.

DRYBACTÆ, or **TRYBACTRÆ**, in *Ancient Geography, a people of Asia, in Sogdiana. Ptolemy.*

DRYBURG, in *Geography*, a town of Germany, in the circle of Westphalia, and bishopric of Paderburn; seven miles E.N.E. of Paderburn.

DRYDEN, JOHN, in *Biography*, one of the most celebrated poets of which this country can boast, was born about the year 1631, in the parish of Aldwinkle-All-Saints, in Northamptonshire. He was grandson to sir Erasmus Driden, (the name being then spelt with an *i*), of Canons-Ashby, in the same county. The father of our poet possessed a small estate, acted as a county magistrate during the usurpation, and was, in religion, probably, a presbyterian. John laid the foundation of a learned education at Westminster, under the famous Buby, and was thence elected to a scholarship in Trinity college, Cambridge, in 1650. It is said that he was not distinguished for peculiar talents or genius, either at the school or at the university. In the latter he took his degrees, and though he had, at the time of his admission, written two short copies of verses, yet his name is not recorded among the academical poets of the period. His father died in 1654, and John succeeded to so much of the estate as could be spared from the widow, who had other children to provide for. He removed to the metropolis, and was patronized by a distant relation, sir Gilbert Pickering, one of Cromwell's strictest adherents. Dryden was his clerk or secretary, and probably concurred in the

opinions

opinions and practices of the family in which he resided. Hence, says his biographer, "in the history of the changes of the human mind, few facts will appear more extraordinary, than that Milton should have been defended from a catholic and loyalist family, and Dryden from a freitarian and republican one." On the death of Cromwell, Dryden celebrated his memory, in heroic stanzas, which fact has been perpetually referred to in dispraise of the poet, who, on the restoration, ardently embraced the royal cause. It must, however, be admitted, that Dryden's praise of the protector went chiefly to that trait in his character, which enabled him first to put an end to domestic contentions, and then to inspire awe and respect for his country throughout Europe. On the return of Charles II. he published his "Altra Redux," which he followed by "A Panegyric on the Coronation." In 1662, he addressed some lines to lord chancellor Clarendon, in the same strains of loyalty; but it was supposed to be owing to some elegant verses in praise of the modern improvements in philosophy, which he prefixed to Dr. Charleton's treatise on Stonehenge, that he was elected a member of the Royal Society. About the same time he appeared first as a writer for the stage, and his comedy, entitled the "Wild Gallant," was acted in February 1663. By the public this first effort was ungraciously received, but by the interest of Barbara Villiers, afterwards duchess of Cleveland, it obtained a kind reception at court. His next pieces were, the "Rival Ladies," and the "Indian Emperor," in which he displayed a facility of harmonious versification, and a splendour of poetic diction: while his "Essay on dramatic Poesy" exhibited him as an elegant writer in prose, and an able and ingenious critic. About the year 1665, he married lady Elizabeth Howard, daughter of the earl of Berkeley, a connection which promised more advantages than really resulted from it. In 1667, Dryden added to his fame, by the publication of his "Annus Mirabilis," for which the subjects were the fire of London, and the war with the Dutch. He now engaged, under certain conditions, with the managers of the king's theatre, to supply them with three plays annually. His profits under this joint concern have been estimated at nearly 400*l.* a-year, and were probably the principal part of his income. On the death of sir William Davenant, in 1668, he obtained the office of poet-laureat, and soon after the sinecure place of historiographer, the joint salaries of which produced him 200*l.* *per annu.* For some defects in his style as a tragedian, he was attacked under the name of Bayes, in the "Rehearsal." This satire was written by Villiers, duke of Buckingham, in conjunction with other wits of the time. Dryden felt the lash which the burlesque drama meant to inflict, and candidly acknowledged that several of the strokes contained in it were truly appropriate. In 1679 Dryden himself became a satyrilist, but his "Essay" provoked from lord Rochester a severe retaliation by the hands of ruffians hired by his lordship to inflict on the poet a cudgelling, as he was returning from the coffee-house. In 1681, by the royal command, Dryden wrote his celebrated poem of "Abalom and Achitophel," which was an application of the events in the life of David, king of Israel, to the reign of his own sovereign Charles II., relative to the duke of Monmouth and the earl of Shaftesbury. This work was eagerly read, and as it raised him very high in the estimation of the court, so it involved him in irreconcilable enmity with its opponents. The hatred was greatly increased by his "Medal, a satire on sedition," written the same year, on occasion of a medal struck by the whig party, when a grand jury returned *ignoramus* to an indictment preferred against lord Shaftesbury for high treason.

Dryden next tried his powers in literary satire, by the publication of a piece entitled "Mac-Flecknoe," which was written in ridicule of an unequal rival, Shadwell. From this, which cannot well be justified by the poet's warmest admirers, we turn to his more serious poem, the "Religio Laici," which appeared in the same year. Its purpose is to give a compendious view of the arguments for revealed religion, and to ascertain in what the authority of revelation essentially consists. Soon after this, he ceased to write for the stage, but he was then deeply involved in his pecuniary circumstances, and solicited most earnestly any employment, either in the customs or excise, that might be vacant, on the score of absolute necessity. "I have," says he, "three sons, growing to man's estate. I breed them all to learning beyond my fortune, but they are too hopeful to be neglected, though I want.—I am going to write somewhat by his majesty's command, and cannot stir into the country for my health and studies, till I secure my family from want." The case of Dryden, like a thousand similar cases, proved that real want was not the best recommendation to the affluent: his petition was unheeded, and he obtained from those Mæcenases of the age, the book-sellers, that patronage which an ungrateful monarch refused to bestow, upon his needy, but very faithful poet and friend.

Soon after the accession of James II., Dryden conformed to the religion of the king, in the profession of which he continued till his death. Whether this important change be imputable to conviction, or to a desire of the royal favour, has been a subject of much dispute. It is, however, certain, that he never seems to have regarded the business of religion with that attention which its importance demands, and on this account, probably, thought the difference between the protestant and catholic faith of no great moment. He obtained from the new king an additional pension of 100*l.* as a reward of his ready compliance; to which was annexed, it is supposed, a condition that he should employ his pen in defence of the religion which he embraced, and he faithfully performed his part of the contract. The revolution, in 1688, deprived the poet of all his posts and pensions, and the laureateship was bestowed upon his rival Shadwell, to the small mortification of Dryden, and not a little to the disgrace of those who could snatch it from a poet of extraordinary merit, to give it to a man who possessed no qualification worthy of the office.

Dryden, now advanced in life, was obliged to depend wholly upon his own exertions for a security from absolute indigence. Fortunately for him, his faculties were equal to his wants, and what is very surprising, the pieces which he wrote during the last ten years of his life, for actual subsistence, were those which have most contributed to immortalize his name. Among these were his translations of Juvenal and Persius, and Virgil; by the latter he gained about 1300*l.*, it being published by subscription. Soon after the publication of his Virgil, he was solicited by the stewards of the musical celebration of St. Cecilia's day, to write a second ode for the purpose: he had written the first in 1687. This request produced his celebrated "Alexander's Feast," the most popular of all his compositions, and, perhaps, says a good writer, it stands at the head of all the lyric poems in the English language. About this period he meditated a translation of Homer, and agreed, as we are told, to furnish his bookseller with 10,000 lines for the sum of 300*l.* His last work was a collection of fables, of which the subjects are taken from Chaucer, Boccaccio, Ovid, &c. He died on the first of May, 1700, and his body was interred with every mark of respect, in Westminster Abbey, where a monument was erected to his memory, by Sher-

held, duke of Buckingham: his name alone supplied his epitaph.

No modern writer, unless Voltaire be an exception, has possessed equal versatility of talent with Dryden. For the drama he had no original predilection: the beat of his genius would have impelled him to epic poetry: he wrote plays because he was poor: and that he ever wrote them well must be ascribed to the exuberance of his powers. His theatrical pieces are indeed unequal in the extreme. In some he sinks below criticism, in others he soars far above it. The plays of Dryden, though never to be entirely approved, are still read and admired, while those of his competitors are mouldering in oblivion. In his heroic plays, Dryden opened a field of composition peculiarly his own. In the "Conquest of Grenada," he delights by the diversity of his characters, the vivacity of his description, the eloquence of the language, and occasionally the sublimity of the sentiments. What he has produced is not so much a drama as an epic romance, and it has been the subject of regret that he had not leisure to produce a poem on a plan so consonant to his genius. "In his "Don Sebastian," says an elegant writer, "he has rivalled Corneille: in his "Anthony and Cleopatra," he has caught a portion of Shakspere's spirit, and employed it better than his master: in his "Spanish Fryar," he has given the happiest example of a double plot, and in every respect, but morals, of a perfect play. In the drama, therefore, if Dryden sometimes fell short of his own powers, he commonly proves superior to other men; as an original poet he is yet more to be praised. Perhaps no individual writer ever contributed so largely to polish and refine a language: in satire he was a master: his "Medal," his "M-Flexnoc," and his "Absalom," are all original treasures which have enriched succeeding writers: his characteristic excellencies are versatility and strength; his faults are innumerable, but they are redeemed by the originality and energy of his conceptions. As a translator, he deserves much blame as well as praise. His genius assimilated better with Juvenal and Persius than with Virgil. His fables are not the least pleasing of his performances: his "Alexander's Feast," which alone might have immortalized his name, was among the latest of his productions. Such an accession of valuable poetry no other writer has supplied to our language: but his merits are not limited to poetical compositions; in his various prefaces, and in his "Essay on Dramatic Poetry," he has established his reputation as a prose writer. The inequalities so obvious in his verse are not discovered in his prose; he is uniformly graceful and elegant; always animated and various, and sometimes eloquent. To compare Dryden with Pope would be invidious: the latter could not have written so well, had not the former written before him. Under Dryden's auspices, Congreve wrote for the stage: emulous of his genius, Pope slipped in numbers, for the numbers came; Bolingbroke caught the glow of Dryden's fancy; and Addison learnt from him to construct sentences with that exquisite felicity which eludes censure, and baffles imitation."

In private life Dryden was cold and reserved; yet he was friendly and humane. Though his pen was extremely licentious, his manners were decently regular. He was domestic in his habits, and affectionate towards his family. With a due sense of his own superior merit, he was sensible of his defects and patient under criticism. Biog. Brit. Johnson. Hist. of Knowledge, in New Ann. Register.

Our great bard, besides his dramatic works for declamation, single poems of length, occasional verses, epistles, fables, elegies, prologues, epilogues, epitaphs, and translations, is well entitled to eulogy as a lyric poet; having not only written innumerable songs, "Alexander's Feast," and another "Ode

for St. Cecilia's Day," but several dramas expressly for music: as, "The State of Innocence, or, Fall of Man," an opera; "Albion and Albanus," ditto; "King Arthur, or the British Worthies," a dramatic opera; and the "Drama of Dioclesian," written originally by Beaumont and Fletcher, which he formed into an opera for Purcell.

Though the State of Innocence is formed into an opera, it can hardly be called a lyric poem: it is written in regular heroic verse, and in rhyme. There is, indeed, much machinery and picturesque and instrumental music planned; and in the two first acts not a single stanza calculated to form an air or duet. There is, indeed, a dance of devils, among other amusements, between the first and second acts; and it is said in the instructions, that they may sing a song expressive of the change of their condition, from what they once enjoyed, and how they fell bravely in battle, having deserved victory by their valour, and what they would have done had they conquered. In the third act only devils sing, disguised like angels. There is no song or vocal music in the fourth act. In the last scene of the fifth act, soft music and a song are mentioned; but for which no words are provided. Eve's last speech, however, might be set and sung, as an adieu: to the joys of paradise.

This drama, framed from Milton's Paradise Lost, was never brought on the stage, or even set to music, as we have been able to discover. Nor do we know whether the dialogue was intended for recitative or declamation. The author, while he has endeavoured to preserve the beautiful, bold, and daring sentiments of Milton, quitting blank verse, and Milton's epic style, has dressed his thoughts in his own melodious, powerful, and happy versification.

Throughout the preface to his next opera, as it is called, "Albion and Albanus," Dryden, in his usual manner, diffuses entertainment and instruction; and though he probably had never seen or heard a single scene of an Italian opera performed, his definition of that species of drama, and precepts for its construction and perfection, are admirable, and in many respects still applicable to similar exhibitions.

"An opera," says he, "is a poetical tale, or fiction, represented by vocal and instrumental music, adorned with scenes, machines, and dancing. The supposed persons of this musical drama are generally supernatural, as gods and goddesses, and heroes, which at least are descended from them, and in due time are to be adopted into their number. The subject, therefore, being extended beyond the limits of human nature, admits of that sort of marvellous and surprizing conduct, which is rejected in other plays. Human impossibilities are to be received, as they are in fairy; because, where gods are introduced, a supreme power is to be understood, and second causes are out of doors: yet propriety is to be observed even here. The gods are all to manage their peculiar provinces; and what was attributed by the Heathens to one power, ought not to be performed by any other. If the persons represented were to speak on the stage, it would follow of necessity, that the expressions should be lofty, figurative, and majestic; but the nature of an opera denies the frequent use of these poetical ornaments; for vocal music, though it often admits a softness of sound, yet always exacts a melodious sweetness; or to distinguish yet more justly, the recitative part of an opera requires a more masculine beauty of expression and sound: the airs must abound in the softness and variety of numbers; their principal intention being to please the hearing, rather than to gratify the understanding. As the first inventors of any art or science, provided they have brought it to perfection, are, in reason, to give laws to it; so whosoever undertakes the writing an opera, is obliged to imitate the Italians, who have not only invented, but perfected
this

this sort of dramatic musical entertainment. We know that for some centuries, the knowledge of music has flourished principally in Italy, the mother of learning and of arts; that poetry and painting have been there restored, and so cultivated by Italian masters, that all Europe has been enriched out of their treasury.

"It is almost needless to speak any thing of that noble language, in which this musical drama was first invented and performed. All who are conversant in the Italian, cannot but observe, that it is the softest, the sweetest, the most harmonious, not only of any modern tongue, but even beyond any of the learned. It seems, indeed, to have been invented for the sake of poetry and music; the vowels are so abounding in all words, and the pronunciation so manly and so sonorous, that their very speaking has more of music in it than Dutch poetry or song. This language has in a manner been refined and purified from the Gothic, ever since the time of Dante, which is above four hundred years ago; and the French, who now cast a longing eye to their country, are not less ambitious to possess their elegance in poetry and music; in both which they labour at impossibilities: for nothing can be improved beyond its own species, or further than its own original nature will allow: as one with an ill-toned voice, though ever so well instructed in the rules of music, can never make a great singer. The English have yet more natural disadvantages than the French; our original Teutonic consisting most in monosyllables, and those incumbered with consonants, cannot possibly be freed from those inconveniences."

He tells us, that "this opera was only intended as a prologue to a play of the nature of the "Tempest;" which is a tragedy mixed with opera, or a drama written in blank verse, adorned with scenes, machines, songs, and dances; so that the fable of it is all spoken and acted by the best of the comedians; the other part of the entertainment to be performed by the same singers and dancers who are introduced in this present opera." The tragedy here alluded to was "King Arthur," which was not performed till about the year 1690.

By dramatic opera, Dryden, and writers of his time, mean a drama that is declaimed or spoken, and in which songs and symphonics are introduced; differing from real operas, where there is no speaking, and where the narrative part and dialogue is set to recitative. And this is the plan that has of late years been so successfully followed by Bickerstaff and others, in the comic operas that have appeared on the English stage. To say the truth, though recitative was tolerated in Dr. Arne's *Artaxerxes* in favour of the airs, sung by favourite singers, we have properly no national recitative, which, in action, is not languid, or ridiculous.

In the epistle dedicatory to his third opera, "King Arthur," to the marquis of Halifax, the poet makes a very candid, liberal, and unusual concession to the musician, Purcell, who composed the opera, by saying that "these sorts of entertainment are principally designed for the ear and eye; and therefore in reason my art on this occasion ought to be subservient to his."

Dryden, no musician himself, seems to have been more sensible to the charms of music, than any of our poets of the higher class, except Milton and Mason, who knew what they were talking about. Burney.

DRYERS, in *Painting*, are substances, so called from their use in remedying the fault of oils, which dry too slowly. See *Drying Oil*.

DRYINAS, *Oal-snake*, in *Zoology*, a species of *Crotalus*; which see.

DRYITE, in *Ancient Geography*, a people of Africa, in

Mauritania *Cæsariensis*, placed by Ptolemy on mount *Dardus*. —Also, a people of the isle of Crete.

DRYITES LAPID, in *Natural History*, a name given by authors to a substance but ill deserving the name of a stone; it being only fossil wood found in detached masses. There is much of this fossil wood found in Italy, on the banks, and on the shores of rivers. We know also by what we see of the fossil wood of England, that it may be found in all degrees of petrification, from that of almost unaltered wood, to absolute stone, or mineral matter, with only the superficial grain of wood. See *Fossil Wood*.

DRYMA, or DRYME, in *Ancient Geography*, a town of Africa, in Libya, the *Adryma* of Strabo, supposed to be the same with *Adrumetum*.

DRYMÆA, DRYMOS, or *Drymus*, a town of Greece, in the Phocidæ, on the banks of the Cephissus, N.E. of mount Parnassus, and 20 stadia from mount *Tithronium*. In this place was an ancient temple, dedicated to Ceres *Themphora*, or *Legitatrix*, in which was celebrated an annual feast. The statue of the goddess was of marble. Pausanias says that the inhabitants of this town were anciently called *Nauboliani*. It is called *Drymia* by Steph. Byz., and Pliny denominates its territory *Drymia* and *Daulis*.

DRYNESS of a Place, means the state of that place with respect to the want of moisture; and, since dry and moist, dry and damp, dry and wet, are relative terms, a place A may be said to be dryer than another place B; or the place B may be said to be moister than the place A, and the meaning of both expressions is exactly the same. There is no place upon the surface of the earth which is perfectly dry, and there is none that may be called perfectly damp, unless it were entirely covered by water. The philosophical instrument, which measures and indicates the actual degree of dryness, or of moisture, is called an hygrometer, and a vast variety of hygrometers have been contrived and used; but they are mostly imperfect. The best hygrometers at present known, are those of Mr. De Luc, and Mr. Saussure. (See the article *HYGROMETER*.) The general principle upon which hygrometers act is as follows:

A slender piece of animal, or vegetable substance, capable of absorbing and of yielding moisture with readiness, and likewise capable of expanding itself, more or less, in proportion to the quantity of moisture, (of which there is a great number,) is fixed in a proper frame of metal, or wood, or glass, &c. and by means of a graduated scale, its expansion is shewn to the observer; and since this expansion is nearly proportional to the degree of moisture in the hygrometrical substance, which is not materially different from the moisture of the surrounding air; therefore, the degree of expansion of the hygrometrical substance, indicates the contemporary moisture of the surrounding air. But the more general defects of hygrometers are, 1st, that the points of extreme moisture and extreme dryness, or the utmost expansion and contraction of the hygrometrical substance, cannot be fixed on any of them; and, 2dly, that even in the best hygrometers, the animal, or vegetable hygrometrical substance, is apt to alter its degree of expansion and contraction in the course of no great length of time; hence, two or more hygrometers, made upon the very same principle, even by the same workmen, but at different times, will hardly ever be found to agree, when placed in the same situation, and exactly in the same circumstances. The hygrometers of De Luc and Saussure, though superior to all the others, are not quite free from this imperfection. In consequence of these defects, and of the recent invention of the two last mentioned hygrometers, we have not a great number of periodical hygrometrical observations made in different countries; whence, the comparative dryness of

different

different places might be determined. It is not from the observations of one or two years, that a tolerably good estimate of the dryness of a particular place may be derived. A mean of several years constant observation, is the only approximation that can be depended upon. Notwithstanding these defects and these difficulties, the dryness of places frequently forms the subject of common conversation, and common inquiry; for, in truth, the real state of it is a matter of no small consequence to the welfare of the human species.

The dryness, or moisture, of a particular spot, arises from a variety of circumstances, which must be all taken into consideration, in order to form a proper estimate; and, after all, at least in the present state of knowledge, the real state of any particular spot, with respect to dryness, or moisture, may, with more confidence, be derived from visible effect in common occurrences, than from the meteorological journal. The common occurrences we allude to, are the usual colour of vegetables; their growing more or less readily upon walls, houses, trees, &c.; the frequent moisture of common salt, and so forth.

The average quantity of rain which falls upon a country throughout the year, is by no means a sure indication of the nature of that country with respect to dryness; for, if the rains fall seldom, though in abundance, the place may be much dryer than if the rain fell frequently and slightly. In the former case, the great quantity of rain-water is absorbed, or drained, or evaporated; and not long after the place may be remarkably dry. In the latter case, the small quantity of rain which falls at one time is hardly evaporated, or absorbed, before more rain comes down, and thus a succession of moisture is kept up. Dr. Huxham observes, that small rains keep the air moist, while heavy ones render it drier, by beating down vapours. The perpendicular height of water which falls at Barbadoes in one year, measures 67 inches (a remarkably great quantity); yet the air of that island is by no means reckoned damp. In India, the air generally is so remarkably dry, as to absorb moisture, with surprising quickness, from whatever is exposed to it; yet, during the rains, *viz.* the period during which the rain falls almost incessantly, the water that falls, and the copious evaporation of that which has fallen, render the air so very damp, as to loosen all sorts of furniture that are fastened by means of glue, and the hygrometer nearly points to extreme moisture. See the article RAIN.

The dews, which fall much more abundantly upon certain places than upon others, contribute, at least for a particular time, to moisten the air of the place. See the article DEW.

Numerous plants, closely growing, contribute to the dampness of the place; 1st, because they themselves evaporate abundance of water; 2dly, because they prevent the rays of the sun, and the action of the winds, having any effect upon the ground below them.

In general, warm countries, *viz.* those which are situated near the torrid zone, when they are not surrounded by marshes, are drier than those which lie nearer to the poles of the earth; excepting, however, in a hard frost.

Islands, and especially small ones, mostly are less dry than continental tracts. And valleys, together with other places that lie close to hills, mountains, &c. generally are less dry than those which stand in open countries. About the latitude of Great Britain, those places which lie close to the western shores, are less dry than those which are otherwise situated.

The winds which are predominant in any particular country, influence, in a considerable degree, the dryness of the

place; for, according as they mostly come from the sea, or from the land, from the north, or from the south, or elsewhere, for they bring dry, or moist air with them.

In no place does the hygrometer ever reach the points of extreme dryness, or of extreme moisture: excepting, indeed, when it is improperly situated. In London, the mean annual altitude of the hygrometer seems to be about 82°; the whole scale between the points of extreme dryness and extreme moisture being divided into 100 degrees.

The movements of the hygrometer indicate the changes of dryness to moisture, and *vice versa*, in the surrounding air, with sufficient quickness. And from the joint movements of the hygrometer and the barometer, the approaching change of weather may frequently be foreseen. When the barometer falls, and the hygrometer rises, rain is at hand. When the barometer rises, and the hygrometer falls, we may expect fair weather.

DRYNESS, *Extreme Point of*, means a total privation of moisture. But upon the surface of the earth a place so circumstanced does not occur; for the air, in its natural state, is always more or less combined with aqueous vapour; and hot air holds in solution a greater quantity of water, than an equal bulk of colder air can do; so that heated air has a greater drying power, because the additional heat has rendered it capable of dissolving more water; whence, it evidently appears, that heating is not one of the means by which air may be deprived of its moisture; yet, (in consequence of the above-mentioned circumstance,) it is the most effectual method of drying other things.

The only method of depriving air of its moisture, to a very considerable degree, if not entirely, is to expose a given quantity of it to such substances as absorb water with great avidity. Strong sulphuric acid, hot caustic alkalies, and quick-lime recently calcined, have each of them the property of absorbing the humidity of the air. There are other substances which likewise possess the same power, though not in an equal degree, or which may not be used with equal conveniency. For this purpose, the air must be confined into a vessel, so as to have no communication with the external air, and the substance which is to absorb its moisture, must then be introduced to it.

This operation is not frequently required in philosophical experiments; and the principal use to which it is at present applied, is to settle the point of extreme dryness in the construction of hygrometers; and this is accomplished in the following manner: About 10, 15, or 20 pounds weight of quick lime just burned, are placed in an oblong tin vessel, the capacity of which exceeds the bulk of the lime. On one side of this vessel, and against its empty space, there is a pane of glass, through which one may see what passes within the vessel. Now, when the vessel has been charged with the lime, the hygrometers which are finished, so far as to want only the graduation of the scale, are placed within the tin vessel, and exactly behind the pane of glass. The lid of the vessel is then put on, and is waxed, or cemented down, in order to prevent any passage of air either in or out of the vessel. In this situation, the whole is left undisturbed for several days, during which the movements of the indexes of the hygrometers are observed daily through the pane of glass. In proportion as the lime absorbs the moisture of the air, the index of each hygrometer is seen to descend; but, after a certain period, they become stationary; and that point at which the index of each hygrometer stops, gives the point of extreme dryness which is there marked, (for which purpose a few arbitrary marks are made upon the undivided scales of the instruments before they are confined within the tin vessel.) The point of extreme moisture is afterwards determined, by placing

placing the hygrometer under water. And the distance between those two extreme points is divided into a hundred equal parts, called *degrees*.

In the above-described operation, quick-lime has been preferred, principally on account of its continuing to absorb moisture gradually, but for a very long time. For farther particulars relative to the construction and the use of this vessel with quick-lime, see the article *HYGROMETER*.

DRYOPA, in *Ancient Geography*, a town of the Peloponnese, in the Argolide, near Hermione. Steph. Byz.

DRYOPEIA, Δρυοπέια, in *Antiquity*, an anniversary day, observed in memory of Dryops, one of Apollo's sons.

DRYOPIS, in *Ancient Geography*, a country of Greece, situate in the vicinity of Mounts Oeta and Parnassus, and so called, as it is said, from Dryope, the daughter of Eurypylos, or, as the poets feign, a nymph ravished by Apollo; but more probably from δρυς, an oak, and εις, voice, on account of the number of oaks that grew about the mountains and the rustling of their leaves. The Dryopes, however, valued themselves much upon their fabulous origin, and called themselves the sons of Apollo; and therefore, Hercules, having overcome this people, carried them prisoners to Delphos, where he presented them to their divine progenitor, who commanded that hero to take them with him into Peloponnese. Hercules obeyed, and gave them a settlement there, near the Alinean and Hermonian territories; hence the Alineans came to be blended with and to call themselves Dryopes. Pausanias, in Messen.

DRYOPTERIS, in *Botany*, from Δρυς, the oak, and πτερις, a fern, see *POLYPODIUM*. Tragus seems the first modern writer who gave this name to what is now *Polypodium Dryopteris*; but the celebrated Polybody of the Oak is, with English pharmacologists, merely *P. vulgare* happening to grow in that situation, which has been supposed to encrease its reputed medical virtues. The Δρυοπτερις of Dioscorides is described by him as a fern with very finely cut leaves, growing on old mossy oaks, and may as probably be the plant of Tragus as any other.

DRYPIS, { Δρυπις of Theophrastus, so called from δρυπις, to tear, appears to have been a thorny leafless shrub, not now to be ascertained. Anguilara first applied this ancient name to the plant before us, and was followed by Lobel, Gerarde, and Linnæus. It is perhaps the only plant for which the latter quotes Gerarde's herbal.) Linn. Gen. 150. Schreb. 202. Willd. Sp. Pl. v. 1. 1513. Mart. Mill. Dict. v. 2. Juss. 303. Gærtn. t. 128. Clafs and order, *Pentandria Trigynia*. Nat. Ord. *Caryophyllææ*.

Gen. Ch. Cal. Perianth of one leaf, tubular, divided half way down into five segments, permanent. Cor. Petals five; their claws narrow, the length of the calyx; borders flat, deeply divided into two linear blunt segments, and crowned at the base with a pair of small teeth to each petal. Stam. Filaments five, as long as the corolla; anthers simple, oblong, incumbent. Pist. Germen superior, obovate, compressed; styles three, simple, spreading; stigmas simple. Peric. Capsule roundish, clothed with the calyx, small, of one cell, cut all round. Seed solitary, kidney-shaped, polished with spiral cotyledons and embryo.

Efl. Ch. Calyx with five teeth. Petals five, cloven, crowned. Capsule bursting all round, of one cell. Seed solitary.

D. spinosa. Linn. Sp. Pl. 390. Jacq. Hort. Vind. v. 1. 39. t. 49. (Drypis; Ger. em. 1112. *D. italica aculeata*, floribus albis umbellatim compactis; Mich. Gen. 24. t. 23. badly copied in Lamack t. 214.) This is the only known species, nor can any plant constitute a more natural genus, though it belongs to so very natural an order. It grows in Barbary, Italy, and several parts of the Levant. Dr. Sib-

thorp gathered the *Drypis* on mount Parnassus; see Prod. Fl. Græc. v. 1. 209. Jacquin communicated it to the Kew garden in 1775. The root is biennial. Stems decumbent at the base, then ascending, square; or branched in an opposite manner. Leaves opposite, sessile, awl-shaped, pungent; those on the main stem having often two or three spinous segments or teeth on each side, while those on the branches are all undivided and entire. The stem terminates in a forked leafy panicle. Flowers sessile, white or purplish, resembling those of a *Stellaria*. The whole herb is smooth, and of a pale rather glaucous green. Asses are said by Mehell to be fond of it.

DRYS, in *Ancient Geography*, a town of Thrace.—Also, a town of Italy, in Oenotria.—Also, a town of Greece, in Epirus.—Also, a trading sea-port town of Asia Minor, in Bithynia, over-against Nicomedia; it was one of the fauour-bourgs of the town of Chalcedon; and was also called *Rufiniana*.

DRYSDALE, JOHN, D. D. in *Biography*, a distinguished clergyman of the established church of Scotland, was the third son of the Rev. John Drysdale, minister of Kirkaldy; at which place Dr. Drysdale was born, on the 29th of April, in the year 1718. The elementary parts of classical learning he received under Mr. Miller, who kept a school in that town; and had among his contemporaries the learned Dr. George Kay, and the celebrated Dr. Adam Smith. In 1732, he went to finish his studies at the university of Edinburgh; and in the year 1740, was licensed to preach by the presbytery of Kirkaldy. Taking holy orders, he was several years assistant minister of the collegiate church in Edinburgh, and in 1745 was presented to the church of Kirkhillton. After residing there for fifteen years, he was presented to lady Yester's church, by the town council of Edinburgh. This being the first instance in which the magistrates of that city had exercised their right of presentation, and Mr. Drysdale being suspected of favouring in his discourses the *Arminian* tenets; a formidable opposition was made to his institution; but the magistral party proving victorious, he obtained a settlement in lady Yester's church. And the sermons he delivered there, says professor Dalzel, always attracted a great concourse of hearers, whom he never failed to delight and instruct, by an eloquence of the most nervous, and interesting kind. His natural diffidence for some time prevented his appearing as a speaker in the ecclesiastical judicatories; but he was at length induced to co-operate with Dr. Robertson, in defence of what is termed the *Moderate Party*, in the church of Scotland. In 1755, the university of Aberdeen, unsolicited, conferred upon him the honorary degree of doctor in divinity; and on the death of Dr. Jardine, he was preferred to the church of Troo, and appointed a king's chaplain, with the allowance of one-third the emoluments arising from the deanery of the chapel royal. In 1773, having obtained the character of an able and impartial divine, he was unanimously elected moderator of the general assembly of the Scottish kirk; "the greatest mark of respect," observes his biographer, "which an ecclesiastical commonwealth can bestow." In 1784, he was re-elected by a great majority, and again raised to the same dignity. In May, 1788, he appeared at the general assembly, and, the first day, acted as principal clerk, but was taken ill, and died on the 16th of June following, aged 70 years. His general character was that of benevolence and inflexible integrity. His candour obtained him many friends; and even such as were of different sentiments in church affairs, and held different religious tenets, esteemed the man, and with these he kept up a friendly intercourse. "Indeed," adds the professor, "never any man more successfully illustrated what he taught."

taught by his own conduct and manners." His reputation as a preacher was very great; and, on an occasional visit he made to London, Mr. Strahan endeavoured to persuade him to publish a volume of sermons. On his return to Scotland he began a selection for the purpose, but his modesty hindered his proceeding, and induced him, finally, to relinquish the plan. After his death, his friend, professor Dalzel, who had the inspection of his manuscripts, made a selection of his sermons, and published them in two octavo volumes, with biographical anecdotes of his life, from whence this account has been extracted.

DRYSWIATY, in *Geography*, a town of Lithuania, in the palatinate of Wilna; 16 miles S. W. of Braslaw.

DRZEWICZE, a town of Poland, in the palatinate of San'domir; 24 miles W. N. W. of Sandomir.

DSAPRONG, or **TCHAPRONG**, a town of Asia, in the country of Thibet, on the Lantchau; 345 leagues W. of Lassa.

DSARIN, a lake of Thibet, about 12 leagues in circumference. N. lat. $32^{\circ} 10'$. E. long. $77^{\circ} 24'$.

DSATCHOU, or **TSATCHOU**, or *Satchou*, a river of Asia, which rises in Thibet, and passes into the Chinese province of Yun-nan, where it assumes the name of *Lan-tsan*; and after crossing the province of Yun-nan, it is called *Kiou-long*.

DSEPTONG, or **SEPTONG**, a town of Asia, in Thibet; 8 leagues W. N. W. of Rimboou.

DSJABBE-TAR, a small island of Arabia, in the Red sea, about 40 miles W. S. W. of Lohcia. N. lat. $15^{\circ} 32'$. E. long. $41^{\circ} 35'$.

DSJABELL, a small island in the Red sea, about 8 leagues from the coast of Arabia. N. lat. $14^{\circ} 4'$. E. long. $43^{\circ} 34'$.

DSJALIE, a town of Arabia; 24 miles S. E. of Lohcia.

DSJAR, a town of Arabia; 80 miles S.W. of Medina.

DSJEBI, a town of Arabia, in the country of Yemen, 56 miles E. of Hodeida. N. lat. $14^{\circ} 54'$. E. long. $43^{\circ} 43'$. To this town belongs a district of considerable extent, in which are a number of independent sheiks. This district forms with that of Kufma the country of Rema, which is a fertile tract, abounding chiefly in grapes and coffee, and with respect to external appearance, soil, and production, possessing the same character with Kufma.

DSJELLEDI, a town of Arabia, in the country of Yemen; 24 miles E. S. E. of Chamir.

DS JERENANG, in *Botany*, a name by which some authors have called a species of palm-tree, from the fruit of which is procured dragon's blood. Kempter, Amoen. Exot. p. 552.

DSJOBLA, in *Geography*, a town of Arabia, in the country of Yemen; 60 miles N.E. of *Mocha*. This town is the capital of a district, and the seat of a dola. It stands upon the brink of a steep precipice, and contains about 600 houses, of a considerable height and good appearance. Its streets are paved, which is not common in Arabia. The Jews, in this place, and through the whole country of Yemen, inhabit a separate quarter, without the city. This is a place of ancient note, and exhibits the ruins of some mosques. It has neither a castle nor walls. At some distance is a place inclosed with walls, where a Turkish pacha has been interred: whence we may infer, that the conquests of the Ottoman Porte have been extended even over these mountainous regions:

DSJOF, an extensive district of the province of Yemen, in Arabia, reaching southward from Nedsjeran to Hadramaut and eastward from Hafschid-u-Bekil to the Desart, by which Yemen is separated from Oman. It abounds with

d-sart and sandy plains; nevertheless, in several places, the inhabitants want neither cheefe, nor durra, nor any other necessaries of life. The horses and camels of D-sjof are much valued in the Imam's dominions. This country is divided into Bellad-el-Bedoui, a district occupied by wandering Arabs; Bellad-es-Saadin, the highland district, governed by independent chiefs, who assume the title of sultan; and Bellad-es-Scheraf, the district in which the supreme power is possessed by sheriffs.

The wandering Arabs of this country are of a martial character; and in their military expeditions they ride upon horses or camels. Their arms are a lance, a sabre, and sometimes a match fire-lock. Sometimes they put on coats of mail, a piece of defensive armour, which the other Arabs have ceased to wear. They are troublesome to their neighbours, who are settled in villages, plundering them, and often carrying away their young women. But though they are robbers, they are not ferociously cruel. These Bedouins of Dsjof are said to have uncommon talents for poetry, and to excel all the other Arabs in this elegant art. In the district of Bellad-es-Saladin are many petty sovereigns. The title of sultan is no where used in Arabia, except in Dsjof and Jafa; and it seems to distinguish the sheiks of the Highlanders from those of the Bedouins. The most considerable princes in the district of Bellad-es-Scheraf are the three sheriffs of Mareb, Harib, and Raschvan. But the first, although chief of the descendants of Mahomet in this country, possesses only the town of Mareb, with some adjacent villages. (See MAREB.) The only other place in the country of Dsjof, that is at all remarkable, is Kaffer-el-Nat, a citadel which stands upon a lofty hill, and was built by the Hamjari princes.

DSOUKIOAG, a lake of Thibet, 15 leagues in circumference. N. lat. $30^{\circ} 30'$. E. long. $74^{\circ} 24'$.

DSJULFAR, a name given by the Persians to the principality of Seer in Arabia. See SEER.

DUABOS, LE, a town of the island of Cuba; 36 miles E. of Villa-del-Principe.

DUALISM, or **DITHEISM**, an opinion which supposes two principles, two gods, or two independent uncreated beings, of which one is the first cause of good, the other of evil. See MANICHEES.

DUANESBURG, in *Geography*, a post-town of America, in the state of New York, and county of Albany; containing 2787 inhabitants.

DUARE, a town of Venetian Dalmatia; 20 miles E.N.E. of Spalatro.

DUARZE, a river of Spain, in the province of Guipuzcoa, which runs into the Oriz at Tolofa.

DUATUS SINUS, in *Ancient Geography*, a bay of Arabia Felix. Pliny.

DUALTY-QUELIN, in *Geography*, a town of France, in the department of the North Coasts; 3 leagues N.W. of Rostron.

DUBBA FETTEE, a river of Hindoostan, one of the branches of the Sindé.

DUBBING a *Cock*, cutting off his comb and wattles.

DUBCHESKIAIA, in *Geography*, a town of Russian Siberia, in the government of Tobolsk, on the Enisei; 164 miles N.N.E. of Eniseisk.

DUBDU, or **DUBUDU**, a walled town of Africa, on the farther side of the kingdom of Fez, in the province of Shaus or Chaus, near the river Mullavia, seated on an eminence, and surrounded by fertile vallies. This town, supposed to have been built by the ancient Africans, was a considerable place in the 16th century, when the race of Merini

Merini reigned at Fez. At present it contains few inhabitants, though it has a garrison, and a confidential alcade to guard the frontier; 80 miles E. of Fez.

DUBEN, anciently *Dubin*, a small town of the kingdom of Saxony, in the circle of Leipfick, situated on the river Mulde, 20 miles of Leipfick, on the high road to Wittenberg and Berlin, with a population of about 1,300 individuals. It has a flourishing woollen cloth manufacture; and a considerable quantity of pitch is made in the adjacent extensive forest.

The district of Düben comprises, besides the town, 6 villages and 7 hamlets, containing all together about 3000 inhabitants, and is remarkable for its alum works.

DUBENDORF, a small town of Switzerland, in the canton of Zurich, in the neighbourhood of which, at a place called Oeriken, is a spring of mineral water.

DUBENINKEN, a town of Prussian Lithuania; 4 miles E. of Goldapp.

DUBENOW, a town of the duchy of Courland; 20 miles S.E. of Seelburg.

DUBICE, a town of Lithuania, in the palatinate of Wilna; 20 miles W.N.W. of Lida.

DUBIECZ, a town of Poland, in the palatinate of Lemberg; 52 miles W. of Lemberg.

DUBINKY, a town of Lithuania, in the palatinate of Wilna; 24 miles N. of Wilna.

DUBIATIVE CONJUNCTIONS. See CONJUNCTION.

DUBITZA, in *Geography*, a small town of Bosnia, in Turkish Illyncum, in the district of Banialuck, on the river Unna.

DUBITZA, a town and fortrefs of Croatia, on the Unna; 11 miles N.E. of Kattanowitz.

DUBKI, a town of Russia, in the government of Peterfburg, on the gulf of Finland; 16 miles N.N.W. of Peterfburg.

DUBLIN, a county of Ireland, in the province of Leinster, and nearly in the centre of the eastern coast. It has Meath on the north; the same county and Kildare on the west; and Wicklow on the south. It is from north to south 24 Irish miles (30½ English), and from east to west 15 (19 English) miles. It contains in Irish measure 147,840 acres, or about 231 square miles; and in English measure 237,513 acres, or about 371 square miles. Of this, about an eighth part is waste and mountain. The number of houses, as returned in 1792, was 25,510, including the city, which exceeded 14,000; but these must have increased, notwithstanding the circumstances which have since that period contributed to check population. Reckoning the city at 20 to each house, and the rest of the county at 6, this would give a population of about 210,000, which is less than what the city alone has been often estimated. There are 108 parishes, of which 21 are within the city; several of the country ones are without churches. This county is not to be classed among the most fruitful, or the best cultivated; and towards the borders of Wicklow, assumes the mountainous and rocky character of that county. The remainder is flat and uninteresting, except in the neighbourhood of the sea-coast, which, being broken into bays and creeks, affords many picturesque and pleasing prospects. The soil is in general a cold wet clay: but it is not like those deep and tenacious clays so common in England; there being scarcely any part of it without a mixture of gravel; and in most parts there may be found, at no very great depth, lime-stone, or other beneficial gravels, with this uncommon advantage, that the operation of draining the ground generally raises a sufficiency of gravel to manure the whole surface. Great improvements have been made in many parts of this county,

by this practice: and where caution is observed in the mode of sinking in the drains over the sods or other materials, with which the drains are constructed, the practice, aided by the great facility of procuring manures from Dublin and elsewhere, must tend to counteract the bad effects attendant on restive soils. In the northern part of this county, called *Fingal*, the system of husbandry has been rigidified as very bad; but, from the efforts of the Dublin Society, and the Farming Society of Ireland, it may be hoped that it will not long deserve the character given it. The old system of *fallowing* seems to have been more pertinaciously adhered to in this than almost any other district, from its farmers having been formerly in high estimation, and having acquired an opinion of their own superiority, which prevents their attending to the suggestions of others.

The minerals of the county of Dublin are various, but not likely to contribute much to the wealth of the country. The mountains in the southern part consist of granite, which is very useful for building, and for paving the streets of the capital. There is also abundance of lime-stone, lime-stone gravel, and marle. Amongst those which have been reckoned as lime-stone is *calp*, or the black quarry stone of Dublin, first made a distinct species by Mr. Kirwan, and particularly described by Mr. Knox in the Transactions of the Royal Irish Academy. (See *CALP*.) Siderocelcite is often found interfecting and inveting *calp*. Copper and lead have been found in this county, and mines of them have been formerly worked; and a lead mine lately discovered at the Scalp, near the county of Wicklow, which is likely to prove productive. The principal river of this county is the Liffey, or, as it is sometimes called, *Anna*, or *Awin*, i. e. river *Liffey*, which runs nearly through the middle of it, discharging itself into the bay of Dublin. A few other streams of no considerable note empty themselves into this river, and have a number of mills for various manufactures. The navigation of the Liffey will be noticed in another place. (See *DUBLIN City*, and *LISSEY*.) The Dodder, though next in importance, is a small stream, which takes its rise in the mountains bordering on Wicklow, and running by the villages of Rathfarnham, Milltown, and Donnybrook, discharges itself into the bay of Dublin at Rings-end. There are other small streams, which run through different parts of the county, and fall into the Irish sea; but they are too insignificant to be particularly mentioned. But if the county of Dublin cannot boast much of its rivers, it may of its canals; for there are two passing through it, which contribute greatly to its prosperity, and which for extent, if not for usefulness, may vie with almost any in Great Britain. These are the Grand and Royal Canals, of the first of which there is a short account in our article *CANAL*, to which we are now able to add some particulars. The Grand Canal was commenced in 1753, by the commissioners of inland navigation; and in 1772, a company was incorporated for carrying on and completing it, from Dublin to the river Shannon, with a power of levying a toll of 3*d.* per ton per mile. The difficulties to be overcome were, however, such, from the nature of the ground through which the line lay, that, together with some mismanagement, upwards of one million sterling has been expended, of which 116,000*l.* has been from time to time given by parliament. The length of the canal is 62 Irish, or 78½ English miles, from Dublin to Shannon harbour, on the Shannon near Banagher. There is also a branch, of 21 Irish miles, to the river Barrow, at Athy, and two or three shorter branches, making in all 96 Irish, or 122 English miles, on the different parts of which boats are now constantly employed. At Dublin there is a complete floating dock, capable of containing upwards of 400 ships, with three

large graving docks for repairs. The principal commodities carried on it are flour, malt, wheat, oats, and barley, turf, Kilkenny coal, timber, bricks, furniture, and camp equipage. The number of boats plying on it exceeds 400. The amount of freight in the year 1801 was 120,000 tons, since which time it has been completed to the Shannon. When the French landed at Killala, the late marquis Cornwallis found the canal very useful for transporting his troops without the fatigue of marching, and thus had them fresh for service at a considerable distance from the capital. There are 56 locks and eight aqueducts on this canal and its branches. The locks are 70 feet long, and 14 feet six inches wide. Their average fall is nine feet. The summit level is well supplied with water; its height is 240 feet above the sea. The depth of the canal is five feet over the sills of the locks and aqueducts, and five feet six inches in the body of the canal; it is 25 feet wide at bottom and 40 feet wide at water surface. For several miles from Dublin the banks are planted with trees, which have a very pleasing effect. The revenues of the Grand Canal company have been gradually rising. In 1787 the amount was only 6984*l.*, but in 1802 47,100*l.*; and it is expected that it will exceed 100,000*l. per annum.* The Royal Canal commenced, under an act of parliament and a charter from his majesty, in the year 1789, and it also has received large grants from the national purse. These grants amounted to 91,000*l.* previous to 1801, at which time the directors general of inland navigation, in consequence of a reduction of the tolls, agreed to give a further sum of 95,866*l.* The object of this canal is to carry a line of navigation from Dublin to the Shannon, at Tarnonbury, in a north-west direction; and it has been already carried nearly to Mullingar, in the county of Westmeath, which is about fifty English miles from the capital. The ground through which the canal runs is so favourable, that one level is six miles in length, another sixteen, and the summit level will be 17 miles in extent without a lock; into this last the grand supply of water comes from Lough Owel, near Mullingar. The construction of this canal is much approved; the locks are 80 feet clear in length and 14 in breadth; the banks sloping 20 inches for each foot they rise. At present great quantities of goods are carried by this canal; but the national benefit must rise still higher when it reaches the Shannon, as coals, manufactured iron, clays and ores of various kinds, will then be brought from the counties of Roscommon and Leitrim.

To return from a digression, which the importance of the subject, and the want of a better opportunity of introducing it, will, it is hoped, excuse: the coast of the county of Dublin extends for about 30 miles along the Irish sea; on the northern part are several small fishing towns, which were formerly noted for smuggling. The islands of Lambay and Ireland's Eye form interesting objects from the coast, and are frequented by shooting parties. The Hill of Howth is a peninsula projecting considerably into the sea, and forming the northern boundary of Dublin bay. New works have lately been erected on the northern side of it, for maintaining a better communication with England, for an account of which, see HOWTH.

To the south of the bay, the land also projects as far as Howth, and then the coast takes a southern direction. There are no towns of any consequence in this county, except the capital, and, like Middlesex, it has a sessions for administration of justice entirely distinct from the circuits. It is represented in parliament by four members, two for the county and two for the city of Dublin, besides a member for the university. This county of course formed a part of the *English pale*, and contains the ruins of a great number of

castles and religious foundations. Archer's Statistical Account of Dublin. Denton's Remarks on it. Beaufort's Memoir.

DUBLIN, the capital of Ireland; the second city in the British dominions, and sometimes reckoned the fifth for extent in Europe, is on the eastern coast of Ireland, in the province of Leinster, and in the county described in the preceding article. Dublin is seated in view of the sea on the east, and in a fine country, which swells into gently rising eminences on the north and well, whilst lofty mountains bound the horizon on the south. The city itself cannot be seen to full advantage on entering the harbour, but the approach to it from thence exhibits a fine prospect of the country for improvement and cultivation, interspersed with numerous villas, which have a most agreeable effect to enliven this delightful scene. The Wicklow mountains, on the south, with the pointed cone of the figar-loaf, contribute not a little to embellish a landscape so extensive and picturesque as not to be equalled by any one view in Europe, excepting, perhaps, the bay of Naples, to which it has been thought to bear a very striking resemblance. The early history of Dublin, previous to the landing of the English, is not well ascertained; and though its name has employed the talents of many antiquarians, it has not been satisfactorily accounted for. A town, supposed to be on the site of the present Dublin, is mentioned by Ptolemy under the name of *Eblana*, about A. D. 140; and the Danes are supposed to have entered the Liffey, and encircled Dublin with walls in 498. In a charter of king Edgar's, called *Oswald's law*, dated at Gloucester in 664, Dublin is mentioned as a place of consequence, but this charter is by many suspected to be a forgery. The Danes appear to have been in possession of Dublin in the 11th century, and were perhaps the founders of it, as they were of other maritime towns. It was then besieged and stormed by the Irish, under Brian Boromhe, who was killed at the battle of Clontarf; and after this event the Danes, or *Ostmen*, as they were called, seem to have admitted the sovereignty of the king of Leinster, though they were often in rebellion. The contests, indeed, among the Irish chieftains, afforded them a favourable opportunity of re-establishing their independence; and when the league was formed against Dermot M'Morrough, king of Leinster, his Ostmen subjects of Dublin, under their governor M'Tor-kill, or as Cambrensis calls him, Hascuplus, took an active part against him. A strong force, under Raymond le Gros, having reduced Dublin in 1171, M'Torkill escaped by sea, and returned soon after with a strong fleet to recover it; he was however taken prisoner and put to death. Strongbow, who laid claim to the kingdom of Leinster in right of his wife Eva, daughter of Dermot, was soon after besieged in Dublin by the confederate Irish, and reduced to great difficulty, from which he was delivered by the desperate valour of his followers. In the year 1172, Dublin was given up by Strongbow to king Henry, that he might appease his resentment, and we find that this monarch passed the ensuing Christmas in his new acquisition. The Irish chieftains who had submitted flocked to Dublin from all quarters; and we are told, that, as the city afforded no building capable of receiving the royal train, Henry caused a temporary structure to be raised after the Irish fashion, where his new vassals were admitted freely and feasted sumptuously. Soon after he had taken possession of Dublin, Henry granted it, by charter, to a colony of Britons, with the same privileges which they had enjoyed at Bristol; and he, afterwards, confirmed to his burgesses of Dublin, or *Dwelin*, as it is called in ancient records, all manner of rights and immunities throughout his whole land of England, Normandy, Wales, and

and Ireland. On his departure he also appointed it to be the residence of his governor, and ordered a castle to be built there. In 1210, upwards of 20 Irish princes swore allegiance to king John at Dublin, engaging to establish the English laws and customs, and in the same year courts of judicature were instituted. In 1217, the city was granted to the citizens in fee farm, at 200 marks *per annum*. In 1308, the civil government of Dublin was established under a provost and two bailiffs; but in 1409, the title of the chief magistrate was changed to that of mayor, by charter of Henry IV.; and in 1547, the office of bailiffs was changed to sheriffs. Stanhurst, who compiled the description of Ireland for Holinshed, which was re-published by Hooker in 1586, gives a particular account of the hospitality of these magistrates: "They that spend least in their mayoralty," says he, (as those of credit and such as bear the office have informed me) "make an ordinary account of 500*l.* for their viands and diet that year." This was no small sum, when the cheapness of provisions is taken into account. In 1609, the charter of the city of Dublin was renewed by James I. After the restoration, Charles II. gave to the mayor a collar of S.S., and a company of foot guards; and in 1665, he conferred the title of lord mayor on the chief magistrate, and granted him 500*l.* *per annum* in lieu of the foot company. The government of the city was further regulated by the earl of Essex in 1672. It is executed by a lord mayor, a recorder, two sheriffs, 24 aldermen, and a common-council, formed of representatives from the 25 corporations. The aldermen are elected from amongst those who have served or fined for the office of sheriff, and the lord mayor is elected from amongst the aldermen by the common council. The next in rotation is generally chosen; but there have been instances of departure from this rule, when such person has been obnoxious to the commons. The lord mayor tries all offences, even capital ones, except murder and treason, and matters of property for any sum under 20*l.* Though Dublin became early the seat of the English governor, it continued a very small town. In 1610, when a map of it was drawn by W. Speed, the Liffey was not embanked by quays on the north side, and only a part of it on the south. There were only three or four streets on the north side, which west by the name of *Oxmantown*, or *Ossmentown*, and some villages at a short distance, which are now part of the city. On the south of the river it was also very much confined. The college was at some distance from the walls, and, comparatively, a very small part of what is called the Liberty was built. The great increase of population will, however, mark the change which has taken place more strikingly. In 1644, it appears that the inhabitants were numbered by order of government, when there were only 8159 persons. Perhaps at this time the population was less than it had been from the distressed situation of the country. In 1681, the number was 40,000. Between the years 1711 and 1755, above 4000 houses were built, and, in the last of these years, the inhabitants were estimated at 128,570, by the late Dr. Rutty. By the apparently accurate enumeration of the Rev. James Whitelaw, in 1798, of which he has published an account, and which agrees very nearly with the return made by the district committees in 1804, the number of inhabitants appears to be 182,370, including the garrison, house of industry, college, &c. The number of houses, according to the same enumeration, was 16,401, allowing a population of above 10 to each house. It appears evident, therefore, that the population of Dublin is below 200,000, though it is frequently reckoned at 300,000.

Dublin would be a commodious station for shipping, were it not for two sand banks, called the *North* and *South Bulls*,

which prevent large vessels from crossing the bar, and sad experience has proved that the bay is not a safe place for anchorage. In consequence of this a new harbour is forming at Howth, of which an account will be given hereafter. (See HOWTH.) The river, however, has been greatly improved for such vessels as do not draw too much water to cross the bar, by a prodigious work on the south side of it, called the *South wall*, which was begun in 1748, and which extends from the point of Ringsend to the light-house about three miles. It is formed of large blocks of granite strongly cemented, and strengthened with iron cramps. The breadth of the road is near forty feet, rising five feet above high water. About midway, between Ringsend and the light-house, at a place called the *Blackbosse*, a new basin has been formed of an oblong shape which is 900 feet long and 450 broad, where the packets of all descriptions usually lie. The light-house was begun in 1762 under considerable difficulties from the depth of the water, from the power of the winds in such an exposed situation, and from the raging of the seas. These, however, were overcome by the architect, Mr. Smyth, who collected vast rocks, and deposited them in a caisson or chest, which was sunk to the bed of the sea, and afterwards guarded with a buttress of solid masonry, 25 feet broad at the base. On this he raised a beautiful circular structure, three stories high, surrounded by an octagonal lantern of eight windows. It is composed of white hewn granite, firmly cemented, gradually tapering to the summit, and each story strengthened with stone archwork. A stone staircase, with an iron balustrade, winds round the building to the second story, where an iron gallery surrounds the whole. The lantern is supplied with large oil lamps, the light of which is powerfully increased by reflecting lenses. From Ringsend, up through the whole city, the river is commodiously embanked with quays; and excellent docks are laid out on each side sufficiently large to contain several hundred vessels. There are seven bridges, of which that formerly called *Island bridge*, but which having been rebuilt is now called *Sarah bridge*, has been considered as the *Irish Rialto*. It forms one grand arch that sweeps in a beautiful and well proportioned direction from north to south, extending three hundred and sixty-six feet: the arch is an ellipse, the span of which measures one hundred and four feet, being twelve feet wider than the celebrated Rialto at Venice. Essex bridge was built in imitation of Westminster bridge. Carlisle bridge is remarkably wide, being sixty feet between the balustrades, which leaves ample room both for carriages and foot passengers. The old bridge, which was lately carried away by a flood, will be replaced by a handsome one opposite to the courts of justice, which is to be named Richmond bridge. It was not until the year 1768 that even in London the projecting signs and penthouses were removed, the streets flagged, and the houses numbered. The same regulations were effected in Dublin by an act of parliament in 1774, and another act was passed in 1785 for better paving, lighting, and cleaning the city, by which an additional number of globes with double burners were erected. In consequence of the exertions of the paving board, the streets are, in general, sufficiently wide, and well flagged: there are, however, some exceptions, and in the old part of the city, the buildings are very irregular. The numerous streets and squares which have been added of late years, are magnificent and spacious, and the buildings regular and commodious. Among those on the south side of the river, those wherein persons of distinction reside, lie chiefly to the eastward of the college and Stephen's green. This last, though it does not rank with the new buildings, possesses much grandeur and elegance, being one of the largest squares

DUBLIN.

in Europe: it is an English mile in circumference, surrounded by a gravel walk planted on each side with trees; within this walk is a smooth level meadow, having in the centre an equestrian statue of George II. There are several handsome houses, but they are by no means uniform, and have others amongst them of a very mean appearance. Merriion square, to the east of it, is nearly as extensive, and the buildings are elegant and uniform; the centre is inclosed with iron palisades, and formed into a beautiful garden, adorned with shrubberies, gravel walks, and handsome entrance lodges. On the north side, Rutland and Mootjoy squares are deserving of attention. The garden of the ying-in-hospital, which is surrounded by iron palisades, is in the centre of the former, and that of the latter is laid out like Merriion square. Sackville street, which, though built upwards of sixty years ago, is often reckoned amongst the new streets, has been lately extended, and considerably improved. It is 120 feet wide from Carlisle bridge to the rotunda and public assembly rooms, and having on the other side of that bridge Westmoreland street, extending to the college and national bank. Towards the middle of Sackville street a noble column, with suitable decorations, has been erected to the memory of that illustrious naval officer lord Nelson. The circumference of Dublin, as it now stands, is above ten miles varying to an irregular oval form. A road, called the *Circular*, is carried round the greater part of the city, but whilst in some parts it includes gardens and orchards, some new streets are situated without it in other parts. There is, perhaps, no city of its size, which can boast of such a number of magnificent and useful buildings. Of these, as well as of some valuable establishments, it will be necessary to give some account. The castle of Dublin was built, or at least completed and flanked with towers by Henry de Londres, archbishop of Dublin and lord deputy, about 1213. Of these towers the strongest and most famed was that called Birmingham tower, from sir William Birmingham, who was imprisoned there and afterwards executed about 1331. It was long used as a state prison, but the old tower having been taken down and a new one erected on the site, this has been used for preserving the archives of the kingdom. The castle was dismantled of its warlike garb in the reign of queen Elizabeth, being intended for the residence of the governor. It has continued since that period to be the seat of government, and, at present, like St. James's in London, is the place where the viceroy gives audience, and which is used on other state occasions. There are two courts; the upper court is that in which are the state apartments, and the chief secretary's apartments; in the lower court are the treasury, register office, and an armoury. The whole is enclosed, and since the rebellion, has been fortified, so as to be able to resist a sudden attack. The royal exchange, which adjoins the castle, was finished in the year 1779, at an expence of forty thousand pounds. As this building, however, does not possess all the advantages which the merchants expected from it, a new structure has therefore been erected in Dame street, called the "Commercial buildings," which is more immediately intended for a stock exchange, brokers' sales, ship insurance, &c. The National bank is a most superb structure, and is fronted with a grand arcade of Ionic columns, all of Portland stone. This is the building in which the senators of Ireland were accustomed to assemble; and since the union it has been converted to its present purpose. Opposite to this is the college, of which a separate account will be given, (see *DUBLIN, University of*). The stamp office, in William street, formerly Powercourt house, is another fine building, the architecture of which is chiefly Doric. The barracks on the

north side of the river were founded in 1704, and are reckoned the largest and most commodious in Europe. They consist of five large squares, capable of containing 4000 cavalry and infantry. On the opposite side of the river stands Kilmainham hospital, founded by Charles II. for invalids of the Irish army, on the plan similar to Chelsea in England. The building was finished in 1683, and cost 24,000*l.*; it is of a quadrangular form, with a spacious area in the centre laid out in gravelled walks. The commander in chief, the major and officers, have excellent apartments and gardens. The ground anciently belonged to the knights templars. The new courts of justice on the north side of the river are extremely handsome and convenient; the building is of a circular form; and within, the upper part of the dome is ornamented with the busts of the most celebrated legislators, ancient and modern, adorned at the same time with sculptured devices, executed in a masterly style. A range of law-offices, finished in a striking manner, completes this beautiful edifice. The Linen hall is a neat building, erected in the year 1728, for the purpose of detecting frauds in this the grand manufacture of Ireland. The merchants have rooms where the cloth is sold, and the trade is under the controul of a board consisting of the principal men in the country. The Custom house, if we consider the beauty of its architecture, or the judicious choice of site and accommodations, must be acknowledged to stand at the head of all those establishments erected for commercial purposes among European nations. It is situated on the northern division of the city close by the side of the river. The expence of this magnificent structure, which is larger than the trade of Dublin seemed to require, was no less than 250,000 pounds. The buildings of the Dublin society in Hawkins's street are also extensive. (See *DUBLIN Society*.) The private houses which chiefly deserve attention are, Leinster house, Waterford house, and Charlemont house. The latter contains a valuable library, and some excellent works of Titian and Rembrandt, chiefly collected by the late earl of Charlemont, whose patronage of science, as well as his other public virtues, will long be remembered. Dublin contains 20 parishes, that have nineteen churches and two chapels of ease, fifteen Roman catholic chapels, and about sixteen places of worship belonging to different classes of protestant dissenters. Dublin is the see of an archbishop, and contains two cathedrals, both within the city. Christ church, or the church of the Blessed Trinity, was first built by the O'Men of Dublin about the year 1038. Its situation is nearly in the middle of the city, and the whole building spacious and ornamental, containing a vast number of superb and curious monuments, particularly that of Strongbow, which still continues in good preservation. This church was founded for regular canons and converted into a collegiate to a dean and chapter by Henry VIII. in 1514. The bishop of Kildare unites this deanery to his bishopric. The other cathedral, that of St. Patrick, was founded for thirteen prebends, which number has since been increased to 22. This cathedral, situated on the south side of the city, was erected about the year 1190 by John Comyn, then archbishop of Dublin. In its first constitution it was collegiate, but De Londres, Comyn's successor, made it his cathedral. In the year 1370 archbishop M^onot added to it a high steeple of squared stone; and in 1750 Dr. Sterne, bishop of Clogher, on this steeple erected a lofty and beautiful spire, little inferior to that of Salisbury, and which is seen at a considerable distance. This cathedral contains several excellent monuments, among which that of Dr. Swift, who was dean of St. Patrick's, and whose name is so justly dear to the Irish nation, claims pre-eminent regard. Of the other churches, many are neat structures,

and

DUBLIN.

and capable of containing large audiences, but that which most deserves attention is St. Andrew's, in the neighbourhood of the college. If none of the dissenting meeting houses is remarkable for its appearance, yet two of them can boast of having had as ministers two of the ablest defenders of religion in the English language, Abernethy and Leland. The charitable institutions in Dublin are very numerous, and the buildings in some instances very ornamental. To enter into a detailed account of these would swell this article beyond reasonable bounds, yet there are some which ought not to pass unnoticed. The house of industry was partly founded for receiving such as were by age, sickness, or misfortune, rendered incapable of earning their bread, and for relieving the city from the clamours and impositions of sturdy beggars. Poor persons of every description are always admitted into this house, whether young or old, that are in apparent distress; here they are lodged and fed, but not clothed, it being found to be productive of bad effects, many going into the house merely to be clothed, and afterwards disposing of their apparel for spirituous liquors; they are now, therefore, obliged to supply themselves with this comfort from their own exertions, from shops kept for that purpose within the walls of the institution, and by this means are better clad than formerly. The average number annually maintained is 1718, yet the streets of Dublin are still crowded with beggars. The lying-in hospital is an elegant piece of architecture. It was founded by Dr. Mofse, a physician of Dublin, who obtained a charter for it, and in addition to private subscriptions, it has an annual grant from parliament. There are about 700 females delivered here every year. The Fever hospital is an extensive building, capable of containing above a hundred patients, and is admirably well conducted. The Foundling hospital receives all exposed and deserted children of either sex, and is supported partly by a tax of three-pence in the pound on all houses in Dublin, and partly by a parliamentary grant. There are several infirmaries and medical charities of various kinds, and besides several schools on public foundations, almost every place of worship in Dublin has a school connected with it, which is supported by an annual charity sermon. Besides the University and Dublin Society, which require particular notice, the literary institutions in Dublin are, the Royal Irish Academy, which has published several volumes, the Dublin Library Society, the colleges of Physicians and Surgeons, and the King's Inns, where Irish barristers must now pass a certain number of terms before they can be called, and which has a good library. There are several good private libraries, and some valuable private collections of minerals, and other natural productions. The Farming Society of Ireland, which mostly holds its meetings in the capital, is likely to render most essential service to the country.

Dublin is remarkably well supplied with flesh, fowl, and fish, the latter in much greater perfection than any other capital in Europe. It is supplied with coals chiefly from Cumberland and Scotland, and with turf by the canals. Water is conveyed to the city on the north side from the Lower Liffey, by machines constructed for the purpose at an outlet called Island bridge. The south side is supplied from a reservoir or basin, which joins the grand canal, with the directors of which, the corporation contract for a supply. As a tax is laid on every house, so the supply is general, and there are besides fountains erected in various parts of the city, for the convenience of the poorer inhabitants. The Phoenix park is a fine extensive enclosure at the west end of the town, which is diversified with woodland, champaign, and rising ground, and is a most interesting ride.

It is seven miles in circuit, and contains the Vice Regal Lodge, where the lord-lieutenants now constantly reside, the seat of the principal secretary, and some other handsome lodges. In this park are also a magazine for powder, and a battery that commands the city. In 1747, a fluted pillar, thirty feet high, with a phoenix on the top, was erected in the centre of a ring in this park, by the celebrated earl of Chesterfield, when lord-lieutenant of Ireland. Such is Dublin, a city which rapidly increased for many years, and was beautified at the national expence. It was asserted, previous to the act of union, that the effect of that measure would be to ruin Dublin, and that grass would soon grow in the streets. It must be admitted that no place was likely to receive so much injury as Dublin from that important change, but the parliament would not have been justified in rejecting an arrangement beneficial to Ireland in general, because it might interfere with the interest of those who inhabited the capital. The injury sustained, however, does not appear so great as was apprehended. The nobility have indeed in great measure forsaken Dublin, and their mansions have become the habitations of bankers or wealthy merchants; and in some instances have been converted into splendid hotels. Some particular classes of tradesmen also appear to have suffered, and the often beneficial bustle occasioned by the meeting of parliament is no longer felt. There are, however, many causes which draw numbers to the capital, and the high rent of houses, with the exception of very splendid ones, is a proof that they do not yet exceed the demand for them, though some new streets have been laid out since the union. Dublin is represented by two members in the imperial parliament, who are chosen by the freemen at large. It is sixty miles W. from Holyhead in Wales, and 330 miles N.W. from London, in long. 6° 30' W. from Greenwich, and in 53° 14' N. lat. Archer's Survey of Dublin. Dodd's and Wilson's Directories, &c. &c.

DUBLIN, *Archbishopric of*, one of the four provinces into which Ireland is divided, which contains five sees under four prelates, viz. the archbishop of Dublin, and the bishops of Kildare, Leighlin and Ferns, and Ossory. The first mention of the see of Dublin is in the 7th century. In the year 1152, it was erected into an archbishopric. At the time of the landing of the English, it was filled by a prelate named Laurence, who appears to have had great influence in the country, and who was afterwards canonized. In the year 1214, the bishopric of Glendalough, which had been founded in the 6th century, was incorporated with it. This see is 50 miles in length from north to south, and 36 in the greatest breadth, containing the whole county of Dublin, the most of Wicklow, and part of the counties of Wicklow and Wexford. It contains 209 parishes, which form 86 benefices. In these are 82 churches, twenty of which are in the city of Dublin. Amongst those who have filled this see was Dr. King, author of an esteemed work on the "Origin of Evil." The archbishop of Dublin is primate of Ireland, and is the second in point of dignity. It was long the policy of the English government, as appears from the letters of archbishop Boulter, to confine the chief offices to men of English birth, regarding those who had been born and settled in Ireland, although of English extraction, as not sufficiently attached to the interest of England. At that time the archbishopric of Dublin was the highest dignity an Irishman could obtain. Dr. Beaufort's Memoir. *Abp. Boulter's State Letters.*

DUBLIN *Society.* This society, which, as Mr. A. Young observes, has the undisputed merit of being the father of all the similar societies now existing in Europe, was established in the year 1731, and owed its origin to one of the most patriotic individuals.

dividuals which any country has produced, Dr. Samuel Madan. For some years it was supported only by the voluntary subscriptions of the members, forming a fund under a thousand pounds a-year, but for a long time past parliament has regularly granted ten thousand pounds each session in aid of the subscriptions. To enter upon the history of this society, and detail the various objects which formerly engaged its attention, would be tedious; but some account of its present objects, and the progress made in accomplishing them, will be interesting to many readers. The society was incorporated in 1749, by the title of the Dublin Society, for promoting husbandry and other useful arts in Ireland. The members of it have accordingly adopted many measures for the improvement of agriculture, plants, &c. They have contributed in particular to the increase of plants, and to the formation of large and extensive nurseries. They also, like the London Society, give premiums for all useful inventions, and for proficiency in the fine arts. They purchased the celebrated Leskean collection of minerals, and have adopted different measures to encourage the study of mineralogy. They have established annual lectures on chemistry, with a particular view to its application to manufactures. They have appropriated above 27 English acres to a botanic garden, at Glasnevin, in the neighbourhood of Dublin, in which particular attention is paid to promote a practical knowledge of botany, so far as it is useful to the farmer, the grazier, the planter, and the artificer, and they have also established lectures on this science. They have further established lectures on natural philosophy, and on the veterinary art. They have procured surveys to be made of the counties of Ireland, which have been published at their expence. They have formed a valuable library, which is open to the members, and have various collections of objects of natural history, and of models for the imitation of young artists. The buildings of the society in Hawkin's-street are very extensive and convenient, and if useful knowledge be not advanced in Ireland, it cannot be attributed to any want of exertion in this society, or of liberality in parliament.

A. Young's Tour—Appendix. Charter and Petition of the Society.

DUBLIN, *University of.* This noble institution was founded by queen Elizabeth in 1591; Loftus, archbishop of Dublin, having prevailed on the corporation of that city to give up for this purpose the monastery of All-hallows, at that time in the neighbourhood of Dublin, on the south-eastern shore; it having been vested in the mayor and citizens, on the dissolution of religious houses. By the charter, the college was erected as "mother of a university," by the style of "the College of the holy and undivided Trinity, of queen Elizabeth, near Dublin." It deserves notice, that the justly celebrated Usher, afterwards promoted to the primacy, was the first student admitted. Several grants of land in different parts of Ireland were made for its support; and the patronage of several livings in the counties planted by James I. was assigned to it. In 1637, the original constitution being found imperfect, a new charter was given to it, and a set of statutes compiled by archbishop Laud, which are still in force. This prelate made several essential alterations in the constitution of the college; the most material of which was the depriving the fellows of the election of their provost, the appointment to that important office being from thenceforth reserved to the crown. To make the fellows some amends for the loss of their first privilege, it was appointed by the new charter that they should be tenants for life in their fellowships, if they remained unmarried, or unprovided with a benefice of more than 10*l.* in the king's books; whereas, by the first charter, they were to quit

their office in seven years after they became of master's standing. At the same time, the number of fellowships was enlarged; and the government of the college was placed in the provost and major part of the senior fellows, from whose decision an appeal was given to the visitors, who are the chancellor of the university, or his vice-chancellor, and the archbishop of Dublin. The office of provost, being of considerable dignity and emolument, has in some instances been given to laymen, and persons previously unconnected with the university; but such appointments are always disagreeable, and, in general, so much respect is paid to the feelings of the members of this learned body, as to place over them one who had for some time filled the office of fellow, and is capable of filling the station with propriety. During the provost's absence, his place is filled by the senior of the fellows, who is always called vice-provost. The provost and seven senior fellows form a council called *the board*, which meets every Saturday, and by which all matters relating to the internal government of the college are decided. The income of a senior fellow, arising from various sources, is generally estimated at about a thousand pounds *per annum*; but it necessarily fluctuates according to the offices held, and, on an average, is probably not so great. The number of junior fellows is at present (1808) sixteen; but it is intended to augment it. These are the tutors of the college; and their income depends, in a great measure, on the number of their pupils. Some who, from merit or interest, have a large number, have 700*l.* or 800*l.* *per annum*. Attempts were made by former provosts, to assign tutors to every young person entering the college, which would give very great influence; but, at present, the parents, or guardians of the pupils chuse the tutor under whom he is placed. The number of livings in the gift of the university is 19, the value of which was, some years ago, from 500*l.* to 1000*l.* *per annum*, and mult have considerably advanced from the increase of tillage. On one of these becoming vacant, it is offered to the clerical fellows in rotation, beginning with the senior, until one chuses to accept of it, who then vacates his fellowship. The professors, also, of divinity and common law mult vacate their fellowships to hold these two offices. The supplying the benefices and professorships as they become vacant, keeps up a constant circulation among the leading members of the university. By this means, there is a constant encouragement to exertion among the students, and the church of Ireland is supplied with some of its most useful and respectable members. There is, perhaps, no patronage so beneficial to the country as this. The mode of filling a senior fellowship, on its becoming vacant is, for the board to elect the senior of the junior fellows, if no objection lie against him, within three days after a vacancy is known. But, to a junior fellowship, admission is obtained only by sustaining publicly one of the severest trials of the human faculties of which there is any account. The candidates for this office, who mult have taken a bachelor's degree in arts, are examined in the public hall, three days successively, for two hours in the morning, and as many in the afternoon of each day; the first morning in logic and metaphysics; first afternoon in all the branches of the mathematics; second morning in natural philosophy; second evening in ethics; third morning in history and chronology; third evening in the Greek, Latin, and Hebrew languages. The fourth day is private, and is devoted to composition. The examination is in Latin; and the days appointed for it are the four days immediately preceding Trinity Sunday. The examiners, who are the provost and seven senior fellows, (or, in the absence of any of these, the next in seniority among the juniors,) after a scrutiny among themselves in the board-room,

on the succeeding Monday, proceed to give their votes, in the most solemn manner, for the candidate, or candidates, they think fittest to supply the vacancies, when, if the provost do not chuse to interpose, the vote of the majority is decisive, and the successful candidate is presently after sworn into office in the college chapel. As the struggle is often close, and the decision, consequently, difficult, the result is naturally expected with much anxiety; for the successful candidate is considered as honourably and happily provided for. It will often happen, that men of great merit will fail from various causes; but, when unsuccessful candidates have answered respectably, they have a sum of money allotted to them at the time; and, if they chuse to decline further attempts, generally succeed in procuring pupils, or entering some of the learned professions, derive benefit from their past exertions. The difficulty, indeed, is so great, that it is considered honourable to have made the attempt, even without success. There are only three of the fellows allowed to be members of the lay professions, one of medicine, and two of law, without an express dispensation from the crown. All the rest must become clergymen of the established church, and take their share of the clerical duties of the university. By the statutes of the college, every fellow, on marrying, may be obliged to vacate his fellowship; but several dispensations have been given by the crown; and, of late years, most of the fellows have married, without any attempt to enforce the penalty. Besides the fellows, there are 70 scholars, who have a right of voting at the election of the member returned by the college to parliament, and who have some other privileges and emoluments. Twenty of these have what are called native places, attended by an additional income; and these are filled up, as vacancies occur, from the most diligent of the scholars. The candidates for a scholarship must have arrived at the rank of sophisters; and are examined, for two days in the week, before Whitsuntide, in the Greek and Latin classes, by the provost and senior fellows. As a scholarship cannot be held by one arrived at the standing of master in arts, it terminates in four, or, at most, five years, from the time of obtaining it; but it is often vacated before that time, as the emolument is trifling, and the necessary attendance on college duties often interferes with professional pursuits, after the completion of the undergraduate course. The students are classed under three ranks, distinguished by the names of *fellows commoners*, *pensioners*, and *sizarars*. The number of the two former is unlimited, and generally exceeds 500. They are publicly examined before admission, by the senior lecturer, and such fellows as he chuses to associate with him, in several Greek and Latin books appointed to be read at schools for this purpose, and in Latin composition, either prose or verse. The candidates admitted, are entered according to their merit; and to obtain the first place on this occasion is esteemed very honourable. Extraordinary rewards are also adjudged, on some occasions, to those who distinguish themselves; whilst those who are shamefully deficient are refused admission, and are obliged to return to school, or to seek refuge in some other college, where the proficiency of the students is less attended to. The fellow-commoners are distinguished by a peculiar gown and cap, and have the privilege of dining at the same table with the fellows, for which they pay a much higher stipend; whilst pensioners, at a less expence, possess all the real advantages which the college affords; and, if they conduct themselves with propriety, receive every attention from their superiors. The sizarars are limited in number to about 30, and receive their commons and instruction *gratis*. As vacancies occur, they are selected, after examination, from a number of competitors. Though

their situation may appear degrading, yet, by good conduct, they may remove any thing that would be painful, and, in a very short time, by continued diligence, they may raise themselves to a higher rank. Some of this class have, indeed, risen to the highest honours of the university; but this does not generally happen. The undergraduate course continues for four years, during the two first of which, the students are called *freshmen*, and the two last sophisters; and there are four examinations in each year in the public hall, in a course of reading appointed by the board. Judgments are given for each branch of the examination, which are publicly read, and those who get a very bad judgment lose the examination for that time. To encourage application, premiums and certificates are liberally, but not negligently, bestowed; and the youth who omits no examination, and obtains good judgments at every one, during his undergraduate course, is honoured with a gold medal, which, being only obtained by the union of respectable talents, with unremitting application, is justly and highly valued. The premiums are books, stamped with the college arms; and the certificates, which are on vellum, are given only to those who, being the best in the division, are precluded from a premium, in order to spread the flame of emulation more widely. Besides these regular rewards, there are occasional ones for composition; and the provost is empowered to give annual sums, called *exhibitions*, to those he esteems deserving. There are also premiums for Hebrew, mathematics, divinity, &c.; for those who, having taken their bachelor's degree, continue in the college, either with a view to a fellowship, or in pursuance of their professional studies. Besides the advantages derived from the regular examinations, &c. there is a society composed of a number of those who have arrived at the standing of sophisters, called the Historical Society, under the patronage of the fellows, in which questions are debated, portions of history examined into, and compositions in prose and verse occasionally read. These exercises serve to call forth the exertions of the students, and have particularly contributed to form some of the most distinguished members of the Irish bar, who here cultivated those powers of oratory, by which they have since risen to the most eminent stations. Having given this general account of the system of education pursued in Dublin college, it may be expected that some notice should be taken of the illustrious characters it has produced. Here, however, if we consider the length of time since its establishment, it must be acknowledged, that the number is very few; and some of those who are most celebrated, appear to have derived little advantage from their *alma mater*. Amongst these last, we must, perhaps, consider Swift, Congreve, and Goldsmith. But though the list will not be great, it will include Usher, Berkeley, Molieaux, and Edmund Burke. To these we may add the less eminent, but truly respectable names of archb. King, bishops Redell, P. Browne, Chandler, H. Hamilton, and Young, Drs. T. Leland, Hellham, Delaney, Lawlor, Murray, Parnell; Messrs. Farquhar and Dodwell, with a long list of distinguished lawyers and statesmen, such as lord chancellor Clare, Yelverton, lord Avonmore, Hussey Burgh, Henry Flood, &c. Persons yet living have been purposely excluded from this list, or it might have been increased by names well known, and highly respected throughout the British empire. It may, however, be asked, why the number of eminent writers is not greater? And it may be answered, that the course of study necessary to obtain a fellowship is very fatiguing; that when this honour is obtained, the time of a fellow is usefully employed in teaching his pupils, and that when after several years of labour, he arrives

at a state in which he can enjoy "otium cum dignitate," it can hardly be expected that he should devote himself to new labours, without that inducement which most authors have of thus providing for the maintenance of a faculty. It requires uncommon exertion in men so situated, to become authors, and it is perhaps rather to be wondered at, that so many have added this to their other labours. Is it then to be inferred, that the university of Dublin is less useful, or its fellows less respectable? Is authorship more honourable than forming the youth of their country for active life? And is it to be desired, that the fellows should cease to labour as tutors, or that they should be compelled by reduced incomes to add to this labour; that Dublin college may be able to rival her sister universities in the production of authors? Is it not rather their first duty and their highest honour to watch over the morals of the youth entrusted to their care, to maintain strict discipline, to encourage and assist rising merit, and to form their pupils for future usefulness? After all, though Dublin cannot boast any name equal to Bacon, Newton, or Locke, yet considering the much greater number of students in Oxford and Cambridge than in it, there will not be as much reason to shrink from the comparison as might at first be imagined. The system of education in Dublin has also been objected to, especially by those who admire that of the Scotch universities. It is said, that learning would be more considerably advanced, by each fellow devoting himself to some one science, and lecturing on it, than by his being obliged to instruct in all. There is some force in this objection; but if the system in Dublin college be not as favourable to the advancement of science, it will be found much more so to the diffusion of it, for every tutor is more interested in the general improvement of his pupils, feeling himself in some degree answerable for it, than if they were merely to attend to a discourse delivered by him. In fact, in education, it is of much more consequence to have good elementary works carefully explained to a student, than that a lecturer should aim at establishing his own character by new discoveries, when more than three-fourths of his hearers probably want to be instructed in the first principles. The consequence is, that at other universities, the youth who has been well trained at school, and who burns with the desire of knowledge, may learn more in a shorter time, than he can do in Dublin, but on the other hand, the many, those who require the stimulus of reward, or the dread of punishment to induce them to study, and who are unable to proceed, without the assistance of a tutor, will perhaps derive much greater advantage in Dublin, than at any other. Besides, though the junior fellows instruct the undergraduates in every part of their course of instruction, the lectures to the more advanced students, are given by professors who have only one pursuit, and the lectures on natural philosophy and mathematics, will not be found inferior to those given at other universities. It may be added, that the attention paid throughout the course to logic and mathematics, lays a very useful foundation for future labours. It may be perceived, from what has been already noticed, that a considerable sum out of the college revenues is devoted to giving rewards to the students, a system pursued here more regularly and extensively than in any other university, and which has been of late years adopted at two or three colleges in Oxford and Cambridge. The advantage of a large revenue is also apparent in other instances. The library, especially since the addition of the Fagel collection, is of the first rank, and is highly creditable to the college. This library is open for four hours each day, from eight to ten in the morning, and from twelve to two in the afternoon, and students may remain in it for the intermediate hours, if they

chuse to be locked in, during the absence of the librarian. Every person who has taken the degree of bachelor of arts in the university is entitled to go there, if he once enter into an engagement to observe the rules of the library, and this privilege is liberally extended, by the special favour of the board, to gentlemen, who, having no claim, may derive benefit from the use of it. If undergraduates cannot obtain this privilege, it is because they are thought to be most usefully employed in preparing for their respective examinations, and the frequenting the library would interfere with their peculiar studies. The manuscript room contains many curious Irish manuscripts, and Dr. Barrett, the present vice-provost, discovered there an old manuscript of the gospel of Matthew, of which he has published a *fac. simile*. The collection of apparatus for lectures on natural philosophy is very valuable, and was in great part a donation from that active promoter of science, the late pious Robinson. The museum is a fine room, and contains many curious articles; the collection of minerals, in particular, has been considerably increased, and would be esteemed valuable, if it were not naturally compared with the neighbouring one belonging to the Dublin Society, which is excelled by very few in the world. The anatomy-house contains the celebrated wax models of the human figure, executed by monsieur de Roue at Paris, and purchased by the earl of Shelburne, who presented them to the college in 1752. On the summit of Dunsink hill, about four miles north-west from the castle of Dublin, an observatory was founded at the instigation of the late Dr. Henry Ulmer, professor of astronomy, and one of the ornaments of the university, of which a particular account is given in the Transactions of the Royal Irish Academy. No expense has been spared to provide the building with the best instruments. Amongst others, a circular instrument, begun by Ramsden and completed by his successor, has been lately brought over at an expense of more than 1000*l*. The board also, with a liberality not often met with, in electing a professor of astronomy to succeed Dr. Ulmer, passed over a respectable candidate of their own college, in favour of a gentleman from another university, who appeared more fit for the situation. A lot of ground, of about four acres, has been lately taken at about a mile distance from the college, for a botanical garden, which is laying out in the best manner, at a considerable expence. Such are the advantages which the university of Dublin possesses, and these advantages are not, as at Oxford and Cambridge, confined to those who can subscribe the articles, or attend on the worship of the established church. The Roman catholic and the Protestant dissenters, may pass through every stage of education, without being required to do any thing inconsistent with their opinions as such, and subscription which is at Oxford required on matriculation, and at Cambridge on taking the lowest degree, is here never asked except on attaining a fellowship, or on admission to a degree in divinity. Such liberal conduct must add considerably to the number of students, though it will be in some measure counteracted by the influence of fashion, and by the unwillingness of many young men to submit to these salutary restrictions which have been introduced, and which, in so large a city, are peculiarly necessary. It may be proper to add a short account of the buildings, which, though formerly only in the neighbourhood, are now within the city, and contribute greatly to its ornament. These buildings consist of two spacious squares. The area of the first; called Parliament square, is 212 feet by 316, and was built chiefly by grants from parliament. It is formed entirely of hewn stone, ornamented with Corinthian pillars, and contains the rector's, chapel, and theatre for lectures and examinations. The front of the theatre is well decorated

decorated with four Corinthian columns, supporting a pediment. The interior, exclusive of a semicircular recess, 30 feet in diameter, is 80 feet long, 40 broad, and 44 high, excellently ornamented with stucco work. A rustic basement supports a range of pilasters of the Composite order, highly decorated, from which the rich mosaicked ceiling rises in groined arches: and in the panels, between these pilasters, are hung the portraits of queen Elizabeth the fondress, and of seven eminent persons educated in the society. The only portrait of a living person, was that of the Right Hon. Henry Grattan. This portrait of one, who must be ever considered an honour to the university, was removed on some disapprobation of his political sentiments, and that of the Right Hon. John Foster substituted in its place. If the removal be regretted, it must however be acknowledged, that the latter gentleman has deserved well of the college and of his country. Directly opposite to the theatre, on the north side of the square, is the chapel with a front exactly similar. In this is placed a noble monument of Dr. Baldwin, a former provost, who left a fortune of 80,000 pounds to the university. This monument was executed by an Irish artist at Rome, and does the highest honour to his abilities. The theatre and chapel were both built from the designs of sir Wm. Chambers. The library extends the entire length of the inner square; it is a double building composed of brick and faced with stone, with a magnificent Corinthian entablature crowned with a balustrade. It is the most superb room in Europe for such a purpose, being 210 feet long, 41 broad, and 40 high. Beyond this is a well planted and extensive park, containing seven acres, on the northern side of which is the printing office, ornamented with a good portico of the Doric order. Opposite to this is a building containing the laboratory, and anatomical lecture room. The grand front of the college is 350 feet in extent, ornamented with Corinthian pillars and other decorations. Over the vestibule, which is an octagon, terminated with groined arches, in the centre of this front, is the museum, a fine room 60 feet by 40. At a small distance to the south side of this front, is an elegant edifice, in which the provost resides. Such is the university of Dublin, yielding to no other in proportion to its extent. It has its defects, but there is a disposition to correct them, and a discussion of them here would swell an article already too long. The writer cannot conclude, what he trusts will be found a fair and impartial account of his *alma mater*, without adding his sincere prayer *esto perpetua*.

DUBLIN, a township of America, in the state of New Hampshire and Cheshire county, seated on a branch of the Muelok river, and north of the great Monadnock, containing 1188 inhabitants; 28 miles S.E. of Charlestown, and 63 W. of Portsmouth; incorporated in the year 1771.

DUBLIN, *Lower*, a pleasant town in Philadelphia county and state of Pennsylvania, 10 miles N.E. of Philadelphia, and as far S.W. of Brillol, containing 1495 inhabitants.—Also, a township of Huntingdon county in Pennsylvania, including 978 inhabitants.

DUBNO, a town of Poland, in the palatinate of Volhynia; 24 miles S.E. of Lucko.—Also, a town of Poland, in the palatinate of Belz; 40 miles N. of Belz.

DUBOJA, a town of Lithuania, in the palatinate of Brzecz; 10 miles W.S.W. of Brzecz.

DUBOIS, WILLIAM, in *Biography*, was born in 1656, at Drive-la-Gaillarde in Limosin, where he received the early parts of his education, and exhibited those nascent talents which evince to the possessor the power of becoming great. When he was very young, he manifested a propensity to falsehood that seems never to have left him. To complete his studies, he entered himself at the college of St. Michael at Paris: such, however, was his indigence, that

he was obliged to serve the principal in the subordinate office of valet. Having acquired a good portion of learning, as well in philosophy as in the languages, he became a preceptor in different families, and at length was sub-governor to the duke de Chartres, afterwards the regent duke of Orleans. Here he acted his part so well, that he was shortly made preceptor, with a considerable salary. The principles of Dubois at this period were pliant and corrupt, so that nothing stood in his way of preferment. He was employed to persuade his pupil to marry the king's natural daughter, madame de Blois; and his success in this was rewarded with the abbacy of St. Jult. He was sent to England in a political character; and on this and other occasions performed the duties required of him with so much diligence, that he obtained very considerable preferment in the church: this being regarded as the only proper method of rewarding the agents of the court. In the year 1715 his pupil became regent; and such was the character of Dubois at this time, that almost the only condition imposed on the prince by his mother was, "that he should not employ the knave Dubois." To this, however, he paid but little attention; and after a short time appointed him counsellor of state; and in 1717, he was sent ambassador into England, where he signed the triple alliance. On his return he was made minister and secretary of state; and shortly after, he obtained the richest archbishopric in the kingdom, *viz.* that of Cambrai, though no man seems to have been less fitted for the office than Dubois. Against this elevation cardinal Noailles entered his protest, regarding it as calculated to destroy all veneration for the church in the minds of the laity. In the next year, 1721, he was made cardinal, but not without meeting with a decided opposition from the pope, Innocent III., who was well acquainted with the infamy of his moral character. In this rank of life he commanded the highest offices of state, and was admitted into the council of regency in 1722, and first minister of state. He also claimed the right of being a member of the French academy, under the title of "Monseigneur;" and, in the following year, the French clergy chose this man to be their first president. Thus, arrived at the summit of power and place, rolling in opulence, and beholding almost every thing crouch in obedience before him, there seemed nothing wanting to render him great and happy, if happiness could be the result of power; but, in the midst of his honours, he was attacked with a fatal disease, the consequence of early debaucheries, which, after a painful chirourgical operation, put a speedy end to his life. He died August, 1723, at the age of 67, leaving behind him a character more infamous than can well be conceived. Moreri.

DUBOIS, JOHN, born at Lille in Flanders, after finishing his course of classics, applied to the study of medicine; and in 1557, he was admitted a doctor in that faculty, at the university of Louvain. On taking his degree, he pronounced a declamation, in Latin, "De Lue Venerea," which procured him some credit. He then went and settled at Valencien, where he distinguished himself so well, as to be appointed principal of the college of St. John. In 1562, he was made professor of medicine, in the university which Philip II. had recently founded, at Douay. In this post, which he filled with credit, he continued 13 years. He died April 5th, 1576. His works are, "De Curatione Morbi Articularis, Tractatus quatuor," 8vo. 1557; "Morbi populariter grassantis Preservatio et Curatio," Lovanii, 1572; "De Studioforum et eorum qui Corporis Exercitationibus addicti non sunt, tueda Valetudine," Duaci, 1574, 8vo. Haller Bib. Mcd. Eloye Diel. Hist.

DUBOIS, FRANCIS, or FRANCIS SYLVIVS DE LE BOE, born at Hanau, in the circle of the Upper Rhine, in 1614,

received the rudiments of his education at Sedan, whence he went to Bale, where he was admitted doctor in medicine in 1637. Not satisfied with his acquirements, he visited several of the universities in France and Germany. At length he went to Leyden; and in 1658 he was appointed to the chair of professor in medicine in that university, which had become vacant by the death of Albert Kypser. His character here, both as a teacher and practitioner, soon became so extended, that as there were few cases in medicine that were difficult in which he was not consulted, so there were none of the classes so numerously attended as that over which he presided. In 1670 he was made rector of the university, and two years after he died, in the 53th year of his age. He attended with his pupils the sick wards of the hospital, explained to them the nature of the diseases with which the patients were afflicted; and he opened before them such of the patients as died, and shewed them the changes which had taken place in the organs that were the seat of the diseases. He had the merit of being one of the most strenuous defenders of the doctrine of the circulation of the blood, as described by Dr. Harvey, and which, we know, at first met with much opposition. He also made considerable advances in the study of chemistry, to which he was much attached. He was, however, too much attached to the humoral pathology, attributing all diseases to some fault in the blood or juices, which he supposed, in most cases, were vitiated by a redundancy of acid. His remedies, therefore, were principally taken from the alkalis, a doctrine which by degrees became general over Europe. Notwithstanding his numerous avocations, he found time to write a considerable number of treatises on various parts of medicine, though few of them were published in his life-time. They have been since collected, and form a large volume in folio. "Opera medica, tam haecenus incerta, quam variis Formis et Locis edita, nunc vero certo Ordine disposita, et in unum Volumen reducia," Amstel. 1679. It has been several times reprinted. For the titles of the several treatises, see Haller's Bib. Med. Eloy D. & Hill.

DUBOIS, or, as he is more commonly called, JAMES SYLVIUS, a learned and voluminous writer of the 16th century, was so attached to the ancients, particularly to Hippocrates and Galen, the greater part of whose works he translated and edited, that he constantly opposed every thing that was novel in doctrine or practice. Hence he kept up a constant warfare with Vesalius, his cotemporary, whose discoveries and improvements in anatomy, although obvious to the senses, he refused to admit. Sylvius was born in the diocese of Amiens, in 1478, and was educated under his brother Francis, who had so far distinguished himself by his knowledge of the Greek and Latin languages, that he was promoted to the office of principal of the college of Tournay. After remaining several years with his brother, and having been initiated in the knowledge of medicine, which he also taught to younger students, to obtain what was necessary for his maintenance, he went to Montpellier in 1529, where, by the favour of the university, and in consideration of his great learning and his age, he was immediately received bachelor, and the year following doctor in medicine. He then returned to Paris, and was appointed professor in medicine; a post which he filled with honour to himself and advantage to his pupils, to the time of his death, which happened on the 13th of January, 1555, in the 76th year of his age.

His works, which were numerous and much esteemed in his time, were collected by Rene Moreau, and published in one volume folio, at Geneva, in 1635, under the title of "Opera medica, jam demum in sex Partes digesta, castigata, et cum Indicibus necessariis instructa." For the titles

of the particular treatises, with the times and order of their publication, the reader is referred to Haller's Bib. Med. As Dubois had suffered much, for want of being able to procure proper aids for his studies in the younger part of his life, and he was old before he attained to affluence, it is probable he could not then give up the habits of parsimony which his indigence had obliged him to adopt. Some wit has laughed that vice with the following:

"Sylvius hic fitus est, gratis qui nil dedit unquam,
Mortuus, et gratis quod legis ista, dolet."

Haller Bib. Med. Eloy D. & Hill.

DUBOIS, SIMON, a painter of portraits, battles, and cattle, was born at Antwerp; and having become rich by his profession, died in 1708.

DUBOIS Lake, in *Geography*. See *Lake Du Bois*.

DUBOS, CHARLES FRANCIS, in *Biography*, was born in the year 1661, in the diocese of St. Flour in Auvergne. He was sent to Paris for education, where, after having gone through a course of classical learning and philosophy, he devoted himself to the study of theology, and took his degrees in the college of the Sorbonne. Many offers of preferment were proposed to him, at length he closed with one from the bishop of Luçon, who appointed him principal archdeacon of his church, and confidential grand vicar. In this situation, he obtained the friendship of the prelate, became an inmate in his house, and entrusted by him with the most important of his concerns. After the death of his worthy patron, he was elected to a deanery under very honourable circumstances. This office he held till the 64th year of his age, when he died. He lived honoured and esteemed by all ranks, and his death was lamented by his friends, to whom he was endeared by the tenderest tie, and by the poor, who had experienced in him a kind and active benefactor. Dubos refused the celebrated "Luçon conferences," which, after the publication of five volumes had been suspended about ten years. To these he added 17 others in 12 mo., and left materials for 15 more. He was also the author of "A sketch of the life of M. Bantou, bishop of Luçon," published in 1700. Moreau.

DUBOS, JOHN BAPTIST, abbot of Refons, was born in 1670 at Beauvois, where he was educated for the church, but some disappointments caused him to turn his attention to the civil law, history, and politics. In 1695, he published his "History of the Four Gordians proved and illustrated by Medals," in which he attempted to prove the existence of a fourth of this imperial family, in addition to the three usually reckoned. After this, he was employed in many foreign negotiations. He came to England to persuade the people to consent to a peace with France; for this purpose he published a work, entitled "The interests of England ill understood in the present War," 1704, which obtained a very limited circulation, and made scarcely any impression on those for whom it was intended. The only thing remarkable in it, is a prediction of the future separation of the North American colonies. In 1709, he published a "History of the League of Cambray against the Venetian republic," which was intended to serve the cause of peace, by affording a striking example of the ill success of a league of many powers against an individual state. Dubos was employed in the negotiations at Utrecht, Baden, and Radstadt, and his labours were rewarded by church preferment. He was an agent in the hands of the duke of Orleans, and cardinal Dubois, but never acted even for these a dishonourable part, though he usually gave them satisfaction. Wearied, perhaps, of a political life, he became distinguished for his zeal in polite literature and the fine arts, and in 1719, published

published a work, entitled "Critical Reflections on Poetry and Painting," in two vols. 12mo. which has gone through several editions. This work obtained for the author the office of perpetual secretary to the French Academy, in the place of Andrew Dacier. He next employed himself in elaborate enquiries relative to the early French history, which led him to publish "A critical History of the Establishment of the French Monarchy in Gaul," in 3 vols. 4to. which was highly esteemed by many of the most eminent authors of the day. He wrote several other pieces, and died in March 1742. Moreri.

The abbé Dubos, an eminent writer on many subjects, was neither so faithful as an antiquary, nor so ingenious in his conjectures as he was long imagined. His agreeable style, and insinuating manner, were such as to make his readers forget to doubt. In his "Reflexions critiques sur la Poésie et sur la Peinture," tom. iii. there are some bold and unqualified assertions concerning ancient music, that seem to require particular notice among musical articles. The abbé does not write ex professo on music; it is chiefly in his dissertation on the theoretical representations of the ancients that he speaks with so much firmness of Greek music, as a good judge might be allowed to do of music which he heard but yesterday.

Voltaire, in characterizing this ingenious writer in his "Siècle de Louis XIV.," says: "he did not understand music, had never written a line of poetry, and was not in possession of a single picture; but he had read much, and seen and reflected much on the arts. He was as well acquainted with ancient literature as the modern, and with ancient and foreign languages as with his own." But it does not follow, that because Voltaire was a man of wit, and a good poet, that he was a good judge of painting and music, for neither of which does he manifest partiality, or discover the least knowledge in its principles.

Dubos's eulge on Lully, whom he styles the greatest poet in music, with whose works he was acquainted; on the suitability of his airs for dancing, &c. ceases to command attention. The same raptures, and still greater, were afterwards expressed in France for the works of Rameau, than for those of Græck and Piccini; and now for those of Haydn, Mozart, and Paisiello. At present, however, there does not remain in France a single idea of that music, which Dubos so exclusively extolled; and his notions of ancient music are still less to be confided in, than the modern: among other absurdities he asserts, boldly, that the performer in the ancient dramas was accompanied by a *basso continuo*, not like that of the French opera, but like the base accompaniment to Italian recitative; and determines, from a passage and plate in Bartholinus, that the instrument upon which this *continued base* was played, was a flute! With the same courage, and the same truth, this lively author asserts, that the *femina*, or musical characters of the Greeks, were nothing more than the initial letters of the names of the sixteen notes in the great system; or diagram! Opinions which merely to mention, is to confute.

Dilettanti, musical critics, without possessing the necessary precogitate, know not what is practicable, what is possible, what is already known, or what is still to be discovered. We have known many gentlemen and ladies who have been admirable performers of the music of others; but when they erect themselves into composers and critics, they discover more ignorance than the lowest and most clumsy professor that was ever admitted into an orchestra or organ-loft.

What Dubos says in defence of the *maske* through which theatrical performers spoke or sung, is more reasonable. "The Spectator," says he, lost but little on the side of *face-playing*, by the introduction of *masks*; for not one-third of the audience was near enough to the actor to discern the

play of muscles, or working of the passions in the features of his face; at least to have received pleasure from them; for an expression must have been accompanied with a frightful grimace and distortion of visage, to be perceptible at a great distance from the stage." But when he says, "foreigners find that the French understand *time* and *rhythm* better than the Italians,"—all must know, except his countrymen of the old school, that the direct contrary is true, and indeed almost all the opinions of this writer, concerning both ancient and modern music, which were respected four score years ago, would be defended now by few, even among the natives of France.

DUBOVKA, in *Geography*, a town of Russia, in the government of Saratof, on the west side of the Volga; 60 miles S. of Kamifchin.—Also, a fort of Russian Tartary, in the government of Caucasus, on the Malwa; 12 miles W. of Kiz'iar.

DUBOURG, MATTHEW, in *Biography*, a very eminent performer on the violin, whose conduct as well as performance, acquired him patrons and friends, which rendered his long life happy, and honourable to himself and profession.

This excellent performer, born in 1703, was the natural son of the celebrated dancing-master, Isaac, and had instructions on his instrument by Gemminian, soon after his arrival in England, 1714. In 1715, the young Dubourg, at twelve years old, had a benefit concert at the great room, afterwards the Tennis-court, in James's Street; and is said to have played, standing on a joint stool, a solo, at Briton, the small coal-man's concert, much earlier. From this time till the year 1720, when the Royal Academy was formed at the opera-house, Dubourg played solos and concertos at almost every benefit concert besides his own. From that period he was sufficiently ready and powerful to lead the band at the concerts, where he performed solos, till the year 1728, when he had arrived at such fame and patronage as procured him the appointment of composer, and master of his majesty's band in Ireland. He resided several years in that kingdom afterwards. But from the year 1735, when he was taken into the service of the late prince of Wales, he frequently visited England. We saw and heard him while at his best in the summer of 1734, at Chesham, and had the pleasure of accompanying him in Corelli's 5th solo, which he performed in a manner so superior to any one we had ever heard, that we were equally astonished and delighted, particularly with the fulness of his tone, and spirit of his execution.

It has been erroneously said, that Dubourg was no composer; he was indeed no publisher, but the odes which he set for Ireland, and innumerable solos and concertos which he composed for his own public performance, are now in the possession of one of his disciples, and of sense of them the composition is excellent.

On the demise of Festing, in 1752, he was appointed leader of the king's band, and upon that and the produce of his place in Ireland, he seems to have enjoyed ease and tranquility to the end of his life, which was terminated in 1767, at the age of 64. He was buried in Paddington church-yard, and on his monumental stone are engraved the following lines:

"Though sweet as Orpheus, thou couldst bring
Soft pleadings from the trembling string,
Uncharm'd the king of terror stands,
Nor owns the magic of thy hands."

DUBRAVITZ, in *Geography*, a town of European Turkey, in the province of Moldavia; 36 miles N.W. of Galatz.

DUBRAW, JOHN, in *Biography*, a German prelate, statesman, and historian in the 16th century, was born at
Puffen,

Pilsen, in Bohemia. He was educated in Italy, and obtained the degree of doctor of laws. He was afterwards employed in a political capacity by Stanislaus, bishop of Olmutz, in Moravia. By this prelate he was engaged in various negotiations of considerable importance, and was entrusted by him with the direction of his troops which he sent to the relief of Vienna. He was afterwards raised to the see of Olmutz himself, which he enjoyed about six years. His character as a divine did not prevent him from continuing his services as a statesman, which in several instances were of the highest interest to his country. He published, in the year 1552, a history of Bohemia in thirty-three books, which is highly commended for fidelity and accuracy, and in the following year he died. A new edition of his work, with additions, was published in 1574, by Thomas Jourdain; and another at Frankfort in 1688, to which is added a history of Bohemia, by Æneas Sylvius Moreri.

DUBROWA, in *Geography*, a town of Lithuania, in the palatinate of Wilna; 74 miles E.S.E. of Wilna.

DUBROWICA, a town of Lithuania, in the palatinate of Brzecz; 46 miles S.E. of B. zefc.

DUBUDY. See DUDY.

DUC, FRONTON DU, in *Biography*, a learned French jesuit, was born at Bourdeaux about the year 1558. He entered into the order when he was nineteen years of age, and was almost immediately appointed to the tuition of the junior members in the principles of rhetoric. As a teacher he was employed, in different places, about twenty years, when he began to be known as an author. His first production of importance was a Latin translation of the works of St. Chryltoftom, in six volumes folio, with notes. He was afterwards engaged in a theological controversy with the celebrated Mornay du Pleffis-Marli, on the subject of the practice and doctrine of the ancient churches, relative to the eucharist. This dispute lasted several years, after which Du Fronton was appointed librarian to the jesuits at Paris, and about the same time Henry IV. had determined upon printing the select MSS. from the collection of the royal library, and had engaged several learned men to employ themselves on editions of the profane writers. The clergy of France, in one of their assemblies, assigned to the jesuits the care of preparing for publication the writings of the Greek fathers, and father Du Fronton was, on account of his great learning, appointed to that business, in which he spent the remainder of his days. The last years of his life were spent in almost incessant pain from repeated attacks of the stone, to which he fell a victim in the year 1624. His various works as an original author, translator, and editor, are enumerated by Moreri. He was esteemed one of the most learned men and ablest critics of his day, and was at the same time unassuming, and pious. He enjoyed the correspondence and friendship of the most distinguished literary characters of the age, as well of the protestant, as of his own communion. Moreri.

DUC, JOHN LE, a painter of animals, was born at Hague in 1636, where he was appointed director of the academy of painting, and died in 1671.

DUCA, in *Geography*, a town of Italy, in the kingdom of Naples, and province of Bari; 6 miles N.W. of Bari.

DUCE, in *Ancient Geography*, a people of Africa, in Mauritania Cesariensis, according to Ptolemy; but as he places them in the vicinity of Sitifi, they seem to belong to Mauritania Siftensis.

DUCAL. The letters patent granted by the senate of Venice, are called ducals: so also are the letters wrote in the name of the senate, to foreign princes.

The denomination of ducal is derived hence; that, at the beginning of such patents, the name of the duke, or doge, is wrote in capitals, thus, "N——— Dei Gratia Dux Venetiarum, &c." The date of ducals is usually in Latin, but the body is in Italian. A courier was dispatched with a ducal to the emperor, returning him thanks for renewing the treaty of alliance (in 1716) against the Turks, with the republic of Venice.

DUCAREL, ANDREW COLTER, in *Biography*, was born in Normandy, in 1713, but was brought to England by his father during infancy. He received his grammar learning at Eton school, and from that seminary he went to St. John's college, Oxford, where he took his degree of LL. B. In 1742, he became a member of the college of civilians in Doctor's Commons; and, in 1752, he made a tour in his native country, of which he published an account soon after his return, which he reprinted in 1767, under the title of "Anglo-Norman Antiquities." He had, however, some years previously to this, been elected to an office in the chapel of St. Catharine near the tower, which was peculiarly grateful to him on account of its affording him a good opportunity of pursuing his antiquarian studies. In 1757, he was appointed librarian of the palace of Lambeth, and in the following year was made commissary and official of the city and diocese of Canterbury. About this period he addressed to the antiquarian society, of which he had been some years an active and indefatigable member, a series of above two hundred Anglo-Gallic, or Norman and Aquitaine coins of the ancient kings of England, exhibited in copper-plate engravings, and illustrated with letter-press. In 1762, he was elected a member of the Royal Society, and was soon after a contributor to its Transactions, in an account of the early cultivation of botany in this country. Dr. Ducarel's situation in the library at Lambeth led him to the study of ecclesiastical antiquities, and he made large collections on the subject. In the year 1763, he was appointed, with sir Joseph Ayloffe and Mr. Aisle, to methodise the records in the state paper office in Whitehall, and in the augmentation office. In 1782, he published "The History of the Royal Hospital and Collegiate Church of St. Catharine," and in the following year, an account of the town and palace of Croydon. In the Bibliotheca Topographica he gave "The History and Antiquities of the Archiepiscopal palace of Lambeth from its foundation to the present time." He continued an unwearied application to business, and his favourite studies till his death which happened in the spring 1785. Independently of the works of which this learned man was the sole author, he contributed to several others connected with antiquarian subjects, and had a considerable share in the "Account of Alien Priories." It was his custom for many years, previously to his death, to take a summer journey, with a single friend, and as privately as possible, for the purpose of pursuing his favourite researches. Biog. Brit.

DUCART, ISAAC, a painter of flowers, generally on satin, was born at Amsterdam in 1630, and died in 1697.

DUCAT, a foreign coin, either of gold or silver, struck in the dominions of a duke; being about the same value with the Spanish piece of eight, or a French crown, of four shillings and six-pence sterling, when of silver; and twice as much, when of gold. See COIN.

The origin of ducats is referred to one Longinus, governor of Italy; who, revolting against the emperor Justin the Younger, made himself duke of Ravenna, and called himself *Exarcha*, i. e. without lord or ruler; and, to shew his independence, struck pieces of money of very pure gold, in his own name, and with his own stamp, which were called *ducati*, ducats; as Procopius relates the story.

After

After him, the first who struck ducats were the Venetians, who called them also *Zecchini*, or sequins, from *Zecca*, the place where they first were struck. This was about the year 1280, in the time of John Dandolo: but we have pretty good evidence, that Roger, king of Sicily, had coined ducats as early as 1240. And Du-Cange scruples not to affirm, that the first ducats were struck in the duchy of Apulia, in Calabria. The chief gold ducats now current, are, the single and double ducats of Venice, Florence, Genoa, Germany, Hungary, Poland, Sweden, Denmark, Flanders, Holland, and Zurich. The heaviest of them weighs five penny-weights seventeen grains, and the lightest five penny-weights ten grains: which is to be understood of the double ducats, and of the single in proportion.

The Spaniards have no ducats of gold; but, in lieu thereof, they make use of the silver one; which, with them, is no real species, but only a money of account, like our pound. It is equivalent to eleven rials. (See *RIAL*.) The silver ducats of Florence serve there for crowns.

DUCATOON, a silver coin, struck chiefly in Italy; particularly at Milan, Venice, Florence, Genoa, Lucca, Mantua, and Parma: though there are also Dutch and Flemish ducatoons.

They are all nearly on the same footing; and, being a little both finer and heavier than the piece of eight, are valued at two-pence or three-pence more, *viz.* at about four shillings and eight-pence sterling.

There is also a gold ducatoon, struck and current chiefly in Holland: it is equivalent to twenty florins, on the footing of one shilling and eleven-pence halfpenny the florin.

DUCE, in *Geography*, a small town of France, in the department of La Manche, chief place of a canton in the district of Avranches; 6 miles S. E. of that place, with a population of 1611 individuals. The canton has an extent of 120 kilometres, and comprizes 12 communes, with 8754 inhabitants.

DUCENARIUS, in *Antiquity*, an officer in the Roman army, who had the command of two thousand men.

The emperors had also *ducenarii* among their procurators, or intendants, called *præcuratores ducenarii*. Some say, that these were such whole salary was two hundred sesterces; as in the games of the circus, horses hired for two hundred sesterces, were called *ducenarii*. Others hold that *ducenarii* were those who levied the two hundredth penny, the officers appointed to inspect the raising of that tribute. In the inscription at Palmyra, the word *ducenarius*, in Greek *δουκένιος*, occurs very often.

DUCENTESIMA, a tax of the two hundredth penny, exacted, by the Roman emperors.

DUCES TECUM, in *Law*, a writ commanding one to appear at a certain day in the court of chancery, and to bring with him some evidences, or other things, which the court would view.

DUCES tecum licet languidus, a writ directed to a sheriff, who, having in his custody a prisoner, in a personal action, returns, upon a *habeas corpus*, that he is *adeo languidus*, that, without danger of death, he cannot have his body before the justices. This is now out of use. Where a person's life would be in danger by removal, the law will not permit it to be done.

DUCHAL, JAMES, in *Biography*, was born at or near Antrim in the year 1697. For the principal part of his early education he was indebted to the celebrated Mr. Abernethy. His college studies he pursued at Glasgow, from

whence he removed to, and settled among, a small congregation of dissenters at Cambridge, where he remained several years, improving the advantages which the situation afforded in the best manner possible. About the year 1735, he accepted an invitation to Antrim, to succeed his friend and preceptor Mr. Abernethy, whom he again succeeded at Dublin in the year 1740. In the year 1752, Mr. Duchal published his work, entitled "Presumptive Arguments for the Truth and divine Authority of the Christian Religion, in ten sermons: to which is added, a sermon upon God's Moral Government." Almost immediately upon the appearance of this volume, the author had the degree of doctor in divinity conferred upon him by the university in which he had been educated. He died in the year 1761, deeply regretted by his friends. He ever maintained a high character for piety, and every Christian virtue. In his religious sentiments he was liberal, and candid, and as a preacher he maintained a high rank among his contemporaries. After his death three volumes of his sermons were published, which have been highly esteemed on account of their excellent tendency. Besides these, Dr. Duchal published three discourses while he was at Cambridge, entitled, "The Practice of Religion recommended;" and he is supposed to have been the author of various occasional publications, both in England and Ireland, which related to the theological controversies of the period in which he flourished. *Biog. Brit.*

DUCHESS, in *Geography*. See *DUTCHESS*.

DUCHESS, *La*, a town of Naples, in the province of Abruzzo Ultra; 11 miles S.S.W. of Aquila.

DUCHOUTSCHINA, a town of Russia, in the government of Smolensk; 24 miles N. of Smolensk, and 300 S.S.E. of Peterburg.

DUCHY COURT of Lancaster. See *COURT*.

DUCK, STEPHEN, in *Biography*, was an English poet, more distinguished by his fortune and his fate than by the brilliancy of his genius, or the excellency of his poetry; and whose labours excited more attention, and received more patronage, than any contemporary writings, though far superior in meritorious claims. For a rustic genius was then a novel thing, and a poet from the barn appeared as great a prodigy as a dictator from the plough. He was born at an obscure village in Wiltshire, A.D. 1700. His early education was such as was afforded by a common country school; where he learned to read and write, to which was added a little knowledge of arithmetic. At the age of 14, he was taken from school, and employed afterwards in all the menial offices of a country life. His inclination for learning, however, must have been prodigiously great; for he was married in fervice; was possessed of no books, nor money to purchase them. He contrived, by working over-hours, to obtain sufficient money to buy a few, and others he borrowed of his friends. These he perused, by frequently stealing a few hours from sleep. Though limited in time, he could read but little; yet he thought more. His scanty library consisted chiefly of works in verse, which probably turned the bias of his mind in favour of poetry. And the scattered pieces in the Spectators induced him to try, if he could not succeed in making verses himself. A very early poem, though not the first written, was that on his own occupation, entitled, "The Thresher's Labour," addressed to the Rev. Mr. Stanley; and which, excepting the one on "Friendship," is perhaps the best in the whole collection. Duck now became noticed as a surprising genius, and obtained some little notice from the neighbouring gentry. But had it not been for his friend and admirer Mr. Spence,

he might have written verses, and still been doomed to plod on in the lame dull round of abject servitude, till the close of life; and continued to complain:

“ Thus as the year’s revolving course goes round,
No respite from our labours can be found:
Like Sisyphus, our work is never done;
Continually rolls back the restless stone:
New-growing labours fill succeed the past;
And growing always new, must always last.”

The Tarether’s Labour.

Through the means of Mr. Spence, he was introduced to queen Caroline, who took him under her patronage, and allowed him a pension of 30*l.* per annum; which he gratefully acknowledged in the dedication of his poems. After he had taken holy orders, he was presented to the valuable living of Byfleet in Surrey. But it does not appear that this preferment, though great, contributed at all to his happiness: for he was observed ever afterwards to be melancholy. Whether his ambition had been disappointed, in not being exalted still higher; or his vanity hurt at the diminution of his early popularity; or that conscience accused him for having assumed an office, for the duties of which his previous learning by no means had qualified him, and which he had accepted as a kind of sinecure, or at least with a view to the emoluments attached,—is not known. Perhaps cessation from his usual labours might have been the cause. In a fit of insanity, he threw himself into the Thames, and was drowned, in the month of June, in the year 1736. His works were published in 8vo. London. 1730; and in 4to. with an account of the author, by Mr. Spence, prefixed, London, 1736.

Duck, in *Geography*, a river of America, in Tennessee, which rises on the N.W. side of the Cumberland mountains, runs a N.W. course, and discharges itself into the Tennessee, in N. lat. 36°. At 5 miles from its mouth, 57 miles westerly of Nashville, it is 200 yards wide; and it is passable by boats for 90 miles.

Duck, a lake of North America. N. lat. 54° 50'. W. long. 108° 30'.

Duck Creek Cross Roads, or Salisbury, a considerable and thriving post-town of America, in the state of Delaware, situated on Duck creek, which in part divides Kent and Newcastle counties. It contains about 100 houses in one street, and carries on a considerable trade with Philadelphia; and is one of the largest wheat markets in the state. It has an episcopal church, and a post-office; 11 miles N.W. of Dover, and 36 from Wilmington.

Duck Island, a small island in the Atlantic, near the coast of Main in America. N. lat. 44° 45'. W. long. 67° 43'.

Duck Islands, called the *real ducks*, lie in lake Ontario, Upper Canada, between Wolf island and Point Travers.

Duck, in *Ornithology*, the name of a large tribe of birds, synonymous with the Linnæan term *ANAS*, and comprehending the whole of those families of the aquatic kind, which are known by the denomination of swans, geese, ducks, and teal. The word duck may be understood to imply only that family which is commonly so named, but, in a general sense, must be considered as the English generic appellation of *anas*. The character of the genus consists in having the bill convex and obtuse, with the edges divided into lamellate teeth; tongue fringed, obtuse; three fore-teeth connected, the hind-one solitary. The following species are described by Linnæus, Gmelin, Latham, and others.

* *Anas*, with the bill gibbous at the base.

CYGNUS. Bill semi-cylindrical, blackish and yellow; cere yellow; body white. *Cygnus ferus*, Linn. *Cygnus fawvage*, Buff. *Wild swan*, Br. Zool. *Whistling swan*, Lath.

This is rather smaller than the tame swan, and inhabits Europe, Asia, and America. The wild swan is gregarious, and is sometimes seen in severe winters in Britain, assembled together in flocks of five, six, or more. It has a remarkable whistling note, whence it derives the name of whistling swan. This note, which it utters chiefly in flight, is so loud as to be often heard when the bird itself is so high in the air as to be imperceptible to the naked eye. It appears that this ability arises from the peculiar construction of the wind-pipe, which is extremely different from that in the common swan: in the first of these, the wind-pipe, after entering the chest a little way, is reflected from thence in the form of a trumpet, and again returning into it, divides into two branches, and joins the lungs; in the other, on the contrary, the wind-pipe enters at once into the lungs, and, in consequence of this, it is enabled only to make a hissing noise. The wild swan runs swiftly, and swims with its neck erect. The female lays four eggs. The flesh of this bird is not only eatable, but held in much consideration in the north of Europe, and in America. The various useful purposes to which the feathers of the swan are applied are well known. Their skins are worn by the Indians, in many parts of America; and having the downy surface turned inwards, afford an article of warm and comfortable clothing. The legs of this bird are sometimes reddish.

PLOU. Bill semi-cylindrical and black; cere black; body white. *Anas olor*, Gmel. *Anas cygnus (majesticus)*, Linn. *Le cygne*, Buff. *Tame swan*, Albuin. &c.

Found in a wild state in Russia and Siberia, from whence they have been conveyed to various parts of Europe and Asia; and being easily tamed and domesticated, form an elegant and appropriate ornament to parks and other grounds, possessing the advantages of an ample sheet of water. Nothing can indeed exceed the grace and dignity with which the swan glides or swims through the watery element, assuming the proudest attitudes, and seeming conscious of deserving admiration. In England, they are protected by law: those kept on the Thames are esteemed royal property, and stealing their eggs is deemed felony. The tame swan is a strong, robust creature, and is said to live to the age of an hundred years. They feed on fish and aquatic plants, and build in high grass near the water. Their eggs, from six to eight in number, are laid one every other day. The young swans are called cygnets, and were formerly considered as a delicacy for the table; the flesh of the adult birds is hard and ill-flavoured.

NIGRICOLLIS. Bill semi-cylindrical and red; head and neck black; body white; legs flesh coloured. Gmel. *Melanocorypha*, Molin. *Black-necked swan*, Bougan. *Black-necked swan*, Lath.

Except in having the neck of a velvet black, the plumage agrees with the tame swan, and is about the same size. The species inhabits the Falkland islands, Rio del Platte, and the straits of Magellan; it likewise met with in Chili.

ATRATA. Black; wings edged with white; bill red. *Black swan*, Phillip’s Voy.

The black swan is rather smaller than the common kind; the upper mandible is blackish at the tip, and marked with a yellow spot; the legs black, with the feet paler. This kind inhabits Botany Bay, and has been introduced into England within the last few years.

BRACHYPTERA. Bill fulvous; body cinereous; wings short; vult and band on the wing white. Lath. *Anas cinerea*, Gmel. *Oiffau gris*, Peruet. *Race-horse duck*, ibid. *Logger head duck*, Phil. Tranf.

Length thirty-two inches; the bill orange, with black tip; fecondary quill-feathers white on the outer edge; posterior part of the belly blueifh-black; on the bend of the wing a yellow knob half an inch long; legs brownifh-orange, with dusky webs and black claws. Thefe inhabit the Falkland iflands, Staaten Land, &c. and were obferved by our navigators with captain Cook to appear generally in pairs. From the fhortnefs of their wings they were unable, it is faid, to fly; but their wings are ferviceable to them on the water, being ufed as oars, with the aid of which they fwim along with aftonifhing velocity. In order to catch them, our failors ufed to furround a flock with boats, and drive them afhore, where, being unable to raife themfelves, they ran very faft, butfoon becoming tired, fquatted down, and being eafily overtaken, were knocked down and killed without difficulty. The flefh is rank and has a fihy flavour.

HYBRIDA. Bill femi-cylindrical; cere red; tail fome-what pointed. *Molin.* Hybrid fwan.

A native of Chili. Its fize is that of a goofe, but the neck is fhorter, and the legs and wings longer; the male is white, with the legs and bill yellow; the female black, with a few feathers edged with white; bill and legs red. Thefe birds are found on the fea-coafs, lay from fix to eight eggs on the fands, and are obferved to fly in pairs.

CYGNOIDES. Bill black and femi-cylindrical; cere gibbous; eye-lids tumid. Linn. *Anfer guineenfis*, Brif. *Oie de Guinée*, Buff. *Spanifh goofe*, or *fwan goofe*, Albin. *Clinfe goofe*, Arct. Zool.

An inhabitant of Europe, Afiæ, and Africa. The length is about three feet; the bill wrinkled near the front, gibbous, afcending, and furrounded at the bafe with a whitifh line; the crown and longitudinal band down the neck and nape tefaceous; back and flanks grey-brown, the plumage edged with whitifh; beneath white; legs tawny, with black claws; protuberance on the chin blackifh.

The variety of cygnoides, called by Linnæus *Orientalis*, and by Albin the Mufcovy gander, is fmall than the other; the bill is orange, the irides yellow; on the forehead is a large knob as in the laft, and which is the fame colour as the bill; beneath the throat is a wattle; the head and neck are brown, deepeft on the hind part; back, wings, and tail the fame, but deeper, and edged with paler; the quills, breast, and belly white; the female is fmall than the male. There appear to be fome other varieties of this fpecies. Thefe birds breed freely with the common tame geefe, and are rather abundant in England at this time.

GAMBENSIS. Bill femi-cylindrical; cere gibbous; body black, beneath white; back purplifh; bill, forehead, and legs red. *Cambenif*, Linn. *Anas chilenfis*, Klein. *Spur-winged goofe*, Lath.

Size of the common goofe, but taller; the bill more than two inches long, of a red colour, with a protuberance of the fame colour at the bafe; the cheeks and chin white, and the bend of the wing armed with a ftrong fpur of a horn colour, and about an inch and a half in length. The fpecies inhabits Gambia and other parts of Africa.

INDICA. Grey, beneath pale afh; head and neck white; lunule on the hind-head and fpot beneath black; rump and vent white. *Barred-headed goofe*, Lath.

A native of India, where it occurs in flocks of an hundred together, in the winter months, and is very deftructive to the corn. It is fuppofed to come from Thibet, and other

parts toward the north, difappearing again as the fummer approaches. The flefh is good. This bird is about the fize of the tame goofe; the bill two inches long and bright yellow, with the nail black; the head, throat, and hind part of the neck are white; at the back part of the head below the eye is a crefcent of black, having the horns curved upwards towards the eye, below this a fecond, and the back of the neck for the moft part under this black; the back part of the belly is brown, edged with white; tail grey, with white tip; and the legs tawny.

GOSCOROA. Bill dilated and round-d at the point; body white. *Molin.* Chili.

This fpecies inhabits Chili. It is of a large fize, the bill and legs are red, and the eyes black.

MELANOTOS. White; bill and caruncle at the bafe black; head and neck spotted with black; back, cuneated tail, and wings black. Gmel. Zool. Ind. &c. *L'Oie broncée de Coromandel*, Buff. *Black-backed goofe*, Lath.

A fpecies common in the ifland of Ceylon, and along the coaft of Coromandel. Its fize is that of a goofe, but of a more fender form; the bill pale, large, and curved downwards at the point; and in the middle a large rounded flefhy knob, the fame colour as the bill; the head, and half the neck is white, dotted with black, and the feathers are ruffled, or reflected; the reft of the neck and under parts are white, tinged on the fides with grey; the back, wings, and tail, black, gloffed with greenifh, and inclining to blue towards the tail; the legs dufky. The female differs from the male in having the caruncle fmall, and the plumage lefs vividly gloffed with green and blue. Both fexes have the fhoulder of the wing armed with a long and dangerous fpur. In India it is known by the name of Neckdab.

GRANDIS. Body blackifh, beneath white; bill black; legs fcarlet. Gmel. *Great goofe*, Lath.

A large fpecies, found in the eaft of Siberia, from the Lena river, as far as Kamfchatka, and is taken in great numbers, according to Pallas, in decoys contrived for this particular purpofe; the bill is black, with the bafe tawny.

HYPERBOREA. Body fnowy; front yellowifh; firft ten quill-feathers black; bill and legs red. Gmel. *Anfer niveus*, Brif. *White brant*, Lawf. Car. *Snow goofe*, Arct. Zool.

Size of the common goofe; the bill fomewhat ferrated at the edges with the upper mandible fcarlet, the lower whitifh. The plumage, in young birds, is of a blue colour, until after the firft year. At Hudfon's bay they are found in vast numbers, and are called by the natives *way-way*, and *wapa*, *wbe wbe*. In the month of October they are taken in abundance by the inhabitants, who pluck them, and after taking out their entrails, put their bodies into holes dug in the ground, which they cover with earth; the furface of the ground freezing, preferves the birds, in a perfectly fweet ftate, throughout the winter, and thus thefe fubterraneous receptacles furnifh an occasional fupply of frefh food to the inhabitants, with little coft or labour, during the feverer months of winter. They are reprefented as very ftupid birds, common in the arctic regions during the fummer, but pafs the winter in more temperate climates.

PICTA. Blackifh-afh, with tranfverfe black lines; head, neck, middle of the belly, bar on the wings, and coverts white. Gmel. *Painted goofe*, Lath.

The length of this bird is twenty eight inches; the bill is fmall, about an inch and a half long, and of a black colour. The legs, primary quill-feathers, and tail, black; wings with an obtufe fpur on the bend. The fpecies was firft defcribed by Dr. Latham, from the drawings of Mr. Jofeph Banks, the bird delineated was met with at Staaten-Land in January.

MAGELLANICA. Rusty brown; body, on the fore part and beneath, transversely varied; bar, across the wings and coverts, white. Gmel. *L'Oie des terres Magellaniques*, Buff. *Magellanic goose*, Lath.

Observed in the straits of Magellan. The length of this bird is twenty-four inches; the bill short and black; wings and tail black; vent grey; legs yellow; and claws black.

ANTARCTICA. Scurvy; bill black; legs yellow (*maf.*) Variegated; belly, vent, rump, and thighs white; legs with a green spot (*fon.*) Mus. Carl. *Anas antarctica*, Gmel. *Antarctic goose*, Lath.

These birds inhabit the Falkland islands, and are from twenty-four to twenty-six inches long. The male entirely white; the female, with the bill, flesh-colour; body brown, with transverse white lines.

VARIEGATA. Body above brown, spotted with white; beneath chestnut, spotted with white and black; bill, tail, and primary quill-feathers black; secondary green; wing-coverts white; rump and vent ferruginous. Gmel. *Variiegated goose*, Lath.

Size of a large duck; the bill an inch and a half long, and black at the tip and base; tail and legs black. This bird inhabits New Zealand, and was found by captain Cook in Dusky bay, in April, where it is called *Pooa duggee duggee*. Dr. Latham considers the antarctic goose as the female of this species, in his Synopsis; but in the Ind. Orn. since published, it appears as a distinct bird.

LEUCOPTERA. White; bill, two middle tail-feathers, primary quill-feathers, and greater wing-coverts black; nape, and upper part of the body, with numerous black lines. Gmel. *L'Oie des Malouines*, Buff. *White winged antarctic goose*, Brown. *Sea goose*, Phil. Transf. *Bushard goose*, Lath.

Inhabits the Falkland islands, and is known by the name of the *bushard goose*. It is a tall bird, and measures nearly forty inches in length; it walks and flies with great ease, and lays six eggs; the flesh is deemed wholesome and palatable. The wings have a blunt spine at the bend, and a dusky green spot; the greater wing-coverts are white at the tip; secondary quill-feathers half black and half white; and the legs black.

TADORNA. Bill knobbed at the base, with the front compressed; head greenish-black; body variegated with white. Linn. *Vulpanser*, Klein. *Shieldrake*, Brit. Zool. Donovan. Brit. Birds.

A native of Europe and Asia, about two feet long, and subsists chiefly on fish, and aquatic plants. The female is smaller than the male, but is not materially different in plumage; it breeds most commonly in deserted rabbit burrows, and has hence acquired the name of *burrow-duck*. The female lays fifteen or sixteen roundish white eggs, and sits about thirty days; the young take to the water as soon as hatched, and swim extremely well. The shieldrake is a bird of elegant plumage, and is common on many of the British sea coasts.

SPECTABILIS. Bill compressed at the base, with a black feathery keel; head hoary. Linn. *Anas friti Hudsonis*, Briff. *Le canard à tete grise*, Buff. *Grey-headed duck*, Arct. Zool.

Inhabits North America, Europe, and Asia. Length about two feet. This bird builds on the sides of rivers, and lays four or five eggs, which are white, and as large as those of a goose. The female is chiefly black and brown; the belly dusky.

FUSCA. Blackish; lower eye-lid, and spot on the wings, white. Linn. *Anas nigra major*, Briff. *Grande, ou double macreuse*, Buff. *Velvet duck*, Brit. Zool.

Native of Europe and South America. The length is about twenty-two inches; the bill black in the middle, at the base gibbous; and the legs red. The female has no gibbosity on the bill; and the body is brown.

NIGRA. Entirely black; bill gibbous at the base. Gmel. *La macreuse*, Buff. *Scoter*, or *Black diver*, Brit. Zool.

Inhabits North America and Europe, and feeds on grass and shell-fish. The length is twenty-two inches, the bill yellow in the middle; head and neck sprinkled with purple; tail sub-emucated. The female has no gibbosity at the base of the bill, and is browner than the male. The flesh of this species is rancid.

REGIA. Caruncle compressed; body blue, beneath brown; collar white. Mohr. Chil.

This is much larger than the common duck, *Anas boschas*. **NILOTICA.** Whitish, with hoary spots; sides of the breast and belly with hoary lines; marginal callosity on the bill and caruncle purple-red. Hasselq. *Niilotic goose*, Lath.

Inhabits the Nile, in Upper Egypt, and is said not to be found in any other parts except on the borders of the Red sea. The species is cultivated, with other domesticated poultry, in Egypt. Its size is less than the common goose; its tail rather long and rounded; legs red, and claws black.

BERINGII. White; wings black; neck blueish; caruncle, at the base of the bill, yellow, radiate in the middle, with blueish feathers. Gmel. *Bering goose*, Arct. Zool.

This is the size of the common wild goose, and was seen by Steller in the month of July, in great abundance on Bering island. The natives pursue them in boats, and kill them in the moulting season, or, at other times, hunt them on land with dogs.

ALBIFRONS. Cinereous; forehead white. Gmel. *Anas erythropus*, (*fon.*) Linn. Faun. Succ. *Anser sibirionialis sylvesteris*, Briff. *L'Oie ricuse*, Buff. *Laughing goose*, Phil. Transf. *White-fronted goose*, Arct. Zool.

Inhabits the north of Europe and Asia, and is likewise met with in America. Length two feet four inches.

ERYTHROPUS. Cinereous, above waved black and white; neck black; face and abdomen white. *Anas erythropus*, Linn. Fa. Succ. (*male*). *Bernicla*, Briff. *Anas helsingen*, Olaf. *Anser brenta*, Klein. *La bernacle*, Buff. *Bernacle*, or *Clakis*, Arct. Zool. Donovan. Brit. Birds, &c.

Common in the north of Britain, and other parts of Europe, and is occasionally seen in America. This is a large species, measuring about two feet in length, and is the true goose of Gerrard and other naturalists about his own time; a bird which they gravely asserted to be generated and hatched in the shell of the bernacle, *Lepas anatifera* of modern authors. This silly conjecture has been long since exploded, but the species still retains the name given to it under this erroneous idea.

** Bill equal at the base.

MARILA. Black; shoulders waved cinereous; belly, and spot on the wings white. (*male*). Linn. *Anas fulter-ranea*, Scop. *Fulgula Gsferri*, Raii. *Scap duck*, Arct. Zool. Donovan. Brit. Birds, &c. *Anas frontata*, Linn. Mus. Carl.

Length about 18 inches; the bill broad, blueish ash; head neck glossed with green; the legs and primary quill-feathers dusky; secondaries white with black tips; tail, coverts, and vent black. The female is brown, with black bill surrounded with a circle of white feathers; neck rusty; belly and bar on the wings white; legs black. Its size rather larger than the male. This species inhabits the north of Europe, Asia, and America, and is found during winter in

in small flocks on the coasts of England. A supposed variety of this species has the head and neck purple green; back and shoulders waved with cinereous, and the belly and wing-lobe white.

LOBATA. Blackish with transverse greyish lines, beneath paler, under mandible lobate beneath. Nat. Misc.

Inhabits New Holland. Its size is that of the common duck; the bill broad at the base and black, the lower mandible with a large, black, flat round wattle, placed longitudinally; the body dark cinereous; paler beneath and on the neck, and waved with numerous transverse whitish lines, legs black.

MONTANA. Head, neck, and quill-feathers red-green. Gmel. *Hill or mountain goose*, Kolben.

Larger than the tame goose, and inhabits the hilly parts of the Cape of Good Hope, and feeds on grass and herbs.

CANA. Reddish-ferruginous; head and neck grey; wing spot green; shoulders white. Gmel. *L'Oie sauvage à tête de Coromandel*, Sonn. *Grey headed goose*, Brown.

Less than the Brent goose, and inhabits the mountains of the Cape, where it is called *Bergenten* by the Dutch. The female differs from the male in having no white on the cheeks, and, in general, the colours of the plumage more obscure. There is a small knob a little below the bend of the wing in this species.

RUFICOLLIS. Black, beneath white; bill small, conic; neck rufous; spot between the bill and eyes white. Pallas. *Red breasted goose*, Arct. Zool.

Native of the north of Russia, and has been twice shot in Britain: it is a very rare and beautiful species.

CASARCA. Rufous; wings and tail black; wing spot white. Linn. *Anas rutila*, Lepech. *Collared duck*, Gent. Mag. *Ruddy goose*, Lath.

Nearly as large as the Mufcovy duck. The species inhabits Russia and Siberia during summer, and migrates into India at the approach of winter. Like the sheldrake it forms burrows under ground, and constructs its nest in holes in the craggy banks of rivers. Their voice is shrill and powerful, and at times resembling that of the peacock. The bill and legs are black; the head and upper part of the neck white, and collar black. This is the male bird, from which the female differs chiefly in being destitute of the black collar.

EGYPTIACA. Bill sub-cylindric; body undulated; crown white, wing spot with a black collar. Linn. *L'Oie d' Egypt*, Buff. *Ganfer*. Albin. *Egyptian goose*, Lath. *Donov. Brit. Birds*.

Native of Egypt, the Cape of Good Hope, and other parts of Africa, from whence they have been imported into England, and have now become generally naturalized; it is a beautiful species, and highly ornamental in pleasure grounds. It is as large as the common goose, and has the bill reddish with the tip black; the body waved with brown and ferruginous; temples, orbits, and spot on the breast chestnut; back, rump, wings, and tail black; belly white; legs red, with black claws. In the female the chestnut patch round the eye is smaller; the chin white; the chestnut spot on the breast smaller, or sometimes entirely wanting; the lesser wing-coverts white; the others pale ash with darker margins; the lower ones fringed with white, and forming a bar on the wing; scapulars and second quills inclining to chestnut. There is a variety with the bill grey; spot on the breast black, and the back, wings, and rump chestnut.

SECTUM. Cinereous, beneath dirty white; bill compressed at the base; tail-coverts white; legs saffron. Gmel. *Bean goose*, Arct. Zool.

Length two feet seven inches; the bill black, reddish in the middle; head and neck inclining to ferruginous; quill-feathers edged with black; tail with white; legs sometimes

reddish brown, with black claws. The species inhabits Europe and America; they breed in the Orkneys, and come in the autumn into the more southern parts of Britain, and depart again in May. They are in particular fond of green wheat, and are therefore very destructive in corn fields.

BOREALIS. Bill narrow; head green; breast and belly white. Gmel. *Greenland duck*, Arct. Zool.

A species of the middle size between the duck and goose; it inhabits the fens of Iceland, and is very rare.

CERULESCENS. Brown, beneath white; wing-coverts and hind part of the back blueish. Gmel. *Blue winged goose*.

Native of North America. Rather smaller than the common goose; the bill and legs red; crown yellowish; rest of the head and neck white; shoulders and tail waved white and grey. Known at Hudson's bay by the name of *Cath-catsue-we-we*.

BERNICLA. Brown, head, neck, and breast black; collar white. Linn. *Brenta*, Bris. *Le Cravant*, Buff. *Brent goose*, or *Brand Goose*, Arct. Zool.

Less than the Bernacle goose, inhabits the north of America, Asia, and Europe, and migrates towards the south in autumn; feeds on sea plants, berries, and marine insects. The plumage of the female is more obscure in colour than the male, and in young birds the white on the side of the neck is small or entirely wanting. Like the Bernacle goose, these birds are frequent on our coasts during winter. On the coasts of Holland they are often taken at that season in nets placed across the rivers. Buffon relates, that they are sometimes so abundant on the coasts of France as to become extremely troublesome; and mentions in particular, that, in the year 1740, they were literally a pest to the inhabitants, not only destroying the ears of corn, but tearing up the stalks by the roots. They are easily tamed, and, when fattened, are esteemed delicate eating. In Shetland it is called the *Horra* goose, being found in the found of that name.

CANADENSIS. Cinereous; head and neck black; cheeks and chin white. Linn. *L'Oie à cravate*; Buff. *Canada goose*, Catsby. &c.

Length three feet and a half; the bill, tail, rump, and primary quill-feathers black; a triangular white spot reaching from the back of the head to the chin; the nape, tail-coverts, vent, and lower part of the belly white; legs lead colour. The species inhabits North America, where it appears to be met with in vast flocks during the summer, when they retire farther northward. In the vicinity of Hudson's bay they constitute a principal article of food, the Indians killing some thousands annually, which are either eaten fresh or salted and barrelled. It is said the Indians wait the arrival of these birds with much expectation, and form a row of huts, constructed of the boughs of trees, at a musket shot distance from each other, across those parts where the birds are expected to pass, where they lie secreted, and, when the geese fly near, so exactly mimic their note as to decoy them near enough to kill them with their musket shot. These birds are very shy, but an expert marksman by this means has been known to take two hundred geese in one day. The flesh is good and the feathers in much request, being equally fine as those of the common goose.

MOLLISSIMA. Bill cylindrical; cere on the hind part bifid and wrinkled. Linn. *Anser langinosus*, Brit. *Eidergans*, *Waulbaum*. *Oie à duvet*, Buff. *Eider*, or *Cuthbert duck*, Arct. Zool.

The Eider duck inhabits the north of Europe, Asia, and America, extending to the highest northern latitudes, and becoming scarce towards the south. In Britain it is seldom found more southerly than the Farn Isles, or in America than New York. They are numerous in the Esquimaux islands, and

in Greenland. The male has the bill, legs, front-band across the eyes, breast, and lower part of the back and belly black; middle of the head, upper part of the back, shoulders, and wing-coverts white, and beneath the hind part of the head a blotch of pea-green. In young birds the neck and breast are commonly spotted black and white, and the crown of the head black; and it is said, when they attain a great age, which sometimes does happen, the plumage becomes entirely grey. The female is in general of a reddish brown, barred with black, and the hind part of the neck marked with longitudinal dusky streaks; two bars of white on the wing; tail dusky, and legs black.

These birds are smaller than the common goose, and feed on shell-fish, in search of which they dive under water to a great depth; their flesh is good, and the down obtained from their nests in the breeding season so abundant, and of such an excellent quality, as to render it an article of considerable commercial importance in the north of Europe. The quantity of down found in one nest weighs only about three quarters of an ounce, yet is sufficient to fill the crown of a man's hat. Salerne relates, that three pounds of this down may be compressed into a space not larger than one's fist, notwithstanding it is so dilatable as to fill a quilt five feet square. That found in the nests is called live-down, and is more valued than the down plucked from the skins of the dead birds.

ANSER. Bill semi-cylindrical; body above cinereous, beneath paler; neck striated. Linn. *Anser sylvestris*, Bris. *Anas Araki*, Fork. *Wild geese*, Will. *Grey Lag geese*, Arct. Zool.

β. var. domesticus. Varies much in colours by domestication.

The wild goose weighs about ten pounds; its length is two feet nine inches, and breadth five feet. The bill is flesh colour, with the tip white; the rump and vent white; the legs flesh colour, and claws black. These birds inhabit the fens of England, and are supposed not to migrate from hence, as in many other countries on the continent, being met with throughout the summer, and being also known to breed in Lincolnshire, and Cambridgehire. During the winter season they associate in large flocks. On the continent they migrate in flocks of five hundred together; their columns, when their flock is large, are somewhat triangular, with one point foremost, but when small, appear in a direct line. The geese, in a wild state, seem pretty generally diffused over the globe: they are met with in Iceland, and from Lapland to the Cape of Good Hope. In Arabia, Persia, and China they are frequent; indigenous to Japan, and on the American continent from Hudson's bay to Carolina. They are also met with in the straits of Magellan, in the Falkland isles, and at Terra del Fuego. They are easily tamed, and have from seven to eight young at a time.

In a state of domestication the grey lag goose varies from its parent origin in the colour of the plumage, but in a much slighter degree than either the mallard or the cock, being more or less grey, and having both the vent and tail-coverts almost constantly white. Tame geese are no where seen in greater abundance than in the fens of Lincolnshire, many persons keeping no less than a thousand breeders. The use of the quills and feathers is well known, and for the sake of these the birds are frequently stripped of their plumage whilst alive; about Michaelmas they are despoiled of both quills and feathers, and four times afterwards between that period and the ensuing Michaelmas they are again stripped, but of their feathers only. Numbers die in consequence of this cruel treatment, if the weather prove cold, otherwise they

soon recover their strength, and seem to suffer no very material injury. During their sitting, each bird has its allotted space, in rows of wicker pens placed one above another; and it is said the person, who takes charge of them, and is called a Gizzard or Goose-herd, twice in a day drives the whole to water, and bringing them back to their habitations, places every bird in its respective nest without missing one. In some countries the common price of geese is regulated by that of mutton, the former being stripped of the feathers, and both being the same *per* pound. The usual weight of a fine goose is about sixteen pounds, which, however, may be greatly increased by cramming them with bean meat and other fattening diet. Some nail the geese to the floor by the webs of their feet, during the time of fattening, a proceeding apparently cruel, but which is said to occasion no pain, and is intended to prevent the least possibility of action. The French add to this the refinement of putting out their eyes, an act of barbarity, we conceive, devoid of any useful purpose. The geese in England, when fully fattened, have been known to weigh thirty pounds. The number of geese driven annually from distant counties to the London market appears incredible. They will walk from eight to ten miles a day on the average, travelling from three in the morning till nine at night. In this manner they are often brought to London in droves of many thousands together. The weaker ones are much fatigued, and are fed on oats instead of barley, their usual food, on the journey.

MOSCHATA. Face naked and papillose, Linn. *Anas sylvestris Brasiliensis*, Ray. *Anas Indica Gessneri*, Will. *Le canard musqué*, Buff. *Anitra muta*, Zinnar. *Muscovy duck*, Will.

Larger than the wild duck; the bill two inches long, and red, except about the nostrils, and at the tip, which are dark brown; face red; the crown of the head black; temples, chin, and throat, white, varied with black; breast and lower part of the belly brown, mixed with white; back and rump brown, glossed with golden green; upper part of the belly white; the three first quill-feathers white, the rest brown; tail-feathers twenty in number and golden green, except the outer one on each side, which is white; the legs red. The plumage of the female is more obscure in colour, and the naked papillous space about the head smaller.

The name of Muscovy duck usually given to this species seems to imply that the breed originated in that part of the world; but, according to Ray, it is so called from the musky odour, which it exhales, a scent arising from the gland on the rump; and it appears also from Marcgrave that they are indigenous in Brazil. In an unconfined state, they make their nests on the stumps of old trees; and perch under the shade of the foliage during the heat of the day. The flesh is accounted excellent.

RUFÆ. Cinereous; head and neck rufous; breast black; back lined with brown; wings cinereous brown. Gmel. *Anas ruficollis*, Scop. *Rufous necked duck*, Lath.

Size of the mallard; the bill black; head and neck rufous; breast black; back variegated with brown lines pointing backwards; tail short; legs black. A species described on the authority of Scopoli, the native place not mentioned.

LEUCOCEPHALA. Bill broad; tail-feathers rigid, pointed, grooved; the middle ones longest. Scop. *Anas mersa*, Pallas. *White headed duck*, Shaw. *Ural duck*, Lath.

Rather larger than the common teal; bill large, broad, and tumid above the nostrils, the colour blue; head and part of the neck white; on the crown a large patch of black; breast chestnut, with black streaks disposed transversely; belly grey with small black spots; back rufous; wings reddish,

reddish, with brown dots and lines, small, and without any appearance of a speculum; tail long and wedged, the colour black; legs brown, on the forepart blueish, and placed far behind, as in the divers. The female is entirely brown, except the throat, which is white. The species is not infrequent in the greater lakes of the Ural mountains, and the rivers *Ob*, and *Irtisch*. It is seldom seen on the ground, as it is, from the situation of its legs, scarcely able to walk, but it swims very well, and what is remarkable, the tail is at that time immersed in the water as far as the rump, and serves as a kind of rudder to direct its course, contrary to the manner in which the duck tribe usually swim. The neck is formed of reeds like that of the grebe, and floats in the water.

MONACHA. White, varied with black; bill yellowish with black tip; wing-spot violet green, Scopoli.

Larger than the wild duck; the lores grey; head, bill, and upper part of the breast spotted with black; first quill, and tail-feathers white with brown tip. Native place unknown.

TORRIDA. Head white; neck above black, beneath chequered. Gmel. *Branta torrida*, Scop. Torrid duck.

Native place unknown.

ALBICANS. Front and body beneath whitish, above brown, head and neck brown rufous. Gmel. *Branta albifrons*, Scop.

The feathers of the breast are cinereous, edged with pale rusty, and a rufous bar near the tip; quill-feathers within, and at the tip white.

GEORGICA. Cinereous-waved; wing-spot greenish, edged with white; wings and tail dusky. Gmel. *Georgia duck*, Lath.

Described by Dr. Latham from a drawing in the Banksian collection; the specimen was found in South Georgia in the middle of January; it was a male bird, and the flesh was excellent. The total length of this bird was twenty inches; the bill two inches long, turned up a little at the tip and yellow; irides chequered; wing-coverts pale-ash; legs greenish-grey.

BAHAMENSIS. Grey; bill lead-colour, with a lateral tawny spot; wing-spot green and pale yellow. Linn. *Marca prima Aldr.* Ray. *Le marc*, Buff. *Ilathera duck*, Catesby, Lath, &c.

Native of Brazil and the Bahama islands, particularly that called *Ilathera*, whence its name, but it is not numerous. It is said to perch and roost on trees. Its size is that of the common duck; the crown is reddish ash, neck, back, shoulders, and rump reddish brown; cheeks and throat white; breast and belly rufous-grey, spotted with black; primary quill-feathers and lesser wing-coverts dusky; greater ones green, with black tips; secondary quill-feathers yellow; legs lead-colour.

BRASILIENSIS. Brown, beneath cinereous; between the bill and eyes a yellow spot; chin white; tail wedged and black. Gmel. *Le marca*, Buff. *Marca duck*, Lath.

Inhabits the same country as the former, and with that species is indiscriminately called by the natives *Marca*. The bill is black; upper wing-coverts brown, glossed with green; greater ones edged with blue green, and black at the tip; quill-feathers white at the extremity; legs red.

ERYTHROHYNCHA. Bill red; brown beneath, and temples white; transverse bar on the wings white, and another below yellowish; tail black. Gmel. *Crimson-billed duck*, Lath.

The length of this species is fifteen inches; the bill two inches long, and turning up at the end; legs black. It inhabits the Cape of Good Hope.

ALBOLA. White; back and wings black; head blueish;

the hind head white, (male) Linn. *Querquedula ludoviciana*, Briss. *Anas hyberna*, Briss. *Sarcelle blanche et noire*, Buff. Pl. Enl. *Petit canard a grosse tete*, Buff. Ois. *Spirit duck*, Arct. Zool. *Duffel-headed duck*, Cateby. (Female). *Anas rufica*, Linn. *Querquedula carolinensis*, Briss. *Sarcelle de la Caroline*, Buff. *Little brown duck*, Cateby.

The two sexes of this duck have been described as distinct species. They inhabit North America, and are found at New York in the winter, returning southward in the summer to breed. They arrive about June in Hudson's bay, and make their nests in trees, in the woods near ponds. The male is rather larger than the teal, and about sixteen inches in length; the female only fourteen.

STELLERI. White; hind-head somewhat crested; transverse spot on the nape, and each side of the bill green; tail brown; ten first quill-feathers blackish brown; the rest black blue. Pallas. *Western duck*, Arct. Zool.

A rare species, found on the sea coasts of Kamtschatka, where it breeds in the moist inaccessible rocks, and flies in flocks. Its size is that of the common wigeon; the bill and legs black; orbits lunule at the base of the neck; and band from the wings to the back black. Female ferruginous.

CLYPEATA. Extremity of the bill dilated and rounded with an incurved nail. Linn. *Anas platyrhynchos allura*, Ray. *Anas virescens*, Mars. *Avis latirostris*, Klein. *Souchet*, Buff. *Shoveler*, Brit. Zool.

A native of Europe, Asia, and America; in England the species is scarce, in Germany rather more common, and also throughout the Russian dominions as far as Kamtschatka; its food consists of insects, and shrimps have been likewise found in its stomach on dissection. It breeds in the same places as the summer teal, laying its eggs on a bed of rushes; these eggs are of a rufous colour, and from ten to twelve in number. The size of the male is about twenty-one inches; the bill black; irides yellow; head and neck violet green; breast white; back, wings, and tail brown; belly chequered; vent white; first and second wing-coverts pale blue, greater, brown tipped with white, the rest edged with white; legs tawny. The female is smaller, and in general brown. Both sexes vary occasionally in colour. Dr. Latham considers the *Anas muscaria* of Linnaeus as a variety of this species, as it differs only in having the belly white; and another supposed variety inhabits Mexico; this is the *Tempalabac* of Ray, *Le canard sauvage du Mexique* of Brisson. It is the size of the tame duck. The bill is large and black; the head and neck greenish, glossed with purple; breast white; rest of the body beneath fulvous, with two white spots on both sides near the tail; and the legs red.

MEXICANA. Tawny; above black and white lined; wings brown; lesser coverts white; greater next the body green gold. Lath. *Anas clypeata mexicana*, Briss. *Tucapatlabac*, Ray. *Mexican shoveler*, Lath.

Smaller than the common duck; the bill brownish-red; greater wing-coverts brown; and the legs reddish. The species inhabits New Spain.

RUBENS. Brown; chin and breast chequered; wings tipped with grey; wing-spot purple, edged with white; tail short and white. Gmel. *Red breasted shoveler*, Lath.

Size of the common duck; the bill is broad, and brownish yellow; head large, eyes small, and the legs slender and bay colour. Inhabits Europe.

JAMAICENSIS. Varied with brown, fassron, and rusty; back, wings, and tail brown; upper part of the head black beneath, and chin white, with black spots. Gmel. *Teal of Guiana*, Bancroft. *Jamaica shoveler*, Lath.

Length sixteen inches; the bill broad, blueish, orange at the

the sides; legs orange; back brown, sprinkled with yellowish fattigated dots, and tail cuneated. It is a native of Jamaica, where it first appears in October or November, and retires northward in March.

SCANDIACA. Chestnut; back, wings and tail black; belly white. Gmel. *Anas latiofron*, Brun. *Lapmark duck*, Arct. Zool.

Inhabits Denmark, and is common about Christiansted, and also at Lapmark. Its size is that of the common duck; the bill is broad, with the legs black; the secondary quill-feathers white, with black tips; and the flanks ferruginous. The species frequents both the fresh and salt waters.

STRÉPÉRA. Wing-spot rufous, black, and white. Linn. *Anas platyrhynchos*, Ray. *Chipeau*, Buff. *Gadswall*, Will, &c.

Size of a wigeon; the bill flat and black; legs tawny; rump black; back brown, waved with paler; breast and belly grey, varied with white. The female is marked in a manner somewhat similar to the male, but is more obscure. In the breeding season it is found throughout Sweden, Russia, and Siberia, and as far north even as Kamtschatka; in the winter it appears in France and Italy. It is seen in England during the latter season, but not commonly. This bird is very shy, concealing itself during the day time among the rushes, and venturing out to feed only in the morning and evening. Its voice is like that of the mallard, but louder; and the flesh is good.

FALCARIA. Crested, variegated with hoary and brown; breast scale-waved; front, chin, collar, and bar on the wings white. Pallas. *Anas falcata*, Georgi. *Falcated duck*, Arct. Zool.

This is found in the eastern part of Siberia, from the river Jenisei to the Lena, and beyond lake Baikal, and is supposed to winter in the Mongolian deserts, and in China. Its size is that of the common wigeon; the bill black; crown testaceous, and the rest of the head silky green, with a small white spot on the front; speculum blue black, edged with white; five inner quill-feathers long, falcated and varied with white and violet; legs lead-colour. A variety is described by Buffon under the title of *Sarcelle de Java*, in which the quill-feathers are not falcated; in this the vent is brown and the thighs white. This is described as a native of Java and China, and is perhaps the young or female bird.

DOMINICANA. Rufous; front of the head sooty; wing-spot white; shafts of the tail-feathers deep black. Gmel. *Canard dominicain du Cap de Bonne Esperance*, Sonn. *Dominican duck*, Lath.

Inhabits St. Domingo, and measures in length about twelve inches. The bill is black; breast and belly grey-brown mixed with white, and some of the greater wing-coverts white; wings brown; tail cuneated, the feathers pointed, and the legs brown.

SPINOSA. Brown; crown black; tail-feathers pointed. Gmel. *Sarcelle à queue épineuse*, Buff. *Spinous-tailed teal*, Lath.

A native of Cayenne and Guiana. The bill is blueish; band across the eyes, white in the middle, and black each side; tail short; legs flesh-coloured. Length from eleven to twelve inches.

AFRICANA. Reddish-brown; back, wings, and tail black; spot on the breast and transverse bar on the wings white. Gmel. *Sarcelle d'Egypte*, Buff. *African teal*, Lath.

Rather larger than the garganey, length sixteen inches. The colours of the female agree with those of the male, ex-

cepting in being more obscure, and the white spot on the breast waved with brown. This species is a native of Europe.

MADAGASCARIENSIS. Dusky green, beneath white; cap, front, and chin white; hind-head and neck greenish-black; throat and breast ferruginous, waved with brown. Gmel. *Sarcelle male de Madagascar*, Buff. *Madagascar teal*, Lath.

A native of Madagascar. This species is about twelve inches long, and has the bill yellow, tipped with black; between the ears is a pale green patch of an oval shape; and the legs and wings dusky, the latter marked with a white streak.

COROMANDELIANA. Above glossy-brown, beneath white; crown black, the rest of the head and neck white, spotted with black. Gmel. *Sarcelle de Coromandel*, Buff. *Coromandel teal*, Lath.

Much smaller than the common garganey; its bill is dusky; the lower part of the neck marked with decussating black lines; vent ferruginous at the sides; and the legs black. The female is varied beneath with white and grey. Native of Coromandel.

MANILLENSIS. Head and chin white; neck, breast, and wing-coverts bay; wings and tail pale greenish. Gmel. *Sarcelle de l'isle de Luzon*, Sonn. *Manilla teal*, Lath.

Lies than the common teal, and inhabits the island of Manila.

FORMOSA. Brown; crown black, edged with white; chin reddish, spotted with black; wing-spot black, edged with testaceous, and marked on the fore part with an oblique green spot. Georgi reise. *Baikal teal*, Lath.

Size of the common teal, and inhabits Russia about the lake Baikal. The bill is black; legs dusky red; from the eye to the chin extends a black spot, paler on the hind part, and edged with green; the nape and sides of the neck waved; vent black, with a white band, and tawny at the sides; middle tail-feathers whitish. A variety of this bird inhabits China; it is of a brown colour, with the crown black; head yellowish brown at the sides, and behind the eyes green with a curved black spot.

HINA. Region of the eyes green. Osbeck. *Hina teal*, Lath.

Described on the authority of Osbeck, who does not mention the size; the bill, he says, is blackish grey and soft, the head and chin brown; a white line passes below the eyes, and all the space above is green; the neck and upper part of the back are white, spotted with black; lower part of the back and rump ash-colour; upper part of the neck white, spotted with black, breast and belly white; feathers of the rump edged with white; feet and legs ash-coloured. The female has the head and region of the eyes grey; chin white, above black, and in some parts of a reddish white, spotted with black. In China it is called *Hina-a*.

SPARMANNIA. Beneath dull white, above black, varied with ferruginous and white; scapulars white, edged and lined with rusty-white on the disk. Lath. *Anas alandica*, Mus. Carl.

Length twenty-three inches. The bill and legs black; tail ferruginous, somewhat fasciated with black. Inhabits the vicinity of Aboana.

CLANGULA. Varied black and white; head tumid and violet; at each corner of the mouth a large white spot. Linn. *Le Garrot*, Buff. *Golden eye*, Arct. Zool. *Donov. Brit. Birds*.

Inhabits Europe and the north of Asia and America. It preys on shell-fish, frogs, and other aquatic animals, and forms a nest of galls of a rounded form, lined with feathers from

from the breast, and in which it deposits from seven to ten eggs of a whitish colour. In the Linnæan Fauna Suecica, it is said to build in the hollows of trees. The flesh of this kind of duck is much esteemed.

PERSPICILLATA. Black; crown and nape white; bill with a black spot behind the nostrils. Lath. *Anas perspicillata*, Linn. *Macreuse à large bec*, Marchand, Buff. *Black duck*, Cook's Voy.

Size of the velvet duck, length twenty-one inches. The bill and legs are red; crown and neck marked with a white triangular spot. The female is smaller, footy and without the spot on the nape; on the cheeks two whitish spots. A native of America, breeds along the shores of Hudson's bay, and feeds on grass; the nest is also composed of grass, lined with feathers, and contains from four to six white eggs, which hatch the end of July. It is called by the natives *Misse qua geo ta wovoo*. Captain Cook met with it in Prince William's sound.

GLAUCION. Body blackish; breast waved; wing-spot white and linear. Linn. *Anas peregrina*, S. G. Gmel. *Morillon*, Bris. *Glaucium*, Arct. Zool. Smaller than the golden eye, and inhabits northern regions.

NOVE HISPANIÆ. White, spotted with black; head tawny, varied with blackish and greenish blue; wing coverts and vent blue; spot between the bill and eyes, and bar on the wings white. Gmel. *Querquedula mexicana*. Bris. *Toltecolotli*, Ray. *Canarde du Mexique*, Buff. *Mexican duck*, Lath.

Size of the common teal; the upper mandible of the bill is blue, the lower black; the middle quill-feathers green without, tipped with tawny; legs pale red. The female differs in having the head, posterior part of the neck, back, scapulars, wing-coverts and rump black, some of the feathers edged with fulvous, and others white; beneath black. varied with white, and the legs ash-coloured. It inhabits the lakes of Mexico and Surinam, where it is said to be continually dabbling in the mud with its bill for worms, frogs, fish, &c.

MALACORHYNCHOS. Blueish-lead colour; bill membranaceous at the tip; crown greenish ash; wings with a transverse white spot. Gmel. *Blue-grey duck*, with a soft bill, Cook's Voyage. *Soft billed duck*, Lath.

This bird is about the size of the wigeon, and inhabits New Zealand. Our circumnavigators met with it in Dusky bay in April. The bill is an inch and a quarter in length, of a pale ash-colour, with the tip black; the latter part is membranaceous, and of such a soft and flexible nature, that the bird is supposed to live by suction, or on worms which it finds in the soft mud on the sea shore when the tide is down; it is said to whistle like the whistling duck. The inhabitants of New Zealand call it *He-uegeo*.

AMERICANA. Pale rusty, waved with black; crown and front ochraceous; wing-spot large, white; wings and tail brown. Gmel. *Canard genfer*, Buff. *American wigeon*, Arct. Zool.

Rather larger than the common wigeon, and inhabits America. The bill is lead-coloured, tipped with black; hind-head and neck varied with white and black; behind the eyes a black spot; vent black, and legs dusky. It is found from Carolina to Hudson's bay, but is no where common. They are gregarious, and in Martinico, where they are abundant, associate in large flocks, and do great mischief in the rice plantations during the rainy season. They seldom appear till after sun-set, when they come forth from their hiding places in quest of food; they sit in January, and in March the young are hatched. The flesh is excellent, but that of

the domesticated ones is preferable to those killed in a wild state.

CAPENSIS. Dirty white; back bay; wing-spot, blueish green edged with white. Gmel. *Cape wigeon*, Lath.

Length fifteen inches; the bill red, and black at the base; head speckled with dusky; and the legs red. Inhabits the Cape of Good Hope.

PENELOPE. Tail rather pointed; vent black; head brown; front white; back cinereous waved. Linn. *Anas sibilularis*, Bris. *Canard siffleur*, Buff. *Wigeon*, Arct. Zool. *Donov. Brit. Birds.*

This species is common in various parts of Europe, Asia, and Africa, migrating from Europe as far as Egypt: it is also found in Aleppo during the winter in plenty, and likewise on the borders of the Caspian sea. Both sexes are alike in young birds till the following spring after hatching, when the male about March gains his full plumage. These birds are common in England during the winter months.

ACUTA. Tail pointed, long, beneath black; a white line on each side on the hind-head; back cinereous and waved. Linn. *Anas caudacuta*, Ray. *Anas longicauda*, Bris. *Canard a longue queue*, Buff. *Sea pheasant*, or *cracker*, Will. *Pintail*, *Donov. Brit. Birds, &c.*

Found in England, but in less abundance than in many parts of the continent. It is very common in Russia, appearing in flocks of some hundreds on the borders of the Don, and extending as far as Kamtschatka. In the winter season it is common in France, Austria, and Italy, and in plenty about the lake Baikal in Asia. Upon the sea-coasts of China it is often seen in flocks; and is not uncommon in America. The flesh is fine flavoured and very tender.

FERUGINEA. Reddish-brown; bill dilated and rounded at the tip; legs blueish. Gmel. *Anas rufa*, Linn. *Fn. Suec. Red duck*, Arct. Zool. *Ferruginous duck*, *Donov. Brit. Birds.*

A rare species, found in Denmark and Sweden, and has been once taken in Lincolnshire.

GLACIALIS. Tail pointed, long; body black, beneath white. Linn. *Canard a longue queue*, Buff. *Swallow-tailed sheldrake*, Will. *Long-tailed duck*, *Brit. Zool. (mal.)* *Anas hyemalis*, Linn. (young male.) *Long-tailed duck*, Arct. Zo 1. (female.)

Size of the wigeon; the bill an inch and a half long, and black, except down the middle and at the tip, which parts are orange; the head in front and at the sides are greyish, inclining to red; the posterior part, with the breast and belly, white; on each side of the neck, just below the head, is an oval spot of black; the back, wings, and tail chocolate; the tail is white, except the four middle feathers, which are black, and of these the two middle ones are much longer than the rest, exceeding them by more than three inches; the legs are dull red, sometimes blackish, and furnished with black claws. This is the description of the male bird in the adult state: when young, they vary considerably. The variety described by Linnæus as a distinct species, under the name of *hyemalis*, has the tail nearly as in the preceding, but the two middle feathers rather shorter, the belly white, the back of the head cinereous; the temples, with the breast, back, and wings black. This kind has been described as the female by some authors: but, from recent observations, it appears that the latter sex has the tail short, uncutted, and destitute of the two middle long feathers; the body varied with rufous and grey; the body black, and the collar, with the lower part of the belly, white. This relates to the adult female; for, in young birds, the crown and collar are black, sprinkled with white, and the black dull cinereous.

There

There is still another variety of this species, called by Baffon *Sarcelle de Ferros*, a bird found in the Ferros islands, where it is known among the natives by the name of O'edel. The colour of its plumage is blackish-brown, beneath white; the head pale-grey at the sides; the orbits white; hind-head, chin, and neck spotted with brown; wings with a reddish-brown spot.

These birds inhabit the north of Europe, Asia, and America. In England they are confined chiefly to the Orkneys, where they are met with from April to October. In Sweden, Lapland, and Russia, it is not an uncommon species, and thence extends even to Kamtschatka. In America it is found from Hudson's bay to New York, remaining in Hudson's bay and in Greenland throughout the year. Like the Eider duck, it forms the nest of grass near the sea, and lays from ten to fifteen eggs of a white colour, and the size of a pullet's. The nest is lined with down of a soft and valuable kind, but not in sufficient abundance to reward the labour of collecting it. They fly with swiftness, and swim well; have a loud and singular cry, and subsist principally on shell-fish.

FULVA. Tawny; back, shoulders, wings, and rump transversely streaked with tawny and brown; tail varied with white and black. Gmel. *Penelope mexicana*, Brif. *Quaquachnaulti*, Ray. *Mexican pochard*, Lath.

The size of this bird is uncertain; the bill and legs are dusky, with black claws; and the eyes are black. The species inhabits Mexico.

FERINA. Cinereous waved; head brown; band on the breast, vent, and rump black. Linn. *Anas fera fiskea*, Ray. *Penelope*, Brif. *Poker, pochard, or red-headed wiggon*, Will. Lath.

Native of Europe, the north of Asia, and America, passing from the north to the south in the winter. During the latter season, they are frequently in the fens of Lincolnshire, where they are often caught, and sent in considerable numbers to the London markets; the flesh being much esteemed. With us they are known by the name of *dan* birds. They pass far to the south in the winter, being met with at that time in Egypt. Feed on aquatic insects and shell-fish. Their flight is strong and rapid; their voice a peculiar kind of hissing. The size of the pochard is that of the wiggon; the female is darker in colour than the male, and has the head pale reddish-brown, with the belly and wing-coverts cinereous.

LURIDA. Black; head chestnut; breast transversely lined with red. S. G. Gmel.

Rather larger than the common teal; the belly whitish, spotted with blackish, on the sides and vent snowy; quill-feathers varied with cinereous and black; tail-feathers twelve in number and black. Native of the southern part of Russia, and found by Gmelin in his travels on the borders of the Caspian sea.

KEKUSCHKA. Ochrey-yellow, beneath snowy; back cinereous; rump and tail deep-black; quill-feathers from fifteen to nineteen, the tips white. S. G. Gmelin.

Found on the borders of the Caspian sea. Length twenty inches. The flesh rancid.

QUERQUEDULA. Spot on the wings green; above the eye a white line. Linn. *Garganey*, Brit. Zool. Donov. Brit. Birds, &c.

Length seventeen inches; the bill lead colour; crown dusky and streaked; cheeks and neck purple, with short white lines; breast brown, with semi-circular black bars disposed transversely; belly white, speckled behind; scapular feathers long, narrow, and striped with white, ash-colour,

and black; tail dusky; legs lead-colour. Female brownish-ash, and without a green spot on the wing. Found, but not in any plenty, during the winter season, in Britain and France; retiring towards the north to breed, as the summer approaches. In Sweden, Russia, and Siberia, it is more common; and in Kamtschatka it breeds.

CRECCA. Wing-spot green; a white line above and beneath the eyes. Linn. *Querquedula minor*, Brif. *Krikente*, Bl. *Common teal*, Br. Zool. Arct. Zool., &c.

This well-known bird is about fourteen inches in length, and weighs twelve ounces; the bill is black; head and neck bright-bay; behind the eyes to the nape extends a broad green band, which terminates beneath in a white line; the body is whitish, with transverse blackish lines above, and the fore-part of the neck and breast spotted with black; the vent black in the middle. The female has the head and neck varied with whitish and brown; and the vent totally white. The teal is very abundant with us in winter. It breeds in France, forming its nest of rushes on the borders of ponds; or so contrived that, being placed at the water's edge, it may rise and fall with it. Its food consists of small fish and aquatic plants. The species is found as far north as Iceland, and to the southward as the Caspian sea. The summer teal, *anas cirica* of Linnæus, is supposed by some to be a variety of the common teal.

CAROLINENSIS. Black and white waved; head and upper part of the neck chestnut; throat and breast spotted with black; wing-spot green; line beneath the eyes, and humeral arch white. Lath. *Anas crecca* (var.), Puff. Transf. *American teal*, Arct. Zool.

Inhabits America from Carolina to Hudson's bay, in the last of which places it breeds: most commonly found in woody places near small ponds, and lays from five to seven eggs. The head is marked each side with a green stripe; the wing-coverts are brown, and the legs dusky. The female is reddish-brown-ash, spotted with black; the wings as in the male bird.

HISTRONICA. Variegated with brown, white, and blue; ears, double line on the temples, collar, and pectoral bar white. Linn. *Le canarda collier*, Buff. *Harlequin duck* (male), Arct. Zool. *Anas minuta*, Linn. *Harlequin duck* (female), Lath.

Native of Europe and America, and subsists on the eggs of fishes, shell-fish, and aquatic insects. They delight in shady places, and build their nests on the shores of fresh water streams; their eggs, about ten in number, are of a white colour, and resemble those of the pigeon.

FUSCESCENS. Brownish; head and neck paler; wings cinereous, spot blue, tipped with white; tail dusky. Gmel. *Brown duck*, Arct. Zool.

The length of this species is sixteen inches; the bill large, thick at the base, and bluish, with the tip black; breast pale-brown, edged with rust colour; legs dusky. Native of Newfoundland.

POCILORHYNCHA. Black; cheeks and part of the throat cinereous; wing-spot green, above white, beneath bounded with white and black; secondary quill-feathers white. Ind. Zool. *Spotted-billed duck*, Lath.

Native of Ceylon, where the species is very common. The bill is long and black, with a red spot on each side at the base, and the tip white; band across the eyes, and the vent black; legs yellow.

DAMIATICA. White; head, upper part of the neck, shoulders, and tip of the tail black; nape and neck paler; wings greenish-black. Gmel. *Anas damiatica*, *rosso apice plano lato rotundo*, Hasselq. *Damiata duck*, Lath. Rather

Rather larger than the mallard, and inhabits the shores of Egypt, those especially near the Mediterranean, as the bay near Damietta, and between Alexandria and Roletta. It is conjectured to be of the same species as the black-headed duck of Shaw's travels, which is found in Barbary.

DISCOIRS. Wing-coverts blue; secondary quill-feathers green without; band on the front white. Gmel. *Querquedula americana*, Brif. *Sarcella foveorouva*, Buff. *White-faced teal*, Arct. Zool. *White-faced duck*, Lath.

The male is of the middle size between the teal and widgeon, the female rather smaller. In the first, the head and neck are violet, the cap and bill black; and before the eyes on each side a white streak; the body brown, waved with grey; wing-spot green, edged above with white; the legs yellow. The female has the head, neck, and body, varied with grey and brown, and appears to be the blue-winged teal of Catesby. These birds inhabit the American continent as far to the north as New York; they arrive in Carolina about August, and remain there till October, feeding in the first instance on the rice, and when that fails attack the wild oats. They frequent ponds and fresh waters; and the flesh is fat and well flavoured. The species is found also in South America, at Guiana, and Cayenne. A supposed variety of this bird appears in Hudson's Bay in June, and departs at the same time as the former; it builds no nest, but forms a hollow in decayed stumps of trees, in which it deposits ten small whitish eggs; and is said to feed on grubs at the bottoms of ponds. In this kind the cap and tail are black; the greater wing-coverts marked with a dusky spot; secondary quill-feathers exteriorly, with the chin and belly white.

VIDUATA. BROWN; fore-part of the head white; legs blue. Jacq. Beytr. *Canard, face blanche*, Buff. *Canard du Maragnon*, Buff. *Spanish duck*, Lath.

A beautiful species, called by the Spaniards *Vindila*; it frequents the lakes of Carthage in America, and has a whistling note.

JACQUIN. Chestnut; back blackish; bill and legs black. Jacquin. *Jacquin's duck*, Lath.

Size of the last, and inhabits St. Domingo.

DOMINICANA. Greyish-ash; face and chin white; band across the eyes, with the hind-head, neck, and breast black. Gmel. *Canard Dominiquin du Cap de Bonne Esperance*, Sauer. *Dominican duck*, Lath.

Inhabits the Cape of Good Hope; its bill and legs are black; and the body beneath paler. Its size that of the wild duck.

AUTUMNALIS. Grey; wings, tail, and belly black; wing-spot tawny and white. Jacquin Beytr. *Anas fistularis Americana*, Brif. *Red billed whistling duck*, Lath.

The bill of this bird in the adult state is red, with only the tip black, but in the young that part is entirely black. The species, according to Jacquin and others, is very common at New Grenada, in South America, and is frequently domesticated in farm-yards between the tropics; it is nevertheless of a quarrelsome disposition, and will often desert those places, and retire to the woody swamps. The Spaniards call it *Pisife* from its voice. This is rather a large bird, being about twenty-one inches in length.

LABRADORIA. BROWN; head and neck reddish-white; collar and pectoral band black; scapular and secondary quill-feathers white. Gmel. *Pied duck*, Arct. Zo.

Inhabits the coast of Labrador, and measures about nineteen inches in length. The bill is orange at the base, the lower mandible dusky; from the crown to the nape marked with a black streak; head and neck inclining to rufous; legs yellow. The female has the bill like the male; the plumage

on the upper parts dirty mottled brown; on the wings a white spot; the legs black.

SUPERCILIOSA. Grey; eye-brows white; chin and throat dirty white; wing-spot green-blue, edged with black. Gmel. *Supercilious duck*, Lath.

Described from the drawings of sir Joseph Banks. The species inhabits New Zealand, and was found both in Charlotte foud and Dusky bay, where it is known by the name of *He-turrera*. Its size is that of the mallard. The bill is lead-coloured, and the legs dusky-ash.

CURVIROSTRA. Black; middle tail feathers (of the male) recurvate; chin with an oval white spot; bill hooked. Palas. *Curv-billed duck*, Lath.

Larger than the common wild duck, and inhabits the Netherlands. The irides are fulvous; head, neck, and rump greenish-black; five outer quill-feathers white; chin white; wing-spot deep shining blue.

BOSCHAS. Cincereous; middle tail feathers (of the male) recurvate; bill straight; collar white. Linn. *Anas fersa*, Brif. *Canard sauvage*, Buff. *Wild duck*, Will. Donovan. Brit. Birds.

This is the origin of our common tame duck, the varieties of which are extremely numerous, arising from the various modes of domestication adopted in different countries, and the facility with which it inter-mixes with others of the duck tribe in general. The principal varieties of *Anas Boschas*, enumerated by writers, are the six following; β . *Anas domestica* (tame duck) variable in colour of the plumage by culture. γ . *Boschas major*, Brif. much larger than the tame duck, and having the back footy-black. δ . *Boschas major grisea*, Brif. Size of the last; body tinged greyish. ϵ . *Boschas major navia*, Brif. Same size; the back spotted with yellowish. ζ . *Anas adunca*, Linn. *Hook-billed duck*, Will.

The duck in a wild state is an inhabitant of Europe, Asia, and Africa, frequenting watery places, and subsisting chiefly on frogs, snails, and every kind of offal. Its nest is usually built near the water, or sometimes in trees, and it has been known to deposit its eggs in the deserted nest of the crow or magpie. The wild duck abounds in many of our marshes, but no where appears in greater plenty than in Lincolnshire, where prodigious numbers are annually taken in the decoys, and sent to the markets. They pair in the spring, and lay from ten to sixteen eggs; and the young take to the water as soon as hatched. They breed chiefly in the north of Europe, and are therefore found in far greater numbers in the winter season with us than during summer. In France they are seldom seen, except in winter, making their first appearance in October, and departing in the spring. The means employed by different nations for the capture of the wild ducks is very dissimilar; in England they are chiefly taken in decoys or by shooting; in France they are killed in vast numbers by being enticed within gunshot likewise; but many are taken with hooks and lines baited with offal, and left floating on the waters they frequent. Upon the river Ganges, another method is adopted; a man wades into the water up to the chin, and having his head covered with an empty calabash, approaches the ducks, who being accustomed to see the calabashes frequently in the stream, remain quiet. Thus unperceived the man has time to approach the flock, and pull them by the leg under water one after the other, till he has caught whatever quantity can be conveniently carried away; with these he retires unsuspected by the remaining ducks, and in like manner repeats his visits till he has taken as many as he may think proper. Vast numbers of ducks are hatched by the Chinese from

from the eggs by artificial means, the eggs being placed in boxes of sand, and left on a hearth of brick-work, to which a proper degree of heat is communicated during the time required for hatching them.

GALERICULATA. Crest pendent; on each side the posterior part of the back a recurved, compressed, elevated feather. Gmel. *Querquedula sinensis*, Brisson. *Kimmod suis*, Kempt. *Sarcelle de la Chine*, Buffon. *Chinese duck*, Lath. Rather less than a widgeon, with the bill dull red; the irides chestnut; crest green and red, legs tawny; back brown, glossed with blue-green; the wing-spot blue-green, edged beneath with white; the wings brown, edged with pale grey; the web on one side of the second quill-feathers much broader than the other, and curved upwards in an elegant manner, when the wings are closed; this web is of a pale brownish red, tipped with black, and constitutes a striking character of the species. The female is like that of the summer duck, brownish, with two white bars on the wings, and the breast marked with brown spots. This is a beautiful bird, and inhabits China and Japan; at Canton they are frequently exposed for sale in cages, and are bought by Europeans as objects of curiosity; the common price is from six to ten dollars a pair. Attempts have been made to naturalize them in our climate, but with little success. The English know this species by the name of Mandarin duck.

SPONSA. Pendent crest double, varied with green, blue, and white. Linn. *Anas sibilatrix*, Brisson. *Yortation Tahabiqui*, Ray. *American wood-duck*, Brown. *Summer duck*, Cateby.

This beautiful species inhabits Mexico, and some of the West India isles, migrating in the summer season to the northward. It makes its nest in the hollows of rotten trees, or between the forked branches, whence it has received the name of tree-duck. This bird is about nineteen inches long; the bill and legs red; crest striated; chin white; neck and breast claret, the latter marked with triangular whitish spots; back brown; scapulars blue-green. The female is rather less than the male; the body brown above, beneath dirty white, and varied with triangular whitish spots.

ARBOREA. Brown; head sub-crested; belly spotted with white and black. Gmel. *Anas fistularis jamaicensis*, Brisson. *Siffleur à bec noir*, Buffon. *Black-winged whistling duck*, Lath.

A native of Jamaica, where it is said to build in trees, and make a whistling noise. It also inhabits Guiana, where it is called *opano*. The size is smaller than that of the wild duck. Its bill is black; the crown dusky; hind head, back, and shoulders brown; temples and chin white; throat white, and, with the rufous breast, spotted with black; wings and tail dusky; legs long and lead-coloured, with the claws black.

CRISTATA. Crested; cinereous; throat spotted with pale straw colour; wing-speculum blue, beneath edged with white; wings and pointed tail black. Gmel. *Crested duck*, Lath.

Described from the drawings of Sir Joseph Banks. The species inhabits Staaten Land, and measures in length twenty-eight inches.

OBSCURA. Brown, edged with yellow; wing-spot blue, with a transverse black bar; tail wedged, dusky, edged with white. Gmel. *Dusky duck*, Lath.

Length two feet; the bill, crown, primary quill-feathers, and legs, dusky. The species inhabits New York.

ISLANDICA. Crested, black; throat, breast, and belly,

white; legs saffron. Gmel. *Hrafr-and*, Arct. Zool. *Iceland duck*, Lath.

Native of Iceland.

NOVÆ ZEELANDIÆ. Black, beneath ash-colour; quill-feathers cinereous; the secondary with a white band; tail dirty-green. Gmel. *New Zealand duck*, Lath.

Inhabits Dusky bay, in New Zealand, where it is called *Hypatek*.

RUFINA. Black; head, and upper part of the neck, testaceous; crown reddish, (in the male crested); wings beneath, and at the edge, white; tail brown. Gmel. *Canard siffleur luppé*, Buffon. *Red crested duck*, Lath.

Found on the borders of the Caspian sea, and in the lakes of the deserts of Tartary. The length is more than two feet; the bill red; irides brown; crest rounded; legs brown, and red in front. The female is brown, with reddish bill.

NYRACA. Olive-black; head, throat, breast, and flanks, chestnut; belly white; rump black; vent snowy. Gmel. *Olive-tufted duck*.

Inhabits the Tanaïs, and measures in length about sixteen inches; feeds on fish and vegetables; the flesh excellent. The female is smaller, and reddish in those parts of the plumage, which, in the male, are chestnut.

ARABICA. Grey spotted; beneath, and rump whitish, with cinereous spots; wing-spot blackish, before and behind white. Forsk. *Arabian duck*.

Native of Arabia; the bill yellow, and black in the middle; legs yellowish.

ALEXANDRINA. Bill and rump black; neck cinereous, with white semi-circles; belly whitish, and immaculate. Forsk.

Inhabits the same country as the preceding, and observed most commonly about Alexandria in Egypt.

GATTAR. Fuscous; wings above black, beneath white, edged with brown; quill-feathers 4—20, white in the middle. Forsk. *Egyptian duck*.

Native of Alexandria. The bill is black beneath, above brown; chin black; belly and tail-coverts white; legs blue-ash.

SIRSER. Bill beneath yellow; wing-spot divided obliquely, the upper half silky-green, the lower black before, and behind white. Forsk.

The bill is lead-colour; chin white; crown brown; back brown; the feathers edged with white; belly whitish; legs grey. The species inhabits Arabia.

BALBUL. Bill black; wing-spot above obliquely green, beneath obliquely black. Forsk.

Native of Cahira.

FULIGULA. Crest pendent; body black; belly and wing-spot white. Linn. Fr. Suec. *Anas cirrhata*, Gmel. *Tufted duck*, Donovan. Brit. Birds.

Inhabits Europe, and the north of Asia. The length of this bird is sixteen inches; the bill broad, livid, and black at the tip; head greenish; shoulders blackish-brown, with pale straw-coloured dots; and dusky-blue legs. The female brownish, and without crest.

Duck's Foot, or *May-Apple*, in *Botany*. See **PODOPHYLLUM**.

Duck's Meal. See **LEMNA**.

Duck's Meat, *Starry*. See **CALLITRICE**.

DUCKING, or plunging in water. Olaus Magnus tell us, this was a diversion anciently practised among the Goths, by way of exercise; but among the Celtæ and Franks it was a sort of punishment. Tacitus likewise assures us that it was executed, among the ancient Germans, on the lazy and infamous. At Marseilles and Bourbon, their men and women,

women, of scandalous life, are condemned to the *cale*, as they call it; that is, to be shut up, naked to the *flust*, in an iron cage, fastened to the yard of a shallop, and ducked several times in the river. The same is done also at Thou-louise to blasphemers.

DUCKING is also a punishment for seamen; who are thrown into the sea from the top of the yard of the main-mast several times, according to the quality of their offence. Sometimes a cannon-ball is fastened to their feet, to make the fall the more rapid.

There is also a kind of dry-ducking, wherein the patient is only suspended by a rope, a few yards above the surface of the water: this is a species of strapada.

The punishment is usually made public by the discharge of a cannon.

DUCKING is also a penalty, which veteran sailors pretend to inflict on those who, for the first time, pass the tropic of Cancer, the equator, or the straits of Gibraltar, in consequence of their refusal or incapacity to pay the usual fine levied on this occasion.

DUCKING-STOOL, in our *Customs*. See CUCKING-STOOL.

DUCKSTEIN, in *Geography*, is a celebrated fine pale ale brewed at Konig's Lutter, a village of Germany, in the duchy of Brunfwick Wolfenbützel, which now constitutes a part of the new kingdom of Westphalia.

DUCTRAP. See LINCOLNVILLE.

DUCKUP, a word used at sea by the steersman, or him that is at the helm, when either main-sail, fore-sail, or sprit-sail, hinder his sight, so that he cannot see to steer by a land-mark, or the like; for then his word is duckup the clew-lines of those sails; and as to the sprit-sail, when a shot is to be made by a chase-piece, and the clew of that sail hinders his sight, they say duckup the clew-lines of the sprit-sail; that is, hale the fall out of the way.

DUCLER, or DUCLAIR, in *Geography*, a small town of France, in the department of the Lower Seine, chief place of a canton, in the district of Rouen, situated on the river Seine; 12 miles W. of Rouen. It contains 1360 inhabitants; its canton has 25 communes, and a population of 14 540 individuals, upon a territorial extent of 232½ kilometres.

DUCCLOS, CHARLES DINEAU, in *Biography*, was born, in 1705, at Dnant, in Brittany. He was educated at Paris for the law; a profession which he followed for a short time only, when his talents and manners introduced him, with eclat, into the society of men of letters. He was soon distinguished as a writer, and was admitted into the academy of Inscriptions in 1739, and into the French academy in 1747. In the latter he succeeded the celebrated Mirabeau as perpetual secretary. He was ennobled and pensioned by the king, and was appointed to the office of historiographer of France. He published works in many of the departments of literature. His novels are said to be ingenious and interesting, of which the best is intitled "Confessions du Comte ***." As an historian, he is known for a history of Lewis XI., in three volumes, 12mo. 1745, to which was added another volume, by way of supplement, in the following year. This is a work of considerable research, written in a concise and elegant style. As a moral writer, he published "Considerations sur les Mœurs de ce Siecle," which is much esteemed for the truth of its maxims, and the ingenuity of its discussions. He had a considerable share in the Dictionary of the French academy, and wrote some judicious remarks on the grammar of the Port Royal. He died in 1772, and since his death have appeared "Secret Memoirs of the reigns of Lewis XIV. and XV." in 2 vols. 8vo., which have been imputed to the pen of Duclos, and which contain

many free and curious particulars of the periods treated on. Duclos was a man of great integrity, a faithful friend, and a patron of merit. He was firmly attached to sound morals, and abhorred the relaxation of principle which prevailed in the modern school. Gen. Biog.

DUCT, or DUCTUS, in *Anatomy*, a name given to various tubes in the body, and chiefly to those which convey fluids secreted in glands to their ultimate destination; these are called *Excretory ducts*.

Ductus *Adiposi*, tubes described by some anatomists, as conveying the adipous substance, which they supposed to be secreted in glands. See *CELLULAR substance*.

Ductus *ad Nasum*, or *Nasalis*, the tube which conveys the tears from the lacrymal bag to the nose. See *EYE*, and *NOSE*.

Ductus *Alimentarius*, or *Alimentalis*, a name sometimes given to the whole alimentary tube, from its commencement at the mouth to the anus. See *STOMACH* and *INTESTINE*.

Ductus *Cyliferus*, the thoracic duct. See *ABSORBENTS*.

Ductus *Communis choledochus*, is that part of the hepatic duct between the junction of the cystic and the duodenum. It derives its name from the circumstance of its conveying into the duodenum both the hepatic and cystic bile. The pancreatic duct also opens into it just before it penetrates the intestine. See *LIVER*.

Ductus *Cysticus*, the canal by which the bile passes to and from the gall bladder. See *LIVER*.

Ductus *Excretorii*. See *DUCT*.

Ductus *Galaethophori*, the excretory tubes of the mammary gland. See *BREAST*.

Ductus *Hepaticus*, the excretory duct of the liver. See *LIVER*.

Ductus *Hepato-cystici*, tubes conveying the bile from the liver directly into the gall bladder. These do not exist in the human subject, but are found in birds.

Ductus *Lacrymales*, the tubes which convey the fluid secreted in the lacrymal glands. See *EYE*.

Ductus *Lactiferi*; the excretory tubes of the Breast, which see.

Ductus *Pancreaticus*, the excretory tube of the *Pancreas*, which see.

Ductus *Pecqueti*, the thoracic duct, so called from a Frenchman, who discovered it. See *ABSORBENTS*.

Ductus *Salivales*, the excretory ducts which convey the saliva into the mouth. See *DEGLUTITION*.

Ductus *Stenonis*, or *Stenonianus*, the duct of the parotid gland, so named in honour of Steno, its discoverer. See *DEGLUTITION*.

Ductus *Warthorei*, the duct of the submaxillary gland, named after Warthore, its discoverer.

Ductus *Wirsungii*, the pancreatic duct, which was found out by a German anatomist, Wirsung. See *PANCREAS*.

Ductus *Pneumaticus*, in *Ichthyology*, the name of a certain duct or canal, found in all those fish which have an air-bladder, reaching from that bladder to the orifice of the stomach, or some other part of it. This duct is variously situated in the different kinds. Artedi *Ichthyolog*. See *AIR BLADDER*.

DUCTILITY, (from the Latin *ductile*;) means the property, or the capability, of becoming extended. The word *expansibility* has been more commonly applied to denote the enlargement of such bodies as consist, or seem to consist, of separate parts, like the effluvia of odoriferous substances, colouring pigments, cotton, wool, &c. But the word *ductility*, denotes the enlargement of the dimensions of solids, without losing their continuity and consistence. This property almost exclusively belongs to metallic bodies; for it can hardly be discerned in a few other bodies.

DUCTILITY.

The methods of extending metallic bodies may be reduced to three: *viz.* by the strokes of a hammer, by the more equable pressure of flattening or rolling mills, and by drawing the metal through small holes in a steel plate, as is practised in wire-drawing. And since the first of those methods has been more generally and more usually practised; therefore the words malleability and ductility have been indiscriminately used to express the same thing.

To these impressions certain metallic bodies yield much more readily than others, and some there are which will not yield at all; so that, when pressed or hammered, they will rather break into fragments than expand.

Previous to the statement of the various degrees of ductility, it will be necessary to say a few words with respect to the nature of dilatation itself, in order to prevent a wrong notion which unexperienced persons are liable to adopt. When a piece of metal, in consequence of its ductility, is said to be extended; the meaning is not that the bulk of the metal is enlarged; but that one or two of its dimensions, (*viz.* the length, the breadth, or the thickness,) is enlarged, whilst one or both the others are diminished. For instance, a cubic inch of gold is one inch long, one inch broad, and one inch thick; and the product of these three dimensions, which gives the solidity, is one inch. Now if, by hammering, you extend the length of it, so as to make it two inches long, the breadth remaining the same, the thickness will be reduced to half an inch; and the product of these three dimensions; *viz.* two inches, one inch, and half an inch, is equal to one inch, as before; which shews that the solid contents remain the same.

It must, however, be observed, that, strictly speaking, the bulk of a piece of metal is a little contracted by the hammering or pressing; so that a sort of concentration and hardening take place at the same time. In fact, the specific gravity of a piece of ductile metal is greater after the hammering or pressing than before. Both this additional hardness and increased specific gravity are removed by heating the piece of metal to a certain degree.

Though we have mentioned the drawing through holes as one of the methods of extending metallic bodies; yet a necessary distinction must be pointed out with respect to this operation.—In the present state of philosophy, ductility is distinguished from tenacity. The meaning of the former has already been explained; but the tenacity is measured by the resistance which a wire of the metal opposes, without breaking, to the action of a certain force which draws it at one extremity, while the other extremity is fixed. Now it is upon this tenacity that the drawing of metals through holes depends. And, in fact, certain metals which shew under the hammer, or under the flattening mill, a much greater degree of ductility than others, are, at the same time, less capable of being drawn into fine wire, and *vice versa*; as will appear from the following lists.

Of all the metallic bodies some are ductile, whilst others are not, and this difference caused them to be distinguished into two classes; and calling the former metals, and the latter semi-metals, or imperfect metals; but the limits of these classes being very indefinite, little regard is now paid to this nominal distinction.

Ductile Metallic Bodies arranged in the Order of their Ductility.

Gold, Platina, Silver, Copper,		Iron, Tin, Lead,
---	--	------------------------

Metallic Bodies arranged in the Order of their Tenacity.

Gold, Iron, Copper, Platina,		Silver, Tin, Lead.
---------------------------------------	--	--------------------------

For farther particulars respecting the tenacity of metals, see the articles TENACITY, and WIRE DRAWING.

The ductility of gold exceeds that of every other metallic body, and since its value and its beauty have at all times encouraged the industry of workmen, no pains have been spared in endeavouring to expand the surface of it to the utmost limit of practicability: and a single grain weight of gold is now commonly extended into a surface equal to 50 square inches and upwards. Mr. Magellan says, that the finest gold leaf is extended by hammering between new skins, and that each troy ounce of pure gold must be alloyed with three grains of copper, otherwise it would be too soft to pass over the irregularities of the skins. When extended to the utmost, 2000 leaves of such gold, each containing a surface of 10.89 square inches, weigh less than 384 grains; so that each grain weight of the metal will produce about 57 square inches of gold leaf; and it is easily determined by calculation, that the thickness of such gold leaf is about $\frac{1}{237,000}$ th of an inch. However, this is a considerable thickness, in comparison of that of gold spun on silk in our gold thread.

To conceive this prodigious ductility, it is necessary to have some idea of the manner, wherein the wire-drawers proceed. The wire and thread we commonly call gold thread, &c. which is only silver wire gilt, or covered over with gold, is drawn from a large ingot of silver, usually about thirty pounds weight. This they round into a cylinder, or roll, about an inch and a half diameter, and twenty-two inches long, and cover it with the leaves prepared by the gold-beater, laying one over another, till the cover is a good deal thicker than that in our ordinary gilding; and yet, even then, it is very thin; as will be easily conceived from the quantity of gold that goes to gild the thirty pounds of silver: two ounces ordinarily do the business; and, frequently, little more than one. In effect, the full thickness of the gold on the ingot rarely exceeds $\frac{1}{237}$ th, or $\frac{1}{250}$ th part: and sometimes not $\frac{1}{237}$ th part of an inch.

But this thin coat of gold must be yet vastly thinner: the ingot is successively drawn through the holes of several irons, each smaller than the other, till it be as fine, or finer, than a hair. Every new hole lessens its diameter; but it gains in length what it loses in thickness; and, of consequence, increases in surface: yet the gold still covers it; it follows the silver in all its extension, and never leaves the minutest part bare, not even to the microscope. Yet, how inconceivably must it be attenuated while the ingot is drawn into a thread, whose diameter is 9000 times less than that of the ingot!

M. Reaumur, by exact weighing, and rigorous calculation found, that one ounce of the thread was 3232 feet long; and the whole ingot 116,352 feet, Paris measure, or 96 French leagues; equal to 126,440 English feet, or 240 miles English; an extent which far surpasses what Fa. Merfenne, Furetiere, Dr. Halley, &c. ever dreamt of.

Merfenne says, that half an ounce of the thread is 100 toises, or fathoms long; on which footing, an ounce would only be 1200 feet; whereas, M. Reaumur finds it 3232. Dr. Halley makes six feet of the wire one grain in weight, and one grain of the gold ninety-eight yards; and, consequently, the ten thousandth part of a grain, above one third of an inch. The diameter of the wire he found one 156th part of an inch; and the thickness of the gold one $\frac{1}{154,500}$ th part

DUCTILITY.

part of an inch. But this, too, comes short of M. Reaumur; for, on this principle, the ounce of wire would only be 2680 feet.

But the ingot is not yet extended to its full length. The greatest part of our gold thread is spun, or wound on silk, and, before they spin it, they flat it by passing it between two rolls, or wheels of exceedingly well polished steel; which wheels, in flattening it, lengthen it by above one seventh. So that our 240 miles are now got to 274. The breadth, now, of these laminæ, or plates, M. Reaumur finds, is only one 8th of a line, or one 96th of an inch; and their thickness, one 3072d. The ounce of gold, then, is here extended to a surface of 1190 square feet; whereas, the utmost the gold beaters can do, we have observed, is to extend it to 146 square feet. But the gold, thus exceedingly extended, how thin must it be! From M. Reaumur's calculus, it is found to be one 175,000th of a line, or one 2,100,000th of an inch: which is scarce one 13th of the thickness of Dr. Halley's gold. But he adds, that this supposes the thickness of the gold every where equal, which is no ways probable; for in beating the gold-leaves, whatever care they can bestow, it is impossible to extend them equally. This we easily find, by the greater opacity of some parts than others; for where the leaf is thickest, it will gild the wire the thickest.

M. Reaumur, computing what the thickness of the gold must be where thinnest, finds it only the 3,150,000th part of an inch. But what is the one 3,150,000th part of an inch? Yet this is not the utmost ductility of gold: for instead of two ounces of gold to the ingot, which we have here computed upon, a single one might have been used; and, then, the thickness of the gold, in the thinnest places, would only be the 6300,000th part of an inch.

And yet, as thin as the plates are, they might be made twice as thin, yet still be gilt; by only pressing them more between the flatter's wheels, they are extended to double the breadth, and proportionably in length. So that their thickness, at last, will be reduced to one thirteenth, or fourteenth millionth part of an inch.

Yet, with this amazing thinness of the gold, it is still a perfect cover for the silver: the best eye, or even the best microscope, cannot discover the least chasm, or discontinuity. There is not an aperture to admit alcohol of wine, the subtlest fluid in nature, or even light itself, unless it be owing to cracks occasioned by repeated strokes of the hammer. Add, that if a piece of this gold-thread, or gold-plate, be laid to dissolve in aquafortis, the silver will be all excavated, or eat out, and the gold left entire, in little tubules.

It should be observed, that gold, when it has been struck for some time by a hammer, or violently compressed, as by gold wire-drawers, becomes more hard, elastic, and stiff, and less ductile, so that it is apt to be cracked or torn: the same thing also happens to the other metals by percussion and compression. But ductility and tractability may be restored to metals in that state, by annealing them, or making them red-hot. Gold seems to be more affected by percussion and annealing, than other metals.

Platina, silver, and copper, may, likewise, be expanded into leaves, but not nearly so thin as those of gold.

With respect to the arrangement of iron and tin in the first of the above-stated hills, we are not quite determined as to which of them the preference may be due.

Zinc has the remarkable property of being malleable, or ductile, not in the usual temperature of the atmosphere, but in a higher temperature. When heated to between 210° and 300° of Fahrenheit's thermometer, zinc is perfectly malleable, and may be stretched into wires, or into pretty thin plates. And when so treated, it will afterwards remain mal-

leable. Some metallic substances do not suffer the strokes of a hammer nearly so well as the more uniform pressure of the flattening mill; and this is peculiarly the case with zinc.

It is not with zinc alone, but with all other ductile metals, that their ductility is greater in a certain temperature, which generally exceeds that of the atmosphere; thus iron in a red heat is incomparably more ductile than at a lower temperature. Heat, in short, tends to soften the metal; or, which amounts to the same thing, to increase its ductility; and as hammering or rolling hardens the metal at the same time that it extends it, the workmen, in the course of their operation, find it necessary to soften the metal by the application of heat, in order to render it capable of farther extension. This heating or softening is, in some cases, repeated several times before the work is quite finished.

The alloys of two or more metallic bodies are less ductile, than the pure metals themselves; yet such alloys are highly useful in a variety of cases, and the pure metals are often alloyed for no other purpose than for diminishing their softness and ductility. In the coinage of most countries the noble metals are generally alloyed with a little copper, which increases their hardness and elasticity.

The most extensively useful alloy is that of copper and zinc, which forms *brass*.—Its colour, its ductility, and its not being easily oxydized, have rendered it peculiarly useful for a variety of purposes, and especially in watch-work, where no other metallic substance has been found nearly so useful.

Brass, when properly made, is ductile and tenacious to a considerable degree. It will extend pretty well under the hammer, and it may be easily drawn into very fine wire. A slight degree of heat will, in some measure, increase its ductility; but when heated to about 300°, or upwards, then the strokes of the hammer will reduce it to powder. It is a sort of brass (but the precise proportion of the ingredients is kept secret,) that is expanded into leaves like gold; and is commonly sold under the name of *Dutch gold*.

Though tin is more ductile than zinc; yet the alloy of copper and tin is, upon the whole, less ductile than that of copper and zinc. Parner says, that much copper and little tin form a malleable compound, as well as much tin and little copper; but that when the two metals are alloyed from eight to ten parts of copper to one of tin, then the alloys are brittle and untractable.

The alloy of lead and antimony forms the metal which is used for printer's types, and its ductility may be varied by varying the proportion of antimony. According to Glauber, one part of antimony and 12 parts of lead, form a hard alloy, but capable of being beat into sheets. One part of antimony and eight parts of lead, form a compound harder and more fusible than lead, but malleable; and such is also the case with one part of antimony and three of lead; but with a smaller proportion of lead the compound is too hard to bear the strokes of the hammer.

An alloy of zinc and lead has, on account of its brilliancy and hardness, been recommended for the construction of economical and other articles. When a great deal of zinc is alloyed with lead, the compound is harder than lead, but very malleable. See METALS, GOLD, &c.

Ductility of Glass. We all know, that, when well penetrated with the heat of the fire, the workman can figure and manage glass like soft wax; but what is most remarkable, it might be drawn, or spun out into threads, exceedingly fine and long.

Our ordinary spinners do not form their threads of silk, flax, or the like, with half the ease and expedition, as the glass spinners do threads of this brittle matter. We have

some of them used in plumes for children's heads, and divers other works, much finer than any hair, and which bend and wave like it with every wind.

Nothing is more simple and easy than the method of making them: there are two workmen employed: the first holds one end of a piece of glass over the flame of a lamp; and, when the heat has softened it, a second operator applies a glass hook to the metal thus in fusion; and, withdrawing the hook again, it brings with it a thread of glass, which still adheres to the mass: then, fitting his hook on the circumference of a wheel about two feet and a half in diameter, he turns the wheel as fast as he pleases; which, drawing out the thread, winds it on its rim; till, after a certain number of revolutions, it is covered with a skin of glass thread.

The mass in fusion over the lamp diminishes insensibly; being wound, as it were, like a pelatoun, or cluc of silk, upon the wheel; and the parts, as they recede from the flame, cooling, become more coherent to those next to them; and this by degrees: the parts nearest the fire are always the best coherent, and, of consequence, must give way to the effort the rest make to draw them towards the wheel.

The circumference of these threads is usually a flat oval, being three or four times as broad as thick: some of them seem scarce bigger than the thread of a silk-worm, and are surprisingly flexible. If the two ends of such thread be knotted together, they may be drawn and bent, till the aperture, or space in the middle of the knot, doth not exceed one 4th of a line, or one 48th of an inch diameter.

Hence M. Reaumur advances, that the flexibility of glass increases in proportion to the fineness of the threads; and that, probably, had we but the art of drawing threads as fine as a spider's web, we might weave stuffs and cloths hereof for wear. Accordingly, he made some experiments this way; and found he could make threads fine enough, as fine in his judgment, as any spider's web: but he could never make them long enough to do any thing with them.

DUCILITY of Spider's Webs. See **WEB**.

DUD. in *Geography*, a town of Africa, in Mosambique, where the king resides.

DUDA, a town of Lithuania, in the palatinate of Wilna; 28 miles E.N.E. of Lida.

DUDAİM, in *Botany*, (Hebr. דודאים), plants mentioned in Genesis, chap. xxx. v. 14, 15, 16, and in Solomon's Song, chap. vii. v. 14, concerning which there have been great disputes among the learned. The Septuagint, the Latin vulgate, and our translation, understand the above word to mean the fruit or apples of the Mandrake, *Atropa Mandragora* of Linnæus, which is unquestionably the *Mandragora* of Dioscorides, and other ancient writers. All that can be gathered from the above chapter in Genesis is, that the Dudaim were found in the fields during the wheat harvest, and, either for their rarity, flavour, or some other quality, were greatly esteemed by women. The same word in Solomon's Song expresses some fruit or flowers, that "give a sweet smell," and are acceptable also to the male sex. No wonder that with so powerful a stimulus to their curiosity, and such light materials to guide it, critics should have taken a very wide range in their inquiries. Some have taken Lilies, Roses, Violets, Daffodils, Snowdrops, or Jasmine for the Dudaim; others Melons, Plantain-fruits, Whortle-berries, Dwarf-brambles, the berries of *Physalis*, or Winter Cherry, Grapes of some peculiar kind, or even the subterraneous *Fungi* called Truffles. Some have supposed the word to mean the ingredients, whatever they might be, of a charm or philter, and hence have again recurred to the Mandrake, celebrated through all antiquity for such imaginary virtues, and whose history is tricked out with all the

traditional nonsense that might confirm the report of these qualities. Perhaps the most judicious writer on the Dudaim is Liechtenk, who, in 1660, after reviewing all that had previously been asserted or imagined, gave it as his opinion that nothing certain could be decided on the subject. His dissertation has gone through numerous editions. Such a dissertation, however, seems only to have stimulated the ingenious to fresh inquiry. The younger Rudbeck published a profound dissertation at Upsal in 1733, intended to refute all the foregoing opinions, and to propose Ratpberries as the Dudaim. His learned fellow-countryman, Olaus Cellsius, in his *Hierobotanicon*, published in 1745, slightly mentioning this suggestion, contends that the object of their common inquiry could be no other than the fruit of *Oenoplia* or *Napeca*, *Rhamnus* (or rather *Zizyphus*) *Spina Christi* of Linnæan writers. The controversy, in short, seemed to be arrived at this point, that as nothing could plausibly be determined, distinction was to be obtained by some new suggestion only.

If we may offer an opinion, as we prefer truth to singularity or novelty, it will be in favour of the Mandrake, whose history is perfectly in union with the slight mention of the Dudaim in Genesis, and whose reputed properties of exciting love and promoting conception, account equally well for the desire of Rachel for this fruit, and for Leah's reluctance to let her partake of it. From the great stress laid on the person who gathered it, "*my son's Mandrakes*," it may be conjectured that some additional virtue was imparted to a plant, otherwise common enough, by its being gathered by a youthful or innocent person. Such notions frequently occur in the history of amorous incantations; for it is the policy of superstition gratuitously to enhance the value of ordinary or worthless things. Finally, the etymology of the Dudaim from דודים Dudim, loves, confirms the idea of a philter, and accords with the Mandrake. But it does not follow that the Dudaim of Solomon's Song must be the very same plant. Superstition or taste has fixed in every country, upon some flower or other with which to associate ideas of affection; and the Mandrakes that "gave a sweet smell" might literally mean any "fragrant flowers of love." S.

DUDDEN, in *Geography*, a river of England, which runs into the Irish sea; about three miles S. from Dalton, in Lancashire.

DUDELDORFF, a small town of France, in the department of Forêts, chief place of a canton in the district of Bittbourg, with a population of 467 individuals only: but the canton contains 7263 inhabitants, dispersed in 16 communes, on a territorial extent of 317½ kilometres.

DUDEN, a town of Asiatic Turkey, in the province of Caramania; 10 miles N. of Satalia—A.fo. a river of Asiatic Turkey, which runs into the sea near Satalia.

DUDENHOFEN, a small town of Germany, in the county of Hanau Munzenberg, which is now in the conscription of the new kingdom of Westphalia.

DUDERSTADT, a small town of Germany, in the lower Eichsfeld, which by the peace of Lunenille was transferred from the elector of Mayence to the king of Prussia, but which the latter lost again at the peace of Tilsit, in 1807. It is at present in the new kingdom of Westphalia.

DUDITH, ANDREW, in *Biography*, was born at or very near Buda, in Hungary, in Feb. 1533. His father was a native of Hungary, and his mother, a noble Venetian, was named Sbardellat, an appellation often applied to her son Andrew. Scarcely had the subject of this article passed the boundary of infancy, before he exhibited a liveliness of imagination and a brilliancy of parts, that prefiged the future great man. At an early period of life his father was killed

killed in battle with the Turks, and the youth was, by the advice of his uncle, the bishop of Watzau, sent to Breslau for his education. At the age of eighteen he was removed to Verona for the completion of his studies. Here he acquired a high reputation for diligence and uncommon talents. He is mentioned in a letter of Paul Manutius as one of the greatest geniuses of the age. In 1554, he attached himself to the train of cardinal Pole, who was nominated papal legate to the court of England, and Dudith recommended himself by his manners and assiduity to the notice and esteem of queen Mary and her sister Elizabeth. Leaving Pole in England, he went to Paris, where he made himself acquainted with the philosophy of the times, and studied more critically the ancient languages. After this, he spent some years at Padua, and obtained the friendship of many of the first literati of the age. While he was in Italy, he translated into Latin "The Judgment of Dionysius Haicarnassensis on the History of Thucydides," and laid the foundation of other literary works. From Italy he went to France, on a mission from the grand duke of Tuscany to the celebrated Catherine de Medicis, whom he addressed in her native language with so much fluency and purity of diction, as to excite her admiration and applause. In the year 1560, he repaired to the court of Vienna, where he was shortly after appointed one of the privy councillors to the emperor Ferdinand II., and afterwards nominated to the bishopric of Tina, in Dalmatia. Two years after this he was deputed by the clergy of Hungary to be one of their representatives in the council of Trent. In this capacity, by his eloquence and judicious advice, he acquired much reputation. His talents, however, soon excited the jealousy of the papal legates, and the more so when they perceived that the powers of Dudith were likely to be employed in exposing their system. The freedom with which he discussed topics of high interest and importance was the means of getting him recalled: but when the king knew from himself what had passed, and how nobly he had acted his part, so far from censuring Dudith, he rewarded him with the bishopric of Clonat, in Hungary. The emperor next sent him as his ambassador to Poland, and on his return gave him still higher church preferment. He was a second time, under Maximilian II., sent ambassador into Poland; here he seems to have abandoned his religious opinions, and to have determined to resign all his preferment in the church of Rome. Having formed the resolution, he without hesitation made a sacrifice of his wealth, and married privately one of the maids of honour to the queen of Poland. This conduct highly exasperated the clergy with whom he had been connected, but he still retained the good-will and confidence of the emperor, who appointed him his resident in Poland, where he made an open and undisguised profession of the protestant religion. In Poland he became acquainted with the Unitarian brethren, and a convert to their faith, for which he was to the end of life a zealous advocate. In 1575 he returned, after much and indelible service performed for the emperor, to the court of Vienna. But on the death of his sovereign, three years after, he retired into Moravia, and from thence to Breslau, where he remained in great privacy until the death of Stephen Batori, in 1579, which gave rise to a contest for the crown of Poland: in this struggle Dudith was employed by the emperor Rudolphus II., to secure the election for his brother Maximilian. He was, however, unsuccessful, and returned to Breslau, where he died in 1589, in the sixtieth year of his age. Dudith was unquestionably one of the most considerable men of the age in which he flourished. Moren says, "that he had been a catholic, protestant, and Socinian; and

that he died without any fixed principles of religion." This is probably a calumny invented by the catholics, whose cause he not only deserted, but whose conduct he sometimes exposed. His works are many, and on various subjects of physics, poetry, and theology; in Moreri's account they are enumerated at length. His life was regular and virtuous; his manners polite and conciliating, and his benevolence warm and unconfined. As a politician he was a man of honour and integrity; and in his diplomatic character he was ardent and strenuous for the interests of the princes by whom he was employed. He was an excellent scholar, and eminently skilled in the languages; and so much an admirer of the writings of Cicero, that he is said to have copied all the works of that author thrice with his own hand. Moreri.

DUDLEY, EDMUND, in *Biography*, was an eminent lawyer and statesman in the reign of Henry VII. who made himself extremely unpopular by the abuse of his legal knowledge, and oppressive measures. He, with sir Richard Empson, another great law officer of a similar characteristic complexion, contrived to obtain the monarch's favours by flattering his weakness, and promoting his avaricious views. Through the latter part of that reign, they became the instruments of regal rapacity; and assisted in filling the coffers of the treasury, by arbitrary and vexatious prosecutions of the people, upon obsolete penal statutes. On the accession of Henry VIII. they both fell into disgrace; and met with their justly deserved fate. The voice of the people for justice became extremely clamorous, and the king, to appease the menacing storm of popular discontent, now rising into turbulent rage, gave up Dudley and Empson as victims; and they were both attainted, and beheaded.

DUDLEY, JOHN, duke of Northumberland, son of Edmund Dudley already mentioned, was born in 1502, and was about eight years of age at the time of his father's execution. He was very soon after this event restored in blood by act of parliament; and when able to serve his country, attended the duke of Suffolk in an expedition to France, where, on account of his gallantry, he obtained the honour of knighthood. He was afterwards patronized by cardinal Wolsey, and lord Cromwell. In 1542, he was raised to the dignity of viscount Lisle, a title which belonged to his mother in her own right, and soon after created knight of the garter. In the next year, he failed, as lord high admiral of England, with a fleet of 200 sail to the straits of Forth, where he landed a body of troops and took possession of Edinburgh. From Scotland he proceeded to assist the king at Boulogne, and very much contributed to the capture of that place, of which, as a reward for his services, he was appointed governor. In 1546, he was appointed lieutenant-general, and commander by sea, and with a very inferior force, not only frustrated an intended invasion by the French, but carried an alarm to their coasts. He was one of the commissioners who received the oath of Francis on the peace, and who made a settlement of the army accounts; for these services he was amply rewarded by grants of church lands, which relieved him from the embarrassments which his extravagance had occasioned. By the last will of Henry VIII. he was nominated one of the sixteen to whom the government of the country was committed, during the minority of Edward VI. In the year 1547, he was created earl of Warwick, with the grant of Warwick castle and manor. He continued to ascend in the scale of preferment, and was successively created lord steward of the household, earl-marshal of England, and finally, in October 1551, he obtained the high title of duke of Northumberland. The duke of Somerset had long been Dudley's rival, and the jealousies fomented between these powerful noblemen, created

ated much anxiety in the breast of the young king, who, if possible, hoped to unite them, by proposing a marriage between Warwick's eldest son and Somerset's daughter, which took place. The conciliation was of short duration; the duke of Northumberland felt that he could rise no higher but by the fall of his rival. The latter was aware of his design, and urged by fears for his own safety, entered the house of Northumberland one morning, with an intent to kill him: but being received with apparent kindness, he was unequal to the execution of the bloody deed. The intention being known, Somerset was committed to the Tower, brought to trial and convicted of compassing the death of a privy councillor. To the disgrace of the age and of his enemy the duke of Northumberland, who sat as one of his judges, he was executed Jan. 1552. He now had the full ascendancy over the mind of Edward, procured a marriage between his fourth son Guilford Dudley, and lady Jane Grey, a branch of the royal family, and then forced the young king to set aside from the succession his sisters Mary and Elizabeth, and to bequeath the crown to his daughter-in-law. This, which he hoped would raise him to the highest point of honour, caused his downfall and death. The king died in July 1553, and the duke immediately proclaimed his daughter lady Jane; but the people little approved of the succession, and an insurrection in Suffolk put a speedy end to his ambitious projects. He headed the army and set out to crush the rebellion, but during his absence from the metropolis, Mary was proclaimed queen, and at Cambridge he was glad to join in the acclamations of "long live queen Mary." This, however, did not satisfy the new government; he was almost immediately arrested, brought to London, and committed to the Tower. In the hope of pardon, or with a view of averting the wrath of the queen from his family, he conformed to the Roman catholic religion. Mercy was not among the attributes of Mary: the duke had resisted her power and insulted her authority, and she determined he should pay the penalty of his life. He submitted to his fate with composure. On his trial he requested permission to ask, if a man could be guilty of treason that obeyed orders given him by the council under the great seal; and if those involved in the same guilt with himself could sit as his judges? Being answered that the great seal of an usurper was of no authority, and that persons not lying under any sentence of attainder, were still innocent in the eye of the law, and might be admitted on any jury; he acquiesced, and pleaded guilty. He suffered, Aug. 22, 1553, in the fifty-second year of his age, leaving several children, of whom Guilford Dudley and the amiable lady Jane suffered for his guilty ambition. Biog. Brit. Hume's Hist.

DUDLEY, ROBERT, earl of Leicester, fifth son of the duke of Northumberland, was born in 1532. He was knighted at an early age, and was a gentleman of the bed chamber in the reign of Edward VI. He was of course involved in the disgrace of his father, but was in a very short time reentered in blood; he even rose in favour under the reign of Mary, and was appointed to the head of the ordinance. When Elizabeth ascended the throne, honours were showered upon him with an unparing hand; he was created master of the horse, knight of the garter, and privy councillor; and to enable him to maintain the splendour of his station, the queen bestowed upon him grants of several manors and large estates. His known favour at court obtained for him rank and honour with the corporations and public bodies throughout the kingdom. In the year 1560 he lost his wife, and as it was known he was ambitious of being thought the suitor of the queen, he laboured under the

suspicion of having been the cause of his lady's death. In 1564, he was created baron Denbigh, and earl of Leicester, and in the same year was elected chancellor of the university of Oxford. He is suspected of having insidiously urged the duke of Norfolk to that courtship of the Scottish queen, which ended in his ruin, Leicester himself being one of the peers who pronounced his condemnation in 1572. He is charged also with having married lady Douglas Howard, and refusing to acknowledge it, compelled her to marry Sir Edward Stafford. With all these stains on his character, he affected extraordinary piety, and put himself at the head of the puritan party. He erected a hospital at Warwick, with a liberal endowment, and gave the mastership of it to the celebrated puritan Thomas Cartwright. In 1575, he had the honour of entertaining his sovereign at Kenelworth castle; and the sumptuous festivities on this occasion, are mentioned among the splendours of that magnificent reign. In 1578, he married the widow of Walter Devereux, earl of Essex, having been suspected of too close an intimacy with her during her late husband's life; so ill, indeed, did the public conceive of him, that it was currently reported Essex was taken off by the contrivance of the earl of Leicester. About the year 1584, the revolted states of the Low Countries offered to throw themselves on the protection and under the government of queen Elizabeth: to this she did not agree, but sent them over assistance, viz. 5000 foot and 1000 horse, under the command of the earl of Leicester. He was attended by many of the nobility and gentry, and sailed in December 1585 to Flushing, where he was received with the most profound respect, and by the States themselves, he was raised to the supreme executive authority, as well civil as military throughout their dominions. This increase of his power gave offence to the queen, who conceived that she should have been consulted before it had been granted by the States, or accepted by her subject. In battle, he was not remarkably successful, and in one of the skirmishes, had the misfortune to lose his nephew, the excellent Sir Philip Sidney. On his return to the Hague, he was received with counsels by the States, and he thenceforth, by his affected zeal for the Protestant cause, and his pretended piety, made a party with the people, and especially with the clergy, who from their pulpits inveighed against the magistrates, and extolled the earl as the champion of true religion. On his return to England, he was favourably received by Elizabeth, who was at that time in great perplexity how to act respecting the queen of Scots. When it was debated in council, whether she should be brought to public trial, Leicester gave his opinion for private assassination, and thus strengthened the suspicions of his own criminal practices against his enemies, which will for ever adhere to his memory. In 1587, he resumed his command in the Low Countries, but with as little success as before; he was accordingly recalled, and accused of mismanagement. Being, however, supported by the queen, he was appointed by her to the office of lieutenant-general of the army, when the nation was threatened with a Spanish invasion. He died in the same year, 1588, at the age of fifty-six, leaving behind him one natural son by lady Sheffield, and was interred in a chapel of the collegiate church of Warwick, where a noble monument was erected to his memory. Biog. Brit. Hume.

DUDLEY, Sir ROBERT, was the natural son of the earl of Leicester already noticed in the preceding article. He was born in 1573, and educated at Christ-church college, Oxford, where he obtained great credit for his industry and talents. By the death of his father, he was left, after the decease of his uncle, the castle of Kenelworth, and the bulk of his estate. Robert was, however, of an enterprising dis-

position, and, having married the sister of Thomas Cavendish the great navigator, he undertook a voyage of adventure and discovery. He wished to have made an expedition, at his own expence, to the fourth seas, which was prevented by government; but he was allowed to sail with a squadron, under his command, in 1594, to the river Oronoque; in which expedition he took and destroyed several Spanish ships. In 1596, he distinguished himself at the taking of Cadiz, and was on that occasion honoured with knighthood. After this he made an attempt to establish the legitimacy of his birth; but failing, he resolved to take up his residence abroad, and fixed upon Florence, where he assumed the title of earl of Warwick. Some time after this he received letters of recal from his sovereign, which he refused to obey, and on that account was deprived of his estate for life, by the statute of fugitives. Kenelworth castle was now vested in the crown, but as it would return to the heirs of Sir Robert at his death, propositions were made to him by the prince for the purchase of it: to this he agreed, but it is probable, that he received very little, if any, of the money which was to be paid for it. Sir Robert was now anxious to return home, and to ingratiate himself with the king, he drew up an extraordinary scheme to enable him to raise money without the intervention of parliament. James did not venture upon the project, which, however, was made known, and some persons suspected to be the authors of it, were imprisoned on the suspicion. Dudley remained at Florence, and was created a duke of the holy Roman empire, upon which he assumed his grandfather's title of Northumberland. Finding no means of returning to his native country, he applied himself to various projects that might be useful to the state in which he found protection. He laid the foundation of many improvements in navigation and commerce, and particularly in pointing out a method of draining the morafs between Pisa and the sea. He is said also to have been chiefly instrumental in making the port of Leghorn a free port. Between the years 1630 and 1646, he published a large work, entitled, "Del Arcano del Mare," &c. in two volumes folio. This work is full of charts, plans, &c. and is replete with projects relative to maritime affairs, which are said to display much genius, and an extensive knowledge. "It is," says the writer of the article in the Biographia Britannica, "a singular treasury of curious and important schemes, which manifestly prove the author's high capacity for the advancement of useful knowledge, no man having ever had a stronger propensity to reduce speculation to practice than he; and the success that attended his labours in this respect ought to derive an extraordinary degree of credit, to whatever he suggests as practicable: though, beyond all doubt, something of the like genius must be required, in such an attempt to make use of any of his projects, which are delivered in a manner not very intelligible to vulgar understandings." Sir Robert was attached to science in general, had some knowledge of chemistry, as it was then understood, and professed himself versed in physic. He gave his name to a medicine, which he either purchased or invented, which was long in great reputation under the name of lord Warwick's powder. When he went abroad, he took with him the daughter of sir Robert Southwell, to the prejudice of his wife, whom, with four daughters, he left at home. At Florence he lived in great state, and by the pope's dispensation he married the lady who went out with him, though his wife was still living in England. He died at his seat near Florence in 1649, leaving a numerous foreign posterity. *Biog. Britan.*

DUDLEY, in *Geography*, a market-town in the hundred of Halshire, in the county of Worcester, is situated on the

northern borders of that shire, where it joins Staffordshire, and is nearly surrounded by the latter. It consists of two parishes, and comprehends 1922 houses, and 10,107 inhabitants. The adjacent country abounds with collieries, and most of the population are engaged in the coal business, and in the making of nails, and hard-ware. At the northern extremity of the town are some considerable remains of a castle, which, according to some writers, is said to have been built by Dodo, or Duddo, a Saxon prince, whose name is perpetuated, and incorporated in that of the town. Leland states, that the castle is within the confines of Staffordshire. It stands on an elevated rock of lime-stone; and, according to Gough, commands "an extensive prospect into five shires, and part of Wales." In the reign of king Stephen it belonged to the Pagens, from whom it descended to the family of Somers, in the time of Henry III. and from them to the Suttons' temp. Edward II. It now belongs to viscount Dudley and Ward, who derives his title from this place. The castle sustained a siege of three weeks in the time of the civil wars, when it was much battered, and has ever since continued a ruin.

In the town are two churches, three charity schools, and several chapels for dissenters. Here are a market on Saturdays, and three annual fairs. At a short distance from the town are the ruins of a monastic building, called Dudley priory.

DUDLEY and Owen Canal, in Worcestershire, Shropshire, and Staffordshire, is about 13 miles in length; it commences in the Worcester and Birmingham canal, at Selby cut, and terminates in the old Birmingham canal at Tipton Green; it has a branch two miles in length, communicating with the Stourbridge canal at Back Dolph, see CANAL. It has been said, that at Wind-mill-hill colliery, to which a branch of this canal extends, a seam of coal, of the amazing thickness of 45 feet, is worked; this thickness, if correct, may probably be owing to several seams of coal, approaching so near together, as to be all worked together, although they may in reality be separated, by thin beds of shale. See COLLIERY.

DUDLEY, a town of America, in the state of Massachusetts, and county of Worcester, containing 1140 inhabitants; 18 miles southward of Worcester, and 60 S. W. of Boston.

DUDSWELL, a township in Lower Canada, about 20 miles N. E. of Apsot, having about 50 inhabitants. The river St. Francis passes through the southern part of this town in a western course, and soon after turns N. W. which course it pursues till it falls into St. Lawrence.

DUDUA, or **DUPUSA**, in *Ancient Geography*, a town of Asia, in Galatia. Ptolemy.

DUDUM, a town of Africa, in Interior Libya, south of the river Niger. Ptolemy.

DUE CURI, *Ital. Mus.* two chorusses or choirs, placed at a distance from each other, sometimes performing in four parts alternately, or antiphonally; and sometimes uniting in eight real parts. We hear of compositions in the fifteenth and sixteenth centuries, not only for eight, but 36 parts; such was a motet by Ockerheim, the master of Jnquin, as all the musical writers of the sixteenth century triumphantly tell us.

Zarlino says, that so great was the rage in his time for multiplying parts in musical compositions, that some masters, not content with three or four, which sufficed to their predecessors, had increased them to fifty; from which, he truly observes, nothing but noise and confusion could arise. However, in another part of his book, he tells us, that Adriano Willaert had invented masses à *Due Curi*, *over a tre*, or *aliove*

some call them, a *Cori Spezzati*, which had an admirable effect. We know not how Ockenheim disposed his parts; but they would have furnished nine choirs of four voices each. In the large churches of Italy, where the performers are divided into two bands, placed in opposite galleries, all the imitations and solo parts are distinctly heard, and when united in at least eight real parts, completely fill the ears of the audience with all the charms of congregated sound. We have never heard this species of composition attempted in our cathedrals, when a powerful band of instruments and additional voices are joined to the usual choral performers. Indeed, all our chanting and common choir service, derived from the ancient antiphonal singing, is of this kind: the performers being equally divided, and placed on each side the choir, form two bands, one of which is called the dean's side, and the other the chanters': *Decani, Cantoris*; but the number of voices in our cathedral establishments is not sufficient to produce the great effects which might be obtained from the united force of all the vocal and instrumental performers that are assembled upon particular occasions, such as the Feast of the Sons of the Clergy at St. Paul's; the Triennial Meetings of the three Choirs of Worcester, Hereford, and Gloucester; the Feast of St. Cecilia, at Salisbury; and occasional performance of oratorios in other cathedrals and churches of the kingdom; but above all from such a stupendous congress of musicians as has been assembled at Westminster Abbey.

We are in possession of a mass composed by Orario Benevoli, in 24 real parts for six choirs, and a song of 40 real parts, or ten choirs, by our venerable countryman Tallis. These are curiosities, harmonical phenomena. But there can be little melody in any of these multiplied parts; but to make them move at all without violation of rule, requires great meditation and experience.

Many of the movements in Corelli's concertos, when the Ripicinos differ essentially from the principal parts, and many of Handel's choruses, are written a *Due Cori*; but their effect is lost by the band being all crowded together in one orchestra. It is only in the two opposite galleries of a church, or other large building, that two galleries fronting each other, such as, before the fire, our beautiful Pantheon contained, that such grand effects can be produced, as we have heard in the churches of Italy.

DUE Terre, in *Geography*, a town of Naples, in the province of Bari; 6 miles S. W. of Bari.

DUEGNAS, or **DUENNAS**, a town of Spain, in the province of Leon, or the Pisuerga, on the frontiers of Old Castile; 3 leagues S. of Palencia.

DUEL, a single combat, at a time and place appointed, in consequence of a cartel, or challenge.

The word is usually derived from *duellum*, used by the barbarous Latin writers. *quasi duorum bellum*.

Duels were anciently allowed by common law, in cases where proof could not be had. In which view, Fleta defines duel. "lingularis pugna inter duos ad probandum veritatem litis; & qui vicit, probasse intelligitur." Stat. de Fimb. Levat. 27 Edw. I.

This duelling was so general a method of terminating differences among the nobility, that even ecclesiastics, priests, and monks, were not excused from the same; only to prevent their being stained with blood, they obliged these to procure champions to fight in their stead; as is shewn at large by father Dacheri, in his *Spicilegium*, tom. viii.

None were excepted from these legal duels but women, sick people, and cripples, and such as were under twenty-one years of age, or above sixty.

The custom was, for the two champions to enter a list,

or small inclosure, appointed by the authority of the ordinary judge, not only on criminal occasions, but on some civil ones, for the maintenance of their right.

The monk Sigebert even relates, that a question on a point of law being presented to the emperor Otho I. *viz.* whether representation had place in direct succession? and the doctors finding themselves embarrassed in the resolution thereof, the emperor remitted the decision to so critical a point to the judgment of arms, and pitched on two bold fellows to maintain the *pro* and the *contra*. The victory fell to him who contended for representation; in favour of whom a law was immediately made, which is in force to this day.

This custom came originally from the northern nations; among whom it was usual to end all their differences by arms, as we are assured by Paterculus. It afterwards passed as a law among the Germans, Danes, and Franks; especially after Gondebaud, king of the Burgundians, admitted it in lieu of swearing. Towards the conclusion of the fifth century, M. Godeau, in his History of the Church, VII. cent. says, that the Lombards first introduced into Italy the barbarity of single combats, whence the custom spread throughout the rest of Europe. This mode of trial was introduced into England, among other Norman customs, by William the Conqueror; but was only used in three cases, *viz.* one military, in the court-martial, or court of chivalry and honour; the second, criminal, in appeals of felony; and the third, civil, upon issue joined in a writ of right, which was the only decision of such writ of right after the conquest, till Henry II. with consent of parliament introduced the alternative of the grand assize, or a peculiar species of trial by jury. See **BATTLE**.

The preparation for the combat, and the process of it, are described under the article **CHAMPION**. We shall only farther observe, that when the day of combat was come, they made choice of four cavaliers to guard the field; and performed divers ceremonies, prayers, oaths, &c. described by Pasquier, and other authors, and quoted by Ducange, who mentions an ordinance of king Philip the Fair in 1306, prescribing the several rules, conditions, and ceremonies to be observed herein.

The method of trial by duel was instituted as a method of causing Providence, to learn who was the criminal; and it was imagined, that God, thus interrogated, would not fail to declare himself in favour of the innocent. But it happened so often, that the unjust accuser came off victorious, that they at length began to be convinced, they must not prescribe to his wisdom the necessity of interrupting the course of second causes. This was giving rules to murder, and disguising assassinations under method and measure.

Saxo Grammaticus observes, that as early as the year 981, the kings of Denmark had abrogated the proof by duel; and in lieu thereof, appointed the proof by red-hot iron, which was also annulled in its turn.

But duels were condemned before by a council held at Valencia, in 855, where the person who killed his enemy was excommunicated; and the person killed was pronounced worthy of burial. Afterwards, the pope, Nicholas I. Celestine III. and Alexander III. likewise interposed; and Frederic I. and II. prohibited them in Germany; Louis VII. began to restrain them in France, in the year 1168; and St. Louis proceeded to abolish them; but his ordinance, A.D. 1260, only took place in his own territories, and not in those of his vassals. After his example, the counts d'Auvergne and Poitou, and several other lords, forbid them likewise. Philip the Fair, following the footsteps of his grandfather, St. Louis, at one time forbid all gages, or pledges of battle; and

and yet he permitted them in four cases, in the ordonnance above mentioned of the year 1306. The last duel of note was in the year 1547, before king Henry II. between Jarnac and Chastaignerie, mentioned by Thuanus, and de Serres.

In England, the trial by duel is disused; though the law on which it is founded be still in force. It appears from Madox's History of the Exchequer, that trials of this kind were so frequent in England, that fines, paid on these occasions, made no inconsiderable branch of the king's revenue, vol. i. p. 319. The last trial of this kind was appointed in the year 1631, between Donald lord Rey, or Rhee, appellant, and David Ramsey, esq. defendant, in the painted chamber at Westminster. But that quarrel terminated without bloodshed, being accommodated by Charles I.; as was also another of the same kind in 1571, by the interposition of queen Elizabeth. Another instance occurs seven years after that in 1631. Rushworth's Observations on the Statutes, &c. p. 260. See BATTLE and COMBAT.

DUEL is also used for a single combat on some private quarrel or occasion. See CHALLENGE.

The duel must be premeditated; otherwise it is only a rencounter.

The folly, or rather madness, of duelling reigned for some ages in France; where the flower of the noblesse perished thereby. It is one of the glories of Louis XIV. to have used all his power and authority for abolishing duels. The severe edicts and laws he made against duellists have, in a great measure, put a stop to the custom.

Deliberate duelling is by the law of England a species of murder; and accordingly, it charges both the crime and punishment of murder on the principals, and on their seconds also. (Blackst. Com. vol. iv. p. 199. 1 Hawk. P. C. 82.) It requires, however, such a degree of passive valour to combat the dread of even undeserved contempt, arising from the false notions of honour too generally received in Europe, that the strongest prohibitions and penalties of the law will never be entirely effectual to eradicate this unhappy custom, till a method be devised of compelling the original aggressor to make some other satisfaction to the affronted party, which the world shall esteem equally reputable, as that which is now given at the hazard of the life and fortune, as well of the person insulted, as of him who hath given the insult. To this purpose Dr. Robertson observes, that the dominion of fashion is so powerful, that neither the terror of penal laws, nor reverence for religion, has been able entirely to abolish a practice unknown among the ancients, and not justifiable by any principle of reason; though at the same time, it must be admitted, that to this absurd custom we must ascribe, in some degree, the extraordinary gentleness and compliance of modern manners, and that respectful attention of one man to another, which, at present, render the social intercourses of life far more agreeable and decent than among the most civilized nations of antiquity. Hill. Ch. V. vol. iii. p. 16, &c. 8vo.

DUEREN, in *Geography*. See DUREN.

DUERO, DOUERO, or Douro, a river, which rises near Agreda in Spain, and pursuing a westerly course, passes Oisma, Aranda-de-Duero, Toro, Zamora, &c. in Spain; and reaching the borders of Portugal, it passes by Miranda, where, taking a south-westerly direction, it separates the province of Tra-los-Montes from Spain, till, a little below Elpadacenta, it again takes a westerly course across the kingdom of Portugal, having the provinces of Tra-los-Montes and Entre-Duero-e-Minho on the north, and Beira on the south, and discharges itself into the Atlantic, a little below Oporto.

VOL. XII.

DUEROZHOF, a town of Germany, in the duchy of Carniola; 4 miles E. of Gurckfield.

DUESME, a small town of France, in the department of the Côte d'or, on the river Seine; 12 miles S. of Châtillon.

DUET, Duo, *Ital.* a musical composition in two parts, whether vocal or instrumental. This title is general for all music in two parts; but in speaking of a dramatic duet, in an opera, the term requires a more extended explanation.

Though many admirable theatrical duets had been composed by the Italians, before Rousseau wrote the musical articles for the Encyclopédie, or collected them into a dictionary; yet he was the first to analyse that species of composition, to point out its forms, and account for its effects. And this he has done so judiciously, and with such enlarged views, that, though long, we shall translate the chief part of his article, for the sake of its ingenuity, and the author's reasoning on the subject.

He observes, that "the rules for vocal duets, and, in general, for all music in two parts, are the most rigorous, with respect to harmony, of any musical productions. Many passages are prohibited, and many movements, which would be admitted to a greater number of parts; for there are passages and combinations, which please when accompanied by a third or fourth part, without which they would shock the ear. Besides, as only two sounds are wanted, it would be unpardonable not to choose the best. These rules were formerly more severe in chamber duets, such as those of Steffani and Clari; but in later times, they have been relaxed, since every one sets up for a composer."

The citizen of Geneva might have assigned other reasons for this relaxation, by allowing dramatic duets, where not only the harmony of two parts was to be selected and polished, but generally two distinct characters to be supported; where perpetual fugue or imitation to the same words was absurd, and where a dialogue was to be preserved almost entire, and where the union of the two voices was reserved for moments of passion, expressive of joy, sorrow, or anger.

"A duet may be regarded in two lights: as a melody in two parts, such, for example, as the first movement of Pergolesi's "Stabat Mater," the most perfect and touching duo (in 1768) which ever dropt from the pen of a musician; or, as imitative and theatrical music, such as the duos in opera scenes. In both species, the duet is of all kinds of music, that which requires the most taste and selection of passages, and is the most difficult to treat without neglecting the *unity of melody*. Let me be allowed here to make a few remarks on dramatic duets, the particular difficulties of which are superadded to those of all other duets in general.

"It has been well remarked, that duets are out of nature in imitative music, where passion is to be painted: for nothing is less natural than to hear two persons talking at once during a certain time, either to say the same thing, repeat the same sentiment, or to contradict it, without ever listening or waiting for an answer; and though this may be admitted in particular cases, it certainly ought not to be suffered in a tragedy, where such indecency is neither suitable to the dignity of the personages, the interlocutors, or to the education which we may suppose them to have received. It is only, therefore, in great transports of passion that the heroic interlocutors can be supposed to interrupt each other, and speak at the same time; and even then, it is extremely ridiculous that such simultaneous discourse should be prolonged in a regular manner.

"The first means, therefore, of avoiding this absurdity, is to place those duets in lively and touching situations, where the agitation of the characters throws them into a kind of delirium,

delirium, capable of making the audience and themselves forget those theatrical decorums, which enforce illusion in cold scenes, and destroy it in the heat of passion. The second means is, to compose duets as much as possible in dialogue. This dialogue should not be formally phrased and divided into long periods, like recitative, but formed of interrogations, replies, and exclamations, short and spirited, which give an opportunity for the melody to pass rapidly from one to the other by turns, without ceasing, to form such a melody as the ear can seize. Another necessary attention is, not to take indifferently for subjects all the violent passions; but only such as are susceptible of a pleasing melody, and are a little contrasted; so as to require a melodious accent and an agreeable harmony, in two parts. Rage and fury march too fast to take a likeness: we distinguish nothing; we only hear a confused roar and barking, and the duo has no effect. Besides, that perpetual repetition of abuse and insult belongs more to watermen and drovers than to heroes: it more resembles the threats of bullies, who wish to make themselves feared more than to hurt. But still more must be avoided that excess of tenderness and feeling, which only talks of charms, chains, and darts; a flat and frigid jargon, with which true passion is totally unacquainted, and which are no more wanted for good music than good poetry. The instant of separation, when one of the two lovers is dragged away to death, or flying to the arms of another;—the sincere return of a rover;—the affecting conflict of a mother and a son, who wish to die for each other;—all these moments of affliction, which draw delicious tears from the spectators: these are the subjects for duets, when treated by the poet with that simplicity of language which penetrates the heart. Whoever has frequented the Lyric theatres must know what tenderness and emotion can be excited in a whole audience, by the single word *addio*. But the moment the poet aims at wit, or lets any affected phrase escape him, that instant the charm is broken, and we must laugh, or die with fatigue.

“These observations regard the poet. With respect to the composer, it is his business to find a suitable melody to the subject, and distribute it in such a manner, that each of the interlocutors, speaking by turns, shall so connect the musical phrases, without changing the subject, or at least the movement, that passing in its progress from one part to the other, without a junction, it shall seem as uniform as if sung by a single voice. The duets that produce the best effects are those of voices of equal pitch, because the harmony is more compressed. And among voices of the same kind, the best effects are produced by *sopranos*, or treble voices, whose diapason being most acute renders the accents most distinct, and their tones more touching. And these are the only duets used by the Italians in their serious operas: and I have no doubt but that the employing *castrati* in male parts was originally owing to this observation. But though there should be an equality between the two voices in a duo, and a unity of melody, it does not follow that the two parts should be exactly alike in the cast of melody; for, besides the necessary diversity of style, it seldom happens that the situation of the two characters is so perfectly similar, that they should express their sentiments in the same manner: so that the composer ought to vary their accents, and give to each the character which best shall paint the state of their minds, especially in their alternate recitative.

“When the two parts unite and sing together, which ought to be seldom used for a short period, a melody should be found that admits of moving in 3ds or 6ths, in which the second part has its effect without disturbing the first. (See *UNITY of Melody*.) Care must be taken to avoid harsh dis-

cords, high and piercing sounds, reserving the *fortissimo* of the orchestra for moments of transport and disorder, in which the performers seem “to forget themselves,” infuse their sufferings into the souls of spectators of sensibility, and make them experience the power of harmony soberly conducted: but these moments ought to be rare, short, and artfully introduced. The ear and the heart must be prepared by a sweet and affecting music for a crisis of this kind; that both may assist the composer and performer in raising such emotions, which must be transient and conformable to human weakness: for when the agitation is too strong, it cannot be durable; and whatever is out of nature never touches the heart.”

He then illustrates his reflections by the exquisite duet in Metastasio’s “Olimpiade,” set by Pergolesi, which has been the model of almost all dramatic duets ever since: recommending to the reader the seeking in the works of that first musician of his time, and of our own, how such a duet should be treated; which, he truly says, is but a recapitulation of the preceding scene:

“Mia vita addio.
Ne’ giorni tuoi felici
Ricordati di me,” &c.

The art, however, has not stood still since the time when the sweet and admirable Pergolesi was prematurely snatched from the musical world. Jomelli, Penz, Piccini, Sacchini, Anfossi, Traetta, Sarti, Mozart, Cimarosa, and Paisiello, though they have adhered to his model, have extended, refined, and polished melody, invented ingenious and picturesque accompaniments, without forgetting the poet, the actor, or dramatic effects.

Duets introduced in *intermezzi* and comic operas, turn on such whimsical circumstances, and are sung by such grotesque characters, that there is no reducing them to rule; yet the Italians, with all their good taste in serious music, have a natural tendency to buffoonery, that, in their burlettas, there is no kind of imitation which they have not tried to tune, or squabble which they have not painted by variety of measures and characteristic melodies. Comic duets are hardly ever sung by two similar voices, but generally by a soprano and tenor or bass: “and (says Rousseau) if they have not the pathos of tragic duets, in revenge, they are susceptible of the most piquant variety. All the subtleties of coquetry, all the peculiarities of the advocati, Dottori, of Pantaloon, Harlequin, Columbine, and the contrail of all the follies of our sex, and the artifice of the other; in short, all the accessory ideas of which the subject is susceptible, all concur to render these duos interesting and amusing.” As a model of perfection among comic duets, he influences “Lo Concoro a quig l’Occhiotti,” in Pergolesi’s “Scuva Padrona,” which, however admirable in its day, has been often far surpassed in agreeable air, unity of melody, simple, pure, and brilliant harmony, accent, dialogue, and taste, by Cimarosa, Paisiello, and Mozart.

DUETTI DA CAMERA, such as those of the elder Bononcini, Steffani, Clari, Haffé, and Handel, are almost all *fugati*. They used to be regarded, particularly those of Steffani, as excellent *solfeggi*, by the great opera singers, a century ago.

DUETTINI, *Ital.*, a little duet, such as those of Apriili, Mottellari, Millico, and others.

DUFF’S GROUP, in *Geography*. See **DISAPPOINTMENT Island**.

DUFFEL, a small town of France, in the department of the two Nethes, chief place of a canton in the district of Malines, on the river Nèthe; 3 miles N. of Malines, and
3 miles

3 miles S.W. of Lierre. It has a population of 2831 individuals. The canton contains 8 communes and 8579 inhabitants, upon a territorial extent of 90 kilometres.

DU-FRESNE, CHARLES DU-CANGE, in *Biography*, a learned Frenchman, was descended from a respectable family, and born at Amiens, in the year 1610. After having acquired the elements of polite literature in the Jesuits' college, at his native place, he studied the law at Orleans, and, in 1631, was sworn-advocate to the parliament of Paris. Having practised at the bar for some time, he declined the exercise of this profession, and returning to Amiens, devoted himself to the general study of languages and philosophy, law, physic, divinity, and history. In 1668 he again settled at Paris, and in pursuance of a proposal laid before Colbert, and approved by him, he was employed in collecting memoirs and manuscripts for compiling a history of France. His plan for the execution of this project, to which he had devoted considerable time and attention, not being approved by the minister, he relinquished this tedious and laborious undertaking; and directed his views to the completion of his glossary of low Latin, entitled, "Glossarium Mædæ et infimæ Latinitatis," which was received by the public with general commendation; and though Valesius discovered in it several mistakes, it is deemed by the learned an excellent and useful work. It was afterwards considerably enlarged; and the edition of Paris by Carpentier, in 1733, comprised 6 folio volumes, to which Carpentier has since added 4 volumes, by way of supplement. The whole has been abridged, consolidated, and improved in an edition, comprising 6 volumes, 8vo., and published at Halle from 1772 to 1784. The next performance of Du-Fresne was a "Greek Glossary of the Middle Age," compiled mostly from MSS., little known, and comprised in 2 volumes, folio. This learned writer was the author or editor of several other works; among which we may reckon his Genealogical Chart of the Kings of France, his History of Constantinople under the Kings of France, and his editions of Cinnamus, Nicephorus, Anna Comæna, Zonaras, and the Chronicon Alexandrinum, with dissertations and notes. Du-Fresne, or as he is commonly called Du-Cange, died in 1688, leaving four children, pensioned by Louis XIV., in consideration of the father's merit.

Though the general merits and abilities of this profound and accurate etymologist have already been recorded, we here with gratitude pay tribute to his memory, for the assistance which he has frequently afforded us as musical historians, when all other resources failed. In the slow progress of the art of music from the time of Guido, whose labours were wholly devoted to the facilitating the study of canto fermo by the monks and choristers; in the glossary "De la Basse Latinité," (6 vols. folio), we find the derivation and early use of musical terms and phrases, particularly in France and neighbouring states; and there is scarcely a term connected with the music of the church, of which an early use may not be found, either in this Glossary, or in its continuation by Carpentier, 4 vols. folio.

For the history of the music of the Greek church, great information may be obtained from "Glossaire de la Langue Grec," of the middle ages, printed at Lyons, 2 vols. folio, Gr. et Lat.

DU-FRESNOY. See **FRESNOY**.

DUFRESNY, CHARLES RIVIERE, was born at Paris in the year 1648. He passed for the grandson of Henry IV., and was thought to have borne some resemblance to that prince. Of the place and manner of his education, little worthy of notice has come down to us. In mature life, he manifested a general taste for the arts, without having made

any of them his particular study. He was a self-taught poet and painter; but especially excelled in the art of laying out gardens, a talent which gained him great credit with his sovereign Louis XIV., to whom he was a servant of the bed-chamber, and who made him also comptroller of the royal gardens. In a short time after, he applied for, and obtained a patent for the manufacture of looking-glasses. With these modes of obtaining an ample competence, he was always poor, and his circumstances so embarrassed, that he was at length obliged to sell the places and privileges which he enjoyed, to extricate himself from debt. When he quitted court, he wrote with success for the stage; and his reputation was so considerable, that he was compared by D'Alembert with Fontenelles, with regard to their comic talents, and declared to be the more original, free, and inventive, of the two. In 1710, he obtained the sole right of printing the "Mercure Galant," of which he profited only a short time, being obliged to sell his privilege. About the time of Law's projects under the regency, he was in a deplorable situation; but the readiness of his invention did not fail him in his exigencies: he drew up and presented a humorous petition to the regent, and obtained the extravagant sum of 200,000 livres. He was twice married, and in both instances he sought the connection to relieve his wants. He died poor, in the year 1724; and in a few years after his decease, his works were collected, and published in 6 vols. 12mo. They chiefly consist of dramatic pieces, poetry set to music, serious and comic amusements, historical anecdotes, &c. Whatever he wrote is characterized by a happy mixture of fire and delicacy, by a species of gaiety entirely his own and unstudied, and by a style which always keeps alive the attention, though no one could successfully take the author as a model. *Moreri*.

DUGDALE, Sir WILLIAM, a learned antiquarian, was born at Shuteoke, near Colchill, Warwickshire, in the year 1605. His father was a country gentleman, who, after his son had received the usual elementary instructions in grammar learning, intrusted him in the laws of his country, and in the principles of general history. After the death of his father he was introduced to the society of some persons conversant in antiquities, and began to make collections for a history of his native country. In 1638 he visited London, when he became acquainted with the celebrated Sir Henry Spelman, by whose means, and the interest of other learned antiquaries, by whom Mr. Dugdale's talents were highly appreciated, he obtained a purveyor's place in the Herald's office, where he came to reside in 1640. Here, and from the records in the Tower, he enjoyed ample opportunities to enlarge his collections. During the civil war he attended the king officially, and was with him at the battle of Edge Hill, and at Oxford, where he was created master of arts. In 1644 he succeeded to the place of Chester herald, and, by the king's express command, he continued at Oxford till it surrendered to the parliament's forces in 1646. He did not spend this time in vain, but employed himself most diligently in investigating all the sources of learning which the university libraries afforded. Here he chiefly collected the materials for the "Monasticon," in which he was engaged with Mr. Roger Dodsworth. To complete this great work he afterwards visited Paris, where, by the indulgence of Andrew du Chesne, and other learned men, he obtained many records relative to the priors alien in England. The first volume of the "Monasticon Anglicanum" was published in 1655. This work contains an account of all the religious houses in England from their foundation to their dissolution. The remaining volumes were published in 1661 and 1673. Two volumes of additions were printed by John Stephens in 1722

and 1723, and the whole is regarded as a valuable collection of national matter, and is now become very rare. The publication of Dugdale's part gave offence to the puritans, who imagined the author's main design was to bring back popery; it was the cause, likewise, of many law-suits, by bringing to light old deeds and other writings, or at least of pointing out where they might be found. In the year 1656, Dugdale published his "Antiquities of Warwickshire illustrated," of which a second edition was printed by Dr. Thomas in 1730. While this work was printing, Dugdale employed his leisure time in collecting materials for a history of St. Paul's cathedral in London, which he published in 1658. Upon the restoration he was advanced to the office of Norroy King at Arms. His next work was "The History of Embanking and Draining of divers Fens and Marshes, both in foreign Parts and in this Kingdom, and of the Improvements thereby." In 1677 he was advanced to the office of Garter King at Arms, to which was annexed the honour of knighthood. After this he published various other works, chiefly relating to heraldry. Besides the volumes of which he was chiefly or solely the author, he edited the second volume of "Sir Henry Spelman's Councils," and the second volume of his "Glossary." He compiled also a work, entitled "Origines Judiciales," which relates to the forms and rules of English courts of justice and the principal law offices, a work that has been recommended by bishop Nicholson as a useful introduction to the legal history of England; nor must we omit his "Baronage of Warwickshire" in three volumes folio. He died at his house in Warwickshire in 1686, being in the 81st year of his age, leaving one son and a daughter; the former was in the Herald's office and was knighted; the latter married Elias Ashmole. *Biog. Brit.*

DUGGA, or TUGGA, in *Geography*, a town of Africa, in the kingdom of Tunis; 70 miles S.W. of Tunis.

DUGHET, GASPARD, in *Biography*, a landscape painter, celebrated under the name of GASPARD POUSSIN.

He was born in France, A. D. 1600, and at a very early age discovered an apt genius for painting. Finding in himself a strong love for that art, he resolved to devote himself to it, and, with a view to the attainment of excellence in his profession, set forward towards Rome, where he was confident of meeting with assistance from Nicolo Poussin, who had then risen to eminence, and who had married Gaspar's sister.

On his arrival at Rome, he was at first employed merely in preparing Poussin's palette, pencils, and colours; but gradually improving himself by the instructions he derived from that great master of his art, by the sight of his works during their progress, and the opportunity of observing his method in painting them; and still more, finally, by the example of his great powers, he grew into considerable reputation as a landscape painter, and, at length, effectually established his claim to celebrity.

Whether he found himself unequal to the higher paths of art, in which Nicolo moved, or whether his good sense dictated to him the impolicy of attempting eminence in the same province with his master, he adopted a style, which though manifestly formed under the superintending genius of Poussin, neither aimed at the same species of composition, nor bore an exact resemblance in manner. The landscape of Nicolo is select, poetic, and aspires to the sublime: Gaspar, although not deficient in poetical composition, chose the task of more humble and minute attention to natural effects and natural scenes. The quiet valley, the slumbering lake, and the rich autumnal foliage of the grove; or the bleak hill, the driving shower, or eddying whirlwind, came from his hand, stamped with a characteristic impression of reality. His pencil was rich, free, and flowing. In this branch of

painting, therefore, though he did not surpass, he might stand in competition with his preceptor; but here his skill terminated; in figures he was so totally incompetent, that he was frequently fain to solicit his master to paint those which he introduced into his landscapes. Whether their places were marked out by him, or chosen by Nicolo, they are always introduced with admirable taste and propriety. His scenery also is excellently chosen in point of natural beauty, as are the sites of his buildings; and those buildings are productive of the most pleasing effect by a mixture of elegance and simplicity. His grounds are agreeably broken; and the force of his figures, trees, and other objects, is so judiciously proportioned to their respective distance, as sometimes even to cause the most pleasing deception. He was exceedingly expeditious in his work; his imagination was scarcely more ready to invent than his hand was to execute; and it is confidently reported by authentic writers, that he finished a large landscape, and inserted all the requisite figures, within the compass of one day!

Gaspar had three manners in his paintings, which are distinguishable without any great nicety. The first was rather dry, and the last, though agreeable, was feeble, and unequal to that of his middle time; his second manner was, by many degrees, his best, as it was at once more simple and more learned; and his colouring appears so fresh, so full of truth and nature, that no eye can behold his landscapes at that period without admiration. The works of Gaspar are deservedly esteemed in every nation where the art of painting is either cultivated or understood.

During his abode in Rome he adopted the family name of his brother-in-law and benefactor, and is commonly spoken of by that only. He died in the year 1663. Partly Pilkington's Dictionary of Painters.

DUGINSKOL, in *Geography*, a cape of Russian Siberia, in the sea of Ochotkoi. N. lat. 59° 15'. E. long. 149° 14'.

DUGNY, a town of France, in the department of the Meuse and district of Verdun; three miles S. of Verdun.

DUGUET, JAMES JOSEPH, in *Biography*, was born at Montbrison, near Lyons, about the year 1649. At a very early age he discovered a strong memory, and a certain quickness for imbibing instruction, which his father took great pains in cultivating. At a proper age he turned his thoughts to the study of theology, which he pursued at Saumur. In 1671, he was appointed professor of philosophy at the college of Troyes, and at the same time was requested to deliver a series of catechetical instructions to the poor; such, however, was his popularity, that persons in the higher ranks of life crowded to hear his lectures, almost to the exclusion of those for whom they were originally designed. In the year 1677 he was ordained priest, and at the same time discharged the duties of professor of theology. At this period he established his celebrated ecclesiastical conferences, which were attended by the most numerous audiences, and procured for him a high reputation for extensive knowledge, judgment, and piety. He laboured so assiduously in the various duties in which he was engaged, that his health was considerably injured, and he was obliged to apply for a relaxation from his employments. In 1685 he retired to Brussels, but finding the air of that city not congenial to his constitution, he returned to Paris, where he lived in a studious retirement, concealed from the greater part of his acquaintance. In the latter years of his life he was involved in much trouble, by the decided part which he took in the controversy between the Jesuits and Janfenists, and was obliged frequently to change his residence. He died at Paris in 1733, being in the 84th year of his age. As an author, he published commentaries or expostions on the greater part of the books of the

the Old Testament, besides many practical pieces in theology and morals; also, "A Collection of Letters on Piety, &c.," in nine volumes 12mo. Of these and other pieces Moreri has given an ample account. Duquet was very highly esteemed by his contemporaries, as well for his piety as for the excellence of his temper and the gentleness of his manners. What he had been in the younger part of life he continued to be in the extreme of old age: so excellent is the advice, "Train up a child in the way he should go, and he will not depart from it when he is old." His writings, which are little known here, are by his countrymen highly applauded for perspicuity, purity, and elegance. Moreri.

DUHAM, in *Geography*, a town of Bohemia, in the circle of Böhlow; 20 miles W. N. W. from Jung Buntzlau.

DUHOKUNDA, a town of Africa, in the kingdom of Jemarrow.

DU JARDIN, in *Biography*. See **JARDIN**.

DUIDA, in *Geography*, a mountain of South America, in the range of Parima, in which is a volcano. N. lat. 3° 13'.

DULLIUS, C., in *Biography, the first Roman who obtained a considerable naval victory, was consul in the year 266 B. C. After his colleague, Cn. Corn. Scipio, had been taken at sea by the Carthaginians in the first Punic war, he proceeded, with a newly-built Roman fleet, to Sicily in quest of the enemy, and, by means of a *corvus*, was enabled to grapple with the enemy's vessels as they approached, and thus to convert the combat into a sort of land fight. By this unexpected manœuvre he took 80, and destroyed 13 ships of the Punic fleet, and obtained, as a reward, a triumph. A naval column was erected in the forum to perpetuate the event, which was standing in Pliny's time, and was found again, with its inscription, in the year 1560. The senate likewise rewarded his valour by permitting him to have music playing and torches lighted, to attend him when he returned from any evening entertainment. Medals were struck in commemoration of the victory. Cic. De Senectute.*

DVINA, in *Geography, a river of Russia, called "Sievnaia Dvina," the Northern Dvina, which name it assumes on its junction with the two rivers, the Sookhona and the Youga, that arise in the government of Vologda. This junction is formed at the city of Utiug, whence the Dvina takes a north-westward course, and at Archangel falls into the White Sea, after having divided itself into two considerable arms. In its course it receives some pretty large rivers, and several lesser streams; such as, on the right, the Lusa, the Vichегда, and the Pinega; and, to the left, the Vaga, the Yemza, &c. The merchant vessels run into the eastern arm of the Dvina, on which the fort Novaia Dvinka is built; but, at first, the western, where stands the monastery Korelkoï Monastir, was the most frequented; but this is no longer passable. In general the shoals increase from year to year in both, and such large ships cannot now run in as formerly. The Dvina has the honour of having given reception, in 1553, to the first English ship that ever came to Russia. This river flows mostly through a swampy and woody region; it is navigable from Utiug, and tolerably abounds with fish.*

DVINA. See **DUNA**.

DUINGEN, **DUIN**, or *Duding*, in *Geography*, a town of Germany, in the circle of Lower Saxony, and principality of Calenberg; 18 miles S. E. of Hameln.

DUINO, **DOINO**, or *Tybein*, a sea-port town of Germany, in the duchy of Carniola; 8 miles N. W. of Trieste, and 174 S. S. W. of Vicina. N. lat. 45° 55'. E. long. 14° 46'.

DUISBURG, or **DUISBOURG**, in Latin *Duisburgum*, *Duisciburgum*, and *Tuisiburgum*, a town of Germany, in the grand duchy of Berg, which, since the accession of the grand

duke, Joachim Murat, to the throne of Naples, has been annexed to the French empire. It is supposed to derive its name from the Tuifcones, and to be the Dispargum, or Duifparcum, in which the Frankish king Clodius, surnamed Long-haired, resided.

Duisburg is situated on the eastern shore of the Rhine. It was formerly a free imperial and Hanseatic city, under the protection of the dukes of Limburg and counts of Berg. In 1290, it was mortgaged to Theodore VIII., count of Cleves, and in 1347 to John, duke of Cleves. In 1805, it was ceded, along with the duchy of Cleves, by the king of Prussia, to the grand duke of Berg.

An university was founded at Duisburg for Protestants in the year 1655, but it was never very flourishing under the Prussian dominion, Halle and Frankfurt on the Oder being generally preferred. In 1800, Duisburg had but 12 professors and 39 students. Murat, as grand duke of Berg, attempted to restore the university of Duisburg to its ancient importance. He increased the number of professors to 18, viz. 6 professors of philosophy, 3 of Calvinist, 2 of Roman Catholic, and 1 of Lutheran theology; 3 of physic, and 3 of law. Count Bork of Hüth was its curator. Its revenue was 20,000 dollars.

Duisburg has two very fine churches, and three monasteries. Its principal manufactures are those of hardware and woollen cloth.

Gerard Mercator, one of the most illustrious geographers of the 16th century, is buried at Duisburg.

DUISBURG, **PETER DE**, in *Biography*, a native of the duchy of Cleves, and a priest of the Teutonic order in Prussia, flourished in the early part of the 14th century. He wrote a chronicle of Prussia in Latin, from the year 1226 to 1325, which was continued, by an anonymous writer, to 1406. It was translated into German verse by N. J. roschius and Wigandus, brothers of the same order to which Duisburg belonged. The original was edited, in 1679, by the learned Hartknock, who subjoined to it nineteen dissertations, which throw great light upon the history of Prussia. Moreri.

DUITZ, or **DUYTZ**, in *Geography*, a town of Germany, in the kingdom of Westphalia, and duchy of Berg, on the east side of the Rhine, opposite to Cologne, chiefly inhabited by Jews, who are not permitted to dwell in Cologne, or even to enter that city, without permission.

DUIVEN, or **DUV'N**, **JOHN**, in *Biography*, a portrait painter, born at Goude, in Holland; a disciple of Walter Crabeth; died in 1640.

DUKANA, in *Geography*, a river of Russian Siberia, which, united with the Ancha, forms the Juna.

DUKE, **DUX**, a sovereign prince, without the title, or quality of king. Such are the duke of Lorraine, duke of Holstein, &c.

The word is borrowed from the modern Greeks, who call *douxas* what the Latins call *doux*.

There are also two sovereigns, who bear the title of grand-duke; as, the grand-duke of Tuscany, and the grand duke of Muscovy, now called the *czar*, or emperor of Russia; the heir of the throne of Russia is now called grand-duke of Russia. The emperor of Germany is arch-duke of Austria. The king of Poland assumes the title of grand-duke of Lithuania.

DUKE, **DUX**, is also a title of honour, or nobility, the next below princes.

The dukedom, or dignity of duke, is a Roman dignity, denominated a *ducedo*, leading or commanding. Accordingly, the first dukes, duxes, were the *duces exercituum*, commanders of armies. Under the late emperors, the go-

wernors of provinces, in war time, were intitled *duces*. In after-times, the same denomination was also given to the governors of provinces, in time of peace. The first governor under the name of duke, was a duke of the Marchia Rhætica, or Grifons, whereof mention is made in Cassiodorus; and there were afterwards thirteen dukes in the eastern empire, and twelve in the western. The Goths and Vanals, upon their over-running the provinces of the western empire, abolished the Roman dignities wherever they settled. But the Franks, &c. to please the Gauls, who had long been used to that form of government, made it a point of politics, not to change anything therein; and, accordingly, they divided all Gaul into duchies and counties; and gave the names sometimes of dukes, and sometimes of counts, *comites*, to the governors thereof.

In England, during the Saxons' time, Camden observes, the officers and commanders of armies were called dukes, *duces*, after the ancient Roman manner, without any addition. After the Conqueror came in, the title lay dormant, till the reign of Edward III, who created his son Edward, first called the Black Prince, duke of Cornwall, which hath ever since been the peculiar inheritance of the king's eldest son during the life of his father, so that he is *dux natus, non creatus*. After whom, there were more made, in such manner as that their titles descended to their posterity. They were created with much solemnity, "per cincturam gladii, cappaque, circuli auri in capite impositionem." However, in the reign of queen Elizabeth, A. D. 1572, the whole order became utterly extinct; but it was revived about fifty years afterwards, by her successor, in the person of George Villiers, duke of Buckingham.

Though the French retained the names and form of the ducal government, yet, under their second race of kings, there were scarcely any such things as dukes; but all the great lords were called counts, *peers*, or *barons*; excepting, however, the dukes of Burgundy and Aquitain; and the duke of France, which was a dignity Hugh Capet himself held, corresponding to the modern dignity of *maitre de palais*, or the king's lieutenant.

By the weakness of the kings, the dukes, or governors, sometimes made themselves sovereigns of the provinces trusted to their administration. This change happened chiefly about the time of Hugh Capet; when the great lords began to dismember the kingdom, so that the prince found more competitors among them than subjects. It was even with a great deal of difficulty they could be brought to own him their superior, or to hold of him by faith and homage.

By degrees, partly by force, and partly by marriages, those provinces, both duchies and counties, which had been rent from the crown, were again united to it. But the title duke was no longer given to the governors of provinces. From that time duke became a mere title of dignity, annexed to a person, and his heirs male, without giving him any domain, territory, or jurisdiction over the place whereof he is duke. All the advantages thereof now consist in the name, and the precedence it gives.

The dukes of our days retain nothing of their ancient splendour, but the coronet on their escutcheon; which is the only mark of their departed sovereignty. They are created by patent, cincture of the sword, mantle of state, imposition of a cap, and coronet of gold on the head, and a verge of gold in their hand.

The eldest sons of dukes are, by the courtesy of England, styled *marquisses*, though they are usually distinguished by their fathers' second title, whether it be that of marquis, or earl; and the younger sons, *lords*, with the addition of their Christian name, as lord James, lord Thomas, &c. and

they take place of viscounts, though not so privileged by the laws of the land. The title of duke is the next dignity to the prince of Wales.

A duke has the title of *grace*; and being writ to, he is styled, in the herald's language, *most high, potent, and noble prince*. Dukes of the blood royal are styled *most high, most mighty, and illustrious princes*.

DUKE, among Hebrew grammarians, is an appellation given to a species of accents, answering to our comma. See ACCENT.

DUKE-DUKE, a quality given in Spain to a grandee of the house of Sylva, on account of his having several duchies, from the miting of two considerable houses in his person. Don Rodrigo de Sylva, eldest son of Don Ruy Gomez de Sylva, and heir of his duchies and principalities, married the eldest daughter of the duke de Infantado; in virtue of which marriage, the present duke de Pastrana, who is descended therefrom, and is grand-son of Don Rodrigo de Sylva, has added to his other great titles, that of duke-duke, to distinguish himself from the other dukes, some whereof may enjoy several duchies, but none so considerable ones, nor the titles of such eminent families.

DUKE'S County, in *Geography*, a county in the state of Massachusetts, N. America, comprehending the islands of Martha's Vineyard, Chabaquiddick, Nonan's and Elizabeth's, and situated in the S. E. coast of the state. The number of inhabitants is 3118, who send three representatives, and, in conjunction with the island of Nantucket, one senator to the general court. The chief town is Edgarton.

DUKE of Gloucester Island, an island in the South Pacific ocean. S. lat. 16° 11'. W. long. 140° 11'.

DUKEE, or DUKI, a town of Asia, in the country of Candahar, in the road from Candahar to Mowitan; 180 miles S. E. of Candahar.

DUKLA, a town of Poland, in the palatinate of Sandomirz; 60 miles S. W. of Sandomirz.

DUKORTCHINA, a town of Russia, and one of the 12 districts of the government of Smolensko, seated on the Dnieper.

DUKOVA, a town of Lithuania, in the province of Minsk; 16 miles S. E. of Minsk.

DULAS, a river of Wales, in the county of Carmarthen, partly separating this county from that of Glamorgan, which runs into the sea, about four miles S. E. of Kidwelly.

—Also, a river of Wales, in the county of Carmarthen, which runs into the Towy, about 1½ mile S. S. W. of Llangatock.—Also, a river of Wales, in the county of Brecon, which runs into the Wye, near Hay.—Also, a river of Wales, in the county of Radnor, which runs into the Ithon, near Llanbader.—Also, a river of Wales, in the county of Montgomery, which runs into the Severn, near Llanidlos.—Also, a river of Wales, in the isle of Anglesea, which runs into the Irish sea, forming a bay and harbour at its mouth, with a village of the same name; 10 miles N. W. of Beaumaris.

DULCIANA, in *Music*, a very pleasing solo stop in the organ, brought hither by Snetzler. It has since been very successfully imitated by Green, Grey, and others. It is a very long and narrow pipe, in unison with the open diapason; is as sweet as a reed-stop, and seldom wants tuning.

DULCIFICATION, in *Chemistry*, is an old term not very accurately defined, but is generally meant to signify the rendering mild, or lessening the corrosive quality of acids or alkalis, by any combination which is not supposed actually to neutralize them. The term, however, is incorrect, and should be disused.

DULCIGNO,

DULCIGNO, in *Geography*, a town of European Turkey, in the province of Albania, on the coast of the Adriatic, containing about 7000 or 8000 inhabitants. The harbour serves as a retreat for corsairs; 15 miles S.W. of Scutari. N. lat. 42° 23'. E. long. 18° 56'.

DULCIMER, a musical instrument in a triangular form, (strung with about 50 wire strings, resting on a bridge at each end; the acute gradually shortening to about 18 inches, and the grave lengthening to about 36; it is struck with a small iron rod in each hand. The base strings are doubled in unison, and its tone is not disagreeable. When played on, it is laid on a table before the performer, who with the small iron rods strikes it with more or less force, as light and shade may be wanting. The instrument has not the honour to be admitted into concerts, and is seldom used, except at puppet-shows, and by itinerant musicians.

DULCINISTS, in *Ecclesiastical History*. See **APOSTOLICI**.

DULCINO, in the *Italian Music*, a wind instrument, otherwise called *quart fagotto*. It serves for tenor to the hautboy, and is no more than a little bassoon. *Broff. Dict. Mus. in voc.*

DULCINUS, in *Biography*, a leader of a religious sect, was a native of Novara, in the duchy of Milan. The sect, sometimes denominated Dulcinists, and sometimes the "sect of the apostles," was founded by Gerard Sagarelli, who was burnt alive, for his heresy, as it is called by Moreri, at Parma, in the year 1300. According to the learned Mosheim, the Dulcinists aimed at introducing among Christians the simplicity of the primitive times, especially the manner of life that was observed by the apostles, as nearly as could be collected from their writings. On the death of the founder, Dulcinus boldly headed the sect, and avowed his faith in the predictions of Sagarelli, viz. that the church of Rome would speedily be destroyed, and that a pure system of religion would be built on its ruins. That he believed what he asserted is evident from the means which he took of defending himself and followers against their enemies and persecutors. For two years the Dulcinists, by force of arms, maintained their ground against the supporters of the papal interdicts; which terminated, however, in the overthrow and capture of their leader, after he had signalized himself in several obdurate and well contested battles. His life was the forfeit of his heroism and honesty. Moreri. Mosheim.

DULCIS *Asa*, or *Afa*. See **ASA**.

DULEGE, in *Gunnery*, a peg of wood which joins the ends of the six fellows, which form the round of the wheel of a gun carriage; and the joint is strengthened on the outside of the wheel by a strong plate of iron, called the dulege plate.

DULEEK in *Geography*, a small town in the county of Meath, province of Leinster, Ireland, situated on the Nanny Water. It is of little importance, but is a thoroughfare to the northern parts. According to a MS. at Cambridge, the first church in Ireland that was built of stones, was erected there. It is twenty-one miles north from Dublin, and four south from Drogheda.

DULGIBINI, in *Ancient Geography*, a people of Germany, so called by Tacitus, and supposed to be a colony of Cherusci, whose chief habitation was the town of Afcalingum, now Lingen, upon the Ems. Ptolemy denominates them *Dulgumini*.

DULIA, ΔΟΥΛΙΑ, *Service*. See **WORSHIP**, **LATRIA**, and **HYPERDULIA**.

DULICHNUM, in *Geography*, one of the islands called Echinades, situated W. of Greece in the Ionian sea. It

was also called Dolicha, and so distinguished by M. D'Anville, who supposed it to have been near Cephalonia, and called it Ithaca. Its name is now Theaki, or Little Cefalonia.

DULKAK, among Arabian writers, a fabulous sea-monster in form of a man, riding on an ostrich, which is said to attack ships, and fight with the men on board. *Hofm. Lex. in voc.*

DULKEN, or **DULKREN**, in *Geography*, a town of Germany, in the kingdom of Westphalia, and duchy of Juliers; 20 miles N.N.W. of Juliers.

DULLAERT, **HEYMAN**, or **HERMAN**, in *Biography*, painter of history and portraits, born at Rotterdam in 1636. He was a disciple of Rembrandt, whom he imitated so successfully, that one of his pictures, representing Mars in armour, was sold at Amsterdam at a public sale, in 1696, for a work of that great master. He is praised by Houbraken for the beauty of his colouring, and freedom of pencil. He is said to have been also well skilled in music. He died in 1684. *Vie des Peintres Flamands, &c.*

DULMA, a Turkish dish, made of any vegetable, as cucumbers, onions, cabbage leaves, &c. stuffed with forced meat. *Pococke's Egypt, p. 153.*

DULMAN, or **DULMEN**, in *Geography*, a small town of Germany, formerly in the bishopric of Munster, in Westphalia, but at present in the kingdom of Westphalia; 22 miles S.W. of Munster.

DULNESS of **HEARING**. See **HEARING**.

DULOPOLIS, in *Ancient Geography*, a town of slaves, a town of Africa, in Libya.

DULVERTON, in *Geography*, a market town and parish in the hundred of Williton Freemannon, in the county of Somerset. It stands in a narrow valley, near the banks of the river Ex, which divides the parish, and also separates the counties of Devon and Somerset, at this place. The town consists of two streets, both of which are paved, and in the principal one is the market-house, a commodious building, and the butchers' shambles. Here is a weekly market on Saturday, and, what is rather unusual, the poor have the rents and tolls of the market distributed among them annually. The town consists of 195 houses and 1049 inhabitants: most of these are occupied in the manufacture of coarse woollen cloths and blanketings.

It appears from some records that the town was occupied by the West Saxon kings, and was possessed by the crown when the Domesday book was composed.

About one mile south of the town is Combe, an ancient seat of the Sydenham family, who purchased it in the time of queen Elizabeth. Half a mile south-east of Dulvertory is Pixton, a pleasant seat of lady Acland. Collinson's History of Somersetshire, vol. iii.

DULWICH, a hamlet in the parish of Camberwell, in the county of Surry, is noted for a large college which was founded here in 1614, by Edward Alleyn, an actor of some professional reputation in the reigns of Elizabeth and James I. The building was erected after a design by Luigi Jones, and contains a chapel, masters' apartments, and chambers for the poor men, women, and children belonging to the foundation. This provided for a master, who must always be of the name of Alleyn or Allen, and who is lord of the manor wherein the building is situated; for six poor men, six women, and twelve boys. The latter, at proper age, are either sent to the university, or put out apprentices. The original revenues have been enlarged by subsequent donations, particularly in 1686, by Mr. Cartwright, a comedian and bookseller, who bequeathed all his library and pictures, with 400*l.* in cash, to the college. In 1750 lady Falkland left a bequest

bequest of 300*l.* Dulwich was formerly celebrated for its mineral waters, but these have either subsided or lost their medicinal qualities. "Lefon's Environs of London."

DUM non fuit compos mentis, in *Law*, a writ that lies for one, who alienates any lands or tenements while not of sound memory or judgment, in order to recover the same from the alienee, against whom the writ is taken. See *LUNATIC*.

DUM fuit infra aetatem, a writ which lies for him, who, before he came to full age, made a feoffment of his land, to recover it again of the vendee. *Fitz. Nat. Br.* fol. 102. See *INFANT*.

DUMA, in *Ancient Geography*, a large village of Palestine, in the southern part of the tribe of Juda, upon the confines of the territory of the town of Eleutheropolis, according to Eusebius and Jerome.

DUMA, in *Geography*, a town of Arabia, in Negerd, in a hilly country called Jot al Siran, between mount Schamer and Sham, or Syria.—Also, a town of Germany, in the kingdom of Westphalia, on a river of the same name, which soon after runs into the Wipper; 14 miles S.E. of Dusseldorp.

DUMANDRE, ANTHONY, in *Biography*, sculptor. He was born of a good family in Lorrain, and served as a cadet in the army of Louis XIV. in the regiment of Picardy, together with his brother Hubert, with whom he also went afterwards to Paris, to study sculpture, and thence into Spain, by the invitation of Philip V. His principal works are in the royal gardens of St. Ildefonso, at Madrid, and at Aranjuez. On the establishment of the academy of fine arts of San Fernando, at Madrid, in 1752, he was appointed director. He died in 1761. *Diccionario Historico de las Bellas Artes en Espana.*

DUMANDRE, HUBERT, sculptor and architect; the brother of Anthony Dumandre, last mentioned, whom he accompanied into Spain. Many works in the gardens of St. Ildefonso are by him, as also the sepulchre of Philip V. in the collegiate church of the same place. He died at Madrid in 1781, at the age of 80. *Diccionario Historico de las Bellas Artes en Espana.*

DUMARING, in *Geography*, a town of the island of Borneo, on the east coast. N. lat. 2° 10'. E. long. 117° 30'.

DUMATHA, in *Ancient Geography*, a town of Arabia, called by Ptolemy *Dumatha*, and placed in Arabia Petraea.

DUMB CANE, in *Botany*. See *ARUM Seguinum*, n. 26.

DUMBARTON, in *Geography*, the county town of Dumbartonshire, or as it was anciently called, the Sheriffdom of Lenox, in the west of Scotland. The town of Dumbarton is situated at the confluence of the Leven with the Clyde, in N. lat 56°. W. long. 4° 32'.

When Britain was under the Roman government, this town formed the extreme post regularly occupied by the Roman legions to the westward: and the remains of the celebrated wall, built to prevent the inroads of the northern inhabitants, and stretching from Dumbarton across the country towards Aberdeen, upon the east coast, are still to be seen on the chain of mountains near Dumbarton. The town is not of great extent, but well built of free-stone, and the principal street is in the form of a crescent, extending nearly from east to west, along the north bank of the river Leven, which serves as a harbour to the town, and where vessels of upwards of 200 tons burthen can discharge and receive their cargoes. The castle of Dumbarton is built upon an insulated rock, about three quarters of a mile from the town, and is still kept as a fortress, although in the modern art of war, it is not probable that it could resist a siege of even twenty-four hours. In former times, however, it was considered a place of considerable importance, and before the

improvements which have taken place within the last two centuries, would probably be deemed impregnable. A singular story of its being taken by surprise is recorded; which consisted the officer who commanded the party, which consisted only of one hundred men, after fixing the scaling ladders, which were placed in the middle of the night to the deepest part of the rock, ascended last, one of his soldiers being seized with a giddiness, either from terror or fatigue, became unable to proceed when far up the ladders. With an astonishing presence of mind he was lashed to the ladder, until his comrades had effected their enterprise, when he was relieved without sustaining any injury after the fort had surrendered. In the present state of this country it is useful as a depot of arms, and is generally garrisoned either by detachments from the veteran battalions, or by skeleton regiments sent home to recruit. It is well supplied with water, and the barracks are pleasantly situated and commodious.

The town of Dumbarton is governed by a provost, magistrates, and common council consisting of fifteen members. It returns a member to parliament in conjunction with the city of Glasgow, and borough towns of Renfrew and Rutherglen. The present member is Archibald Campbell, of Blythwood, esq. Formerly the noble family of Argyll was supposed to possess considerable influence in directing the affairs of this borough; and the present duke, when marquis of Lorne, and afterwards his brother, Lord John Campbell, filled the office of provost or chief magistrate. This influence is now supposed to be upon the decline, and the direction of the borough is placed in other hands.

The trade of Dumbarton is not very extensive; there are, however, very large manufactories of glass in the town, and very extensive print fields upon both sides of the Leven in the vicinity, which must circulate a large sum of money annually in wages. A great deal of grain also is frequently imported from the north of Ireland, for the supply of the western counties of Scotland.

The river Leven, although only about six miles in length from Lochlomond to its confluence with the Clyde, is deep and rapid. The water emptied from the lake is very pure and soft, and is uncommonly well calculated for bleaching, dyeing, printing, and other chemical operations. The Leven abounds with very fine salmon, the fishery of which is the property of the corporation of Dumbarton, and of Sir James Colquhoun of Luis, bart. and yields to the proprietors a considerable annual revenue. The trout also are uncommonly fine and large.

The county of Dumbarton is bounded on the south by the river Clyde, which divides it from Renfrewshire, on the west by Loch Long, an arm of the frith of Clyde, which extends about twenty-four miles, and forms the division between Dumbartonshire and Argyllshire, and on the east and north, by the counties of Renfrew, Lanark, Stirling, and Perth.

This county is neither very extensive nor populous. By the account taken under the authority of the act of parliament, 1801, it is estimated to contain 1546 square miles, and 20,710 inhabitants. The valued Scotch rental of the county, as fixed at the union, is 158,627 pounds Scots, of the value of twenty-pence sterling each; and the real annual rent in sterling money is computed at 109,700*l.* The last is probably too low at the present day, as the arable lands in this, as in most other counties, have risen amazingly at the expiration of the respective leases, and even the moor and pasture grounds being much higher now than formerly. The population of the town of Dumbarton is estimated at 1850.

A great part of the lands of Dumbartonshire are moorish

5th and mountainous, but it also contains much good arable land, particularly in the eastern part, near Killyth, along the bank of the Clyde, and on the banks of Lochlomond. In these places, when the season is favourable, the crops, if not so luxuriant as in some other parts of the island, are generally good and early; and the agriculture has most rapidly improved of late years, and is now almost universally conducted in a judicious and industrious manner. The potatoes of most parts of Dumbartonshire are particularly admired for their superior quality. The eastern part of the county is plentifully supplied with coal and lime, but in the western part, the exertions made to procure these valuable minerals have not hitherto been so successful. The navigation of the Clyde, however, by affording water carriage at an easy rate, in a great measure counteracts this inconvenience.

The chief natural curiosity of Dumbartonshire is Lochlomond, the beauty of which has been so universally admired, and made so often the subject of descriptive writing; that it seems unnecessary to say much of it. Its length is about 24 miles, its greatest breadth about 7 or 8 miles, and besides the purity and transparency of the water, the richly wooded islands with which it abounds, the romantic grandeur of the surrounding scenery, and the delightful seats and vilas with which its banks are covered, form an assemblage of picturesque beauty rarely equalled.

The county of Dumbarton returns one member to parliament; the present member is Henry Glafsford, esq. of Dugaldston. The electors are, as in the other counties of Scotland, freeholders; holding from the crown lands of the value of 400 pounds Scotch of valued rent or upwards. The number of those qualified seldom much exceeds 30.

The chief landed proprietors are, the dukes of Montrose and Argyle, lords Elphinstone (lieutenant for the county,) Blantyre, and John Campbell, sirs James Colquhoun of Luss, and Charles Edmondstone of Duntreath, Messrs. Ferguson of Raith, Dennistown of Colzrain, Buchanan of Ardenconnell, Buchanan of Auchintorlie, Hamilton of Barns, Buchanan of Ardach, Glafsford of Dugaldston, Snollet of Bonhill, Graham of Gartmore, Creefs of Auchintoshan, the Right Hon. Hay Campbell of Succoth, late lord president of the Court of Session, and Archibald Colquhoun of Killermont, lord advocate of Scotland, general Giles of Gileston, Alton of Westerton, Ewing of Keppoch, Colquhoun of Camstradden, Colquhoun of Garscadden, and some others.

DUMBLANE, or DUNBLANE, a parish and town of Perthshire in Scotland. The town appears to have originated from a cell of Culdees, which was established here at an early period: subsequently a bishop's see and cathedral were fixed and erected in this place. Of the latter, some remains still stand to shew the site and style of the building. It stood on an eminence, close to the river Allan, and was founded by king David in 1142. It is now unroofed and verging to decay; yet is venerably grand in its ruins. The choir is still kept in repair, and used as the parochial church. The town contained, by the late population return, 493 houses, and 2619 inhabitants. The parish extends about nine miles in length and six in breadth. Near Kippencrofts in this vicinity is a plane tree, one of the largest in Scotland; its girth being 72 feet. A few miles from Dumblane is Sheriff Mair, a place rendered famous by the battle fought in November 1715, between the royal forces under the duke of Argyle, and the rebel army, commanded by the earl of Marr.

DUMBNESS, in *Pathology*, *mutitas* of the nosologists, an inability of speech, or of uttering articulate sounds.

The power of speech may be lost, in consequence of a palsy of the tongue and other organs connected with the

modulation of the voice; or of a loss of the tongue from cancerous ulceration, or from a wound. But in the condition, which is generally understood by the appellation of dumbness, the organs of the voice are not imperfect; the physical defect being altogether confined to the organs of hearing. Persons in this condition, therefore, are *dumb*, only because they are *deaf*; or, in other words, they are incapable of using language, the sounds of which they have never been able to hear, and consequently never could attempt to imitate. Those who are born deaf, or become so from disease in early infancy, are, therefore, the only subjects of this unfortunate privation. See DEAFNESS.

Of the two most important channels of knowledge, the senses of sight and hearing, a deprivation of the latter would seem, perhaps on a slight view, to be a less fatal impediment to the acquisition of information, than the former; but when it is considered, that a want of the sense of hearing involves with it the loss of the principal medium of mental intercourse, language, it becomes evident that the bar to intellectual improvement is by such a deprivation doubly augmented. Hence a general opinion has prevailed, in all ages, that the deaf and dumb were cut off by nature from the acquisition of knowledge, and they have therefore generally been abandoned to a state of mental destitution, for which no remedy was believed to be discoverable.

“ Nec ratione ullâ docere, suadereque furdis
Quid factû esse opus.”

J. LUCRET.

“ T' instruct the deaf no art could ever reach,
No care improve them, and no wisdom teach.”

It has been proved, however, by the attempts of several individuals, at different periods, in modern times, that this opinion is erroneous; and that it has either arisen from a superficial or mistaken view of the means by which the mind acquires the knowledge of language, and of abstract or general ideas, when the senses are perfect; or from a conviction of the difficulties attending any attempt to imitate the same process, when one sense is shut up. It was from the latter consideration probably, that Dr. Johnson was induced to call the education of the deaf and dumb “ a philosophical curiosity.”

The earliest essay at the education of these unfortunate beings appears to have been made in Spain, by Peter Ponce, a Benedictine monk, towards the end of the sixteenth century, which was attended with success, according to the authority of Vallesius (*de sacrâ philosophiâ*) and Antonio Perez. A countryman of his, Bonnet, secretary to the constable of Castile, whose younger brother had lost the sense of hearing when two years old, undertook a similar task, and published a system, which he formed on the occasion, in 1620, and which he dedicated to Philip III. under the title of “ *Reducción de las letras, y arte para enseñar à traher los mudos.*” The tuition of the deaf was subsequently treated of by Helmont, a German, in a very ingenious publication, entitled “ *A phabeti verè naturalis Hebraici brevissima Delimitatio,*” printed at Salzburg, in 1657; in which the author mentions the trial of his skill upon one pupil only, who became master of his vernacular tongue very expeditiously, and acquired the Hebrew of himself. But a more general reputation for this sort of instruction was obtained by Amman, a Swiss physician, settled in Holland, about 1690, in consequence of his success with the only daughter of Peter-Karlard, a beautiful girl, born deaf. He published a small treatise upon the subject in Latin, under the title of “ *Surdina loquens,*” in 1692; an enlarged edition of which appeared in 1700, with the title of “ *Dissertatio de loquaci.*”

About

About the same time our countryman Dr. Wallis, a man of extensive science and great acuteness, was led to pronounce, on speculation, the practicability of teaching the deaf to speak, and was prevailed upon, some years afterwards, to verify his theory in the tuition of Mr. Whalley, a young gentleman of Northampton. He fully succeeded in this essay, and also with a son of Admiral Popham, and was afterwards employed in the instruction of other deaf and dumb pupils, but without teaching them to speak. He published an account of his "method of instructing persons Deaf and Dumb," in the Philosophical Transactions for the year 1698. Dr. Holder engaged in the same sort of tuition about the same period, but with less extensive practice and reputation than Wallis; and printed his "Elements of Speech," relating to this subject, in 1669.

Dalgarno, one of the schemers of a universal language, employed his pen next upon the tuition of the deaf and dumb, led to the subject not by practical instruction but philosophical disquisition: he examined the topic in an acute and learned performance, entitled "Didascalochus, or the Deaf and Dumb Man's Tutor." The subject was also treated in a more general manner, as a speculative inquiry in a volume, with the title of "Philosophus, or the Deaf and Dumb Man's Friend," by a physician of the name of Bulwer, in 1648; and in "A Treatise concerning those that are born Deaf and Dumb," by George Sibbode, in 1670.

In more recent times this art has been successfully and extensively exercised by Father Vannin and Mont. Perreize, in Paris; by Mr. Heinrich, in Leipzig; by Mr. Baker, in London; by Mr. Braidwood, in Edinburgh; by the Abbé de l'Épée; and at present by the Abbé Sicard, his successor, in Paris; and by Mr. Watson, formerly the assistant to Mr. Braidwood, now teacher in the asylum, for the support and education of the deaf and dumb children of the poor, instituted in London in 1792, as before mentioned. See DEAFNESS.

Although the attempts to lay down systems, and to inculcate the facility of educating the deaf and dumb have been numerous; yet so limited has been the circulation of these writings, (owing, perhaps, in a great degree to the general incredulity as to the practicability of the schemes,) that each of the earlier writers considers himself as original on the subject, being ignorant that his work had been preceded by others of a similar nature. Mr. Braidwood never published any account of his method of instruction: but the benevolent Abbé de l'Épée, and his successor, the Abbé Sicard, have given the world an ample account of their systems. The work of the former was translated into English in 1801, under the title of, "The Method of educating the Deaf and Dumb, confirmed by long experience, by the Abbé de l'Épée;" the volume of the latter, entitled, "Cours d'Instruction d'un sourd-muet de naissance, pour servir à l'Éducation des sourds-muets, &c., avec Figures et Tableaux, par Rochambroise Sicard," was printed at Paris in the year 1800.

The different teachers of the deaf and dumb have had two ends in view: the one was to teach the use of written language, and, through that medium, to enlighten the mind with various species of knowledge, and also to enable their pupils to converse by means of writing, or other symbols; and the other was to instruct them in the actual exercise of the organs of articulation, or to converse by speaking. Dr. Wallis, it would seem, succeeded in teaching the latter to his two first pupils; but, probably, for the same reason which has induced the Abbé Sicard to relinquish the task; viz. that the benefit to the deaf is by no means proportionate to the labour of acquiring *utterance*, he seems to have confined himself afterwards to the instruction of the mind,

Mr. Braidwood, of Edinburgh, however, appears to have carried the difficult and laborious acquirement of *speech* in his pupils to a considerable degree of perfection, and to have enabled them to answer orally the oral propositions of others, which they discerned with surprising readiness, by watching the motions of the organs of speech of those with whom they conversed. But as they were unable, from the want of hearing, to modulate the voice, or correct the articulation nicely, their utterance is said to have been indistinct and discordant, and not always intelligible, like the first words of the infant, to those unaccustomed to hear it; and, in like manner, their understanding of the language of others, not habituated to their strongly marked motions of the tongue, lips, &c. was necessarily imperfect.

Mr. Braidwood is said to have been very desirous of transmitting his art to posterity, but alleged, that he could not communicate it so fully in writing as to enable any other person to teach it. The following imperfect outline of his method has been given by an eye witness of his instructions: His first step was to teach the pupil to pronounce the simple sounds of the vowels and consonants. He pronounced the sound of *a* slowly, pointing out the figure of the letter at the same time, and making his pupil observe the motion of his mouth and throat: he then put his finger into the pupil's mouth, depressed or elevated the tongue, and made him keep the parts in that position: then he took hold of the outside of the wind-pipe, and gave it some kind of squeeze, which it is impossible to describe: all the while he was pronouncing *a* the pupil was anxiously imitating him, but at first seemed not to understand what he would have him to do. In this manner he proceeded till the pupil had learned to pronounce the sounds of the letters. He then went on in the same manner to join a vowel and a consonant, till at length the pupil was enabled both to speak and to read. We have the authority of Mr. Pennant for stating, that Mr. Braidwood's pupils were not only taught the *pronunciation*, but perfectly to understand the *meaning* of what they read. Of this he mentions a striking example, in a young lady of about 13 years of age, who had been some time under the care of Mr. Braidwood. "She readily apprehended all I said," he observes, "and returned me answers with the utmost facility. She read, she wrote well: her reading was not by rote; she could clothe the same thoughts in a new set of words, and never vary from the original sense." But we are not informed of the method or the nature of the signs by which the signification and construction of language were rendered intelligible to Mr. Braidwood's pupils.

The abbé de l'Épée, despising the secrecy and quackery of Heinrich and Perreize, and not seeing the difficulty of exposition which occurred to Mr. Braidwood, published a minute account of his principles and practice in the tuition of the deaf and dumb; of which we shall endeavour to sketch the outline. The purport of such instruction, he observes, is to introduce into the minds of the pupils by the *eye*, what has been introduced into our own by the *ear*; that is, to teach by the use of visible signs or symbols, instead of audible ones. It is obvious that there is no natural connection between articulate sounds, and the ideas which they are employed to express; nor between the same ideas, and the written characters that are used to represent them. The variety of languages, as well as of alphabetical, cypheral, and symbolical writing, incontebly proves the truth of this position. Both words and written characters are, therefore, arbitrary representatives of the objects of our senses, and of the ideas of the mind, agreed upon by national compact; and they convey no idea to those in whose mind they have not been associated, by habit, with the objects which they have

been assumed to represent. Hence, to a person unacquainted with any language, or set of representative signs of ideas, it is as easy to teach one language, or one mode of writing, as another; and a written language may be taught, independently of an oral one, and *vice versa*, by either of which the faculties of the mind may be fully exercised, and the stores of human knowledge laid open to its acquisition.

Now all language is taught, in the first instance, by sensible signs, with which the oral found of the word is accompanied by the teacher. Thus a child learns to connect the idea of a well-known fruit, with the found of the word *apple*, because he hears that word repeated when the fruit is shewn to him: and in the same manner he learns to associate particular words with every other object of the senses, by the habitual conjunction of the audible with the visible sign. Afterwards in learning to read or write, he acquires a similar habit of associating the appearance of certain visible signs or letters, with the same objects, or their oral representative signs; so that when the objects themselves are absent, the ideas of them may be recalled to his mind either by the *visible* signs, in written language, or their *audible* signs, in oral language.

It is clear, then, that although the deaf are excluded from receiving ideas by audible signs, yet it is as possible to instruct them by written characters, always accompanied by some sensible signs, as to instruct those who can hear, by words delivered orally, along with signs or gestures indicative of their signification. This, it is true, is a task of infinitely more labour than oral instruction, in which two senses combine to strengthen the association of words with things. But when it is recollected, how the acuteness of any one sense is increased, when the privation of another causes it to be greatly exercised, part of the difficulty will disappear: and experience has now amply demonstrated the practicability of the scheme. "I soon saw," says the abbé de l'Épée, "that a deaf and dumb person, under the guidance of a good master, is an attentive spectator who acquaints himself with the number and arrangement of the letters of a word presented to him, and that he retains them better than other children, to whom they are not yet become familiar by daily reiterated use."

The first part of the abbé's plan of tuition, then, consisted in instructing the deaf and dumb, by writing and the intervention of methodical signs, in various departments of knowledge. It was some time before he thought of attempting, what Amman had effected in Holland, Bonnet in Spain, and Wallis in England; namely, to make his pupils *speakers*. This was first suggested to him by the work of Bonnet, before mentioned; and it is an enterprize, he says, that does not require great talents, but much patience. We shall first briefly shew his method of teaching written language, with a knowledge of its signification and grammatical construction; and afterwards his mode of teaching articulation, or speech.

In learning our native language, as we have already stated, a sign of the hand or the eye was the sole means by which we were taught to unite the idea of the objects with the sounds (their names) that struck our ear. Whenever we heard those sounds, the same ideas arose in our minds, because we recollected the signs made to us when they were pronounced. Exactly similar are the measures adopted with the deaf and dumb by the abbé de l'Épée. He commences with teaching them a *manual alphabet*, such as boys at school make use of to hold conversation at one end of a form with their companions at the other. Here the visible figure of the fingers, in different positions, is substituted for the audible sounds, which we connect with written letters in ordinary tuition: and the various figures of these letters strike

forcibly the eyes of the deaf and dumb persons, who no more confound them, than we confound the various sounds that strike our ears.

He next writes in large characters, with a white crayon upon a black table, these two words, *the door*, and shews them the door. They immediately apply their manual alphabet five or six times to each of the letters composing the word *door*, (*i. e.* they spell it with their fingers,) and impress on their memory the number of letters, and the arrangement of them: this done, they efface the word, and taking the crayon themselves, write it down in characters, no matter whether well or ill formed; afterwards they will write it as often as you shew them the same object.

The same course is pursued with respect to every object pointed out to them, the name being previously written down. And experience has demonstrated, that a deaf and dumb person, possessing any mental powers, will acquire by this method upwards of eighty words in less than three days: in a very short time, therefore, the pupil will obtain a knowledge of all the words which express the different parts of our frame, from head to foot, as well as of those that express the various objects that surround us, if properly pointed out to him, as we write their names on the table, or on cards put into his hands.

The abbé begins early with verbs and little phrases, and not, as is usual, with the declension of nouns and pronouns, because it is more amusing to the pupils, and furnishes better means of developing their faculties. The first or second day he guides their hands, or writes for them the present tense of the indicative of the verb, *to carry*.

"Several deaf and dumb persons being round a table," he says, "I place my new scholar on my right hand; I put the fore-finger of my left hand on the word *I*, and explain it by signs in this manner: shewing myself with the fore-finger of my right, I give two or three gentle taps on my breast. I then lay my left fore-finger on the word *carry*, and taking up a large quarto volume, I carry it under my arm, on my shoulder, on my head, and on my back, walking all the while with the mien of a person bearing a load. None of these motions escape his observations.

"I return to the table; and in order to explain the second person, I lay my fore-finger on the word *thou*, and carrying my right hand to my pupil's breast, I give him a few gentle taps, making him notice that I look at him, and that he is likewise to look at me. I next lay my finger on the word *carry*, the second person, and having delivered him the quarto volume, I make signs for him to perform what he has just seen me perform: he laughs, takes the volume, and executes his commission very well."

In this ingenious and patient manner the tutor goes through the various persons, singular and plural, both to the instruction and amusement of his pupils. Nevertheless, a small difficulty occurs in the outset. "The pupil, having his left fore-finger upon *I*, carries his right to my breast, thinking that my name was *I*, as he had seen me several times designate myself by that word." This the abbé ingeniously explains, by letting him see that every individual of the group denominates himself *I*. By following out the same plan with different words, the pupil will understand in a day or two every phrase composed of only one of the six persons of the present of a verb transitive with its objective, such as these: "I draw the table; thou draggell the chair; he offers an arm chair; you push the door; they shut the window:" because all these words express actions, of which the signs are caught in an instant; and because the eyes of the spectators testify that these operations are performed.

The abbé then proceeds with the articles, cases, numbers, and

and genders of nouns, furnishing the pupil with signs which distinguish each of these properties that apply to nouns. Thus he is informed, by writing on the table, that *the, of, of the,* connect words as our joints do our bones: after this, the right fore-finger two or three times bent in the form of a book becomes the syllematical sign for an article; and other signs are used for the cases, genders, &c.

"Names of qualities, as *good, great, wise, learned,*" says the abbé, "infer necessarily some noun substantive, expressed or understood, to which they are applied: but if we consider the qualities only which are expressed, without reference to any noun substantive, then these qualities being subject to have other qualities applied to them, become themselves nouns substantive, as *goodness, greatness, wisdom, learning.* Our mode of expressing this sort of adjective is the following: if we would dictate the word *greatness,* for instance, we make the sign for *great,* which is an adjective; then we subjoin the sign for a substantive, which announces that this adjective is *substantified,* or made a substantive, and can itself receive other adjectives. I give several examples, after which my pupil will commit no mistake, either in reading a book, or in writing as we dictate to him."

In this manner the pupil is instructed in the various parts of grammar, in the "whole metaphysic of verbs," their numbers, tenses, and modes, in conjunctions, prepositions, &c. by a series of visible signs, not more arbitrary than the articulate and audible signs of speech. And the abbé has convinced many academicians and learned men, that the deaf and dumb are by these means rendered capable of understanding the grammatical difference of every word in the construction of language. He then proceeds to shew, 1, the fecundity of methodical signs arising out of the sign for the infinitive of the verb; and, 2, that there is no metaphysical idea, of which a very clear explanation may not be given by means of analysis, and the help of methodical signs.

In illustration of the first of these propositions, he observes that "the same operation or disposition of the mind, of the heart, of the body, &c. can be expressed by a verb, by a noun substantive, by a noun adjective, and sometimes by an adverb. Since the operation or disposition is the same, there must necessarily be the same radical sign, to which are joined other signs, to indicate, in verbs, the difference of their persons, their numbers, tenses, and modes; in nouns, whether substantive or adjective, their cases, numbers, and genders; and to characterize nouns adjective made substantive or adverbial.

"This radical sign is the sign for the infinitive of the verb. I take, for example, the verb *to love,* in all its parts, whether active or passive, with all the words derived from or related to it, such as *friendship, love, loved, lovely, lovelling, friend, lovelily, friendly, friendlily, lover, amateur,* &c. All these words have the same radical sign, that of the infinitive *to love.* It is executed by looking at the object in question, and pressing the right hand strongly upon the mouth, while the left is laid upon the heart; then carrying the right with fresh vivacity to the heart, conjointly with the left, and concluding with the sign for the infinitive. The pupil to whom I am dictating a lesson or a letter, must not mistake in the choice of any one of these words, which are upwards of two hundred and forty in number, comprising all persons, numbers, tenses, and modes of the verb active and passive; the cases, numbers, and genders of the nouns substantive and adjective, and the adverbs.

"If a part of a verb is to be dictated, I first make the sign for the personal pronoun, which carries along with it

that for number; then the radical sign; and according to what is requisite, the signs for tense and mode.

"If I want to dictate *friendship,* I make the radical sign, accompanied by the sign for substantive, which will be enough to make it understood that such is the noun substantive I require.

"If *love* is the noun I want, I make the same sign as for friendship, only giving a greater degree of vivacity to my action on the mouth and on the heart, because love is more ardent than friendship.

"The word *beloved* is an adjective, agreeing both to masculine and feminine: the sign for adjective subjoined to the radical sign will suffice.

"Is *amiable* the word? I make the radical sign, then the sign for an adjective, but of one terminating in *able* formed from a verb: to this I must subjoin the sign for possible, or for necessary, as before laid down."

This exemplification is equally applicable to the infinitives of all verbs; and to the words derived from or related to them.

In illustration of the other proposition, the abbé remarks, that there is nothing which cannot be clearly signified by words; and that there is no word in any language, of which the signification may not become intelligible, by analysis, in using other words to a necessary extent: that is, every word signifies something, and is capable of being explained. "The procedure is the same with the deaf and dumb. We continue writing till we attain words, comprehended by signs, which illustrate what was obscure. Instances of being forced to have recourse to a second operation are rare; if they were frequent, it would prove that my ideas were not very clear, and that my expressions were ill chosen." In order to illustrate this point, he gives the following example.

There is perhaps no word more difficult to explain by signs than this, *I believe.* I effect the explanation of it in the following manner: having written upon the table *I believe,* I draw four lines in different directions, thus:

I believe ———— *I say yes with the mind. I think yes.*
 ———— *I say yes with the heart. I love to think yes.*
 ———— *I say yes with the mouth.*
 ———— *I do not see with my eyes.*

Which signifies, my mind consents, my heart adheres, my mouth professes, but I do not see with my eyes. I then take up what is written upon these four lines, and carry it to the word *I believe,* to make it understood that the whole is there comprised.

"If, after this explication, I have occasion to dictate the word, *I believe,* by methodical signs, I first make the sign for the singular of the personal pronoun, as I have shewn in its place: I next put my right forefinger to my forehead, the concave part of it being deemed the seat of the mind, that is, the faculty of thinking, and I make the sign for *yes:* after that, I make the same sign for *yes,* putting my finger to that part, which is commonly considered as the seat of the heart, in the mental economy, that is, our faculty of loving, (we have several times explained that these two faculties are spiritual, and occupy no space in reality:) I proceed to make the same sign for *yes* upon my mouth, moving my lips: lastly, I put my hand upon my eyes, and, making the sign for *no,* shew I do not see. There only remains the sign for the present to be made, and then I write down, *I believe;* but when written, it is better understood by my pupils than by the generality of those who hear. It is perhaps superfluous to repeat, that all these signs are executed in the twinkling of an eye."

In three separate chapters, the Abbé explains; how spiritual operations, which are the objects of logic, may be explained to the deaf and dumb, how they are instructed in the first truths of religion; and how they may be initiated even into the mysteries of our religion, by the use of these methodical signs. In a word, by these means he enables the mind to develop its powers, and to enter into even the more abstruse operations of intellect, into grammatical, logical, and metaphysical research.

To a person unaccustomed to reflect on the sources and means of improving the understanding, and not aware, that there is no actual connection in nature, between articulate sounds and the ideas which they represent, or that visible as well as audible signs, being alike arbitrary, may be equally associated with ideas, by habit, this method of tuition may appear altogether fanciful and impracticable. But experience has demonstrated its practical utility. M. Linguet, a member of the Royal Academy, having asserted that persons thus instructed could be considered as little more than *automata*, was invited by the Abbé de l'Épée to be present at his lessons. M. Linguet complied with the invitation, and the Abbé having desired him to fix upon some abstract term, which he would by signs communicate to his pupils, he chose the word, *unintelligibility*; which, to his astonishment, was almost instantly written by one of them. The Abbé informed him, that to communicate this word, he had used five signs, which, though scarcely perceivable by him, were immediately and distinctly apprehended by his scholar. The first of these signs indicated an internal action; the second represented the act of a mind that reads internally, or, in other words, comprehends what is proposed to it; a third signified that such a disposition is possible; these, taken together, form the word *intelligible*: a fourth sign transforms the adjective into a substantive; and a fifth, expressing negation, completes the word required. M. Linguet afterwards proposed this question, "What do you comprehend by metaphysical ideas?" which being committed to writing, a young lady immediately answered on paper in the following terms: "I understand the ideas of things which are independent of our senses, which make no impression on our senses, which cannot be perceived by our senses."

On reading this account of a human being, raised from a state of mental vacuity, little elevated above the brute, to a condition of high intellectual cultivation, and to the enjoyment of the best faculties and feelings of our nature, we cannot refuse our assent to the splendid eulogy of the dramatic poet (M. Bouilly) in his "Comparative Estimate of Worth."

"Science would decide for D'Alembert, and nature say Buffon; *suit and taste* present Voltaire, and *sentiment* plead for Rousseau; but *genius and humanity* cry out for De l'Épée, and him I call the *best and greatest of all.*" Dram. of "Deaf and Dumb."

It remains that we say a few words respecting the method employed by the Abbé de l'Épée, in teaching articulation and utterance to his deaf and dumb pupils. The principle on which this instruction is conducted, is, the observation on the part of the pupils of the different positions and motions of the tongue, lips, &c. in the speaker, which are connected in his mind with the words uttered, by seeing them written down at the same time on the table: the Abbé began his attempts to make a deaf and dumb person pronounce, by causing him to wash his hands thoroughly clean. This done, the Abbé traced an *a* upon the table, and taking his pupil's hand, introduced it into his mouth, as far as the second articulation; he then pronounced strongly *a*, making

the scholar observe, that his tongue lay still, without rising to touch his finger; he next follows the same course, pronouncing *e*. After these two operations, he put his finger into the pupil's mouth, making him understand that he is to do with his tongue, what the Abbé had done with his. The pronunciation of *a* is commonly effected without difficulty; that of *e* also succeeds for the most part; but the mechanism of it sometimes requires two or three explanations. He proceeds in a similar way with the remaining vowels; and then to the simple combinations of a consonant with each, as *pa, pe, pi*, &c. first writing each syllable, and then teaching the pupil to observe and to imitate the movement and mechanism of the organs of articulation.

It is unnecessary to detail the varieties of this process through the different combinations of vowels and consonants.

The principle is obvious. It sometimes happens, however, in the first lessons, that the pupils, having disposed their organs for the pronunciation of a particular letter, remain, nevertheless, without utterance, because they make no internal motion to expel air from the lungs. The Abbé pointed out the difference in the state of his organs, when he did and did not utter sound, by placing the pupil's hand upon his throat, by making him feel the concussion of air on the back of his hand, &c.; and if all this proved unsuccessful, a pretty sharp squeeze of the little finger would draw sound from him by way of lamentation.

In the commencement of this kind of instruction, it is necessary, 1st, for the deaf and dumb scholar to be directly facing his teacher, in order that he may lose none of the impressions given by the different modifications of the organs of speech in the labial alphabet; 2dly, for the teacher to render these modifications as strong as possible, that they may be the more perceptible; 3dly, for his mouth to be sufficiently open, to leave the different movements of the tongue visible; 4thly, for a slight pause to be made between the syllables of each word that the pupil is to write or pronounce. There is no necessity for the least emission of voice.

The deaf and dumb acquire very early a facility in comprehending the words uttered, from observing the motions of the speaker's mouth, lips, and tongue; and "being, moreover, to the full as curious as other folks to know what is said," the Abbé observes, "especially if they suppose themselves, or any thing interesting to them, the subject, they devour us with their eyes, (an expression hardly metaphorical here,) and, if not prevented by the precaution of turning from them to speak, easily discover all we say. This is a positive fact, evidenced every day in the three houses which are receptacles for these children, inasmuch that I always think it expedient to hint to persons honouring us with visits, to be cautious of uttering any thing before them not proper for them to understand. I confess, indeed, that they conjecture more than they distinctly perceive, when pains have not been taken to teach them the art of writing, solely by inspection of the movement of the lips, without the help of any sign.

"Before I had to instruct the multitude of deaf and dumb that have been successively pressed upon me," the Abbé adds, "my own application to the rules here laid down proved so effective, as to enable Lewis Francis Gabriel de Clement de la Préjode to pronounce, in public, a Latin discourse of five pages and a half; and, in the ensuing year, to lay down a dissertation of philosophy, detail proofs of its accuracy, and defend it in regular disputation, answering, in all scholastic forms, the objections offered against it by Francis Elizabeth John de Didier, one of his fellow students: (the arguments were communicated.) I also enabled another deaf and dumb

dumb scholar to repeat aloud to his mistress the twenty-eight chapters of the gospel according to St. Matthew, and to recite the morning service along with her every Sunday. These two examples must be sufficient."

But this is impracticable, he says, where there is a number of scholars to instruct: and the Abbé Sicard, his successor, for the reason already stated, has ceased to teach articulation, contenting himself with the instruction by writing and signs.

DUMDAH, in *Geography*, a town of Hindoostan, in the Ruttonpou country; 66 miles W. of Ruttonpou, and 112 E. of Nagpou.

DUMÉE, **GUILLAUME**, in *Biography*, a French painter, who was one of those who assisted in executing the works in the Louvre, in the latter part of the 16th century.

DUMEIDSJ, in *Geography*, a town of Arabia, in the country of Yemen; 36 miles N.N.E. of Chanir.

DUMFRIES, a town in the south of Scotland, situated on the river Nith, not far from where that river falls into the Solway frith. The town of Dumfries is airy and well built, and the country round it fertile and well cultivated. Upon the Nith are many beautiful and picturesque views, and many elegant mansions, the chief of which, perhaps, is the castle of Drumlanrig, the seat of the duke of Queensbury. Dumfries, although not properly a commercial or manufacturing town, possesses some coasting trade with the western ports of Scotland, and those situated in the north-west part of England. In general, its principal traffic consists in articles of provision, and those of common use, with which the inhabitants of the town and cultivators of the soil, reciprocally supply each other for mutual accommodation. Many woods in the neighbourhood of Dumfries have been felled of late, (chiefly those of his grace of Queensbury,) and this has occasioned a considerable trade in timber. But this seems rather a transient than a permanent traffic.

Dumfries is governed like the other royal boroughs of Scotland, and along with the boroughs of Sanquhar, Annan, Lochmaben, and Kircudbright, returns a member to parliament. The present is sir J. S. H. Maxwell, bart. For Dumfriesshire, the member is the Hon. W. J. Hope.

Dumfriesshire is fertile in the south, and towards its northern extremity, which is barren and mountainous, abounds in iron stone and lead ore.

DUMFRIES, a port of entry, and post town of America, in Virginia, and chief town of Prince William county. It lies on the north side of Quantico creek, 4 miles above its entrance into the Potowmack, and 10 miles from Colchester. Its public edifices are an episcopal church, a court-house, and a gaol; distant 23 miles N. by E. from Frederickburg, and 185 S.W. from Philadelphia.

DUMFRIESHIRE, a county of Scotland, situated on the southern border of that province, where it unites with England: and is environed with the shires of Kircudbright, and Ayr to the west, Lanark, Peebles, and Selkirk to the north; Roxborough to the east, and Cumberland and Solway-frith to the south. This area of land measures about 60 miles from N. W. to S. E., and 30 in a transverse direction. It comprehends three districts, or shewartries, *viz.* Annandale, Eskdale, or Wauchopedale, and Nithdale, which divisions derive their respective names from the principal rivers in each. The chief part of this county is mountainous, particularly near the middle, and on its eastern borders, where the eminences are lofty, and assume a barren, sterile appearance. They are mostly covered with wild heath, and abound with game. Numerous flocks of sheep and black cattle feed on

them. The vallies are, however, fertile and pleasant, and in these the chief towns, villages, and seats are situated.

In ancient times, this district is said to have been inhabited by a tribe of the Cimbræ, called *Selgove*, who were found here by the Romans when they established the province of Valentia, which extended from Adrian's wall, between the rivers Tyne and Solway, to the wall of Antoninus, between the rivers Clyde and Forth. After the departure of the Romans, a new kingdom was established by Ida, and the Angles in 547, and extended its government over the southern and western parts of Valentia. About the beginning of the ninth century, this was subjugated by the Picts and Scots, who established themselves here for a considerable length of time. Hence they made frequent irruptions into England. The situation of this county, on the immediate borders of each, rendered it a scene of perpetual hostility in the wars between the two kingdoms, and in the "Border History," we find, that the inhabitants of this county and of Cumberland were subjected to repeated depredations, massacres, and all the horrors of savage cruelty, by their neighbouring enemies. See "Beauties of England," vol. iii. in the General History of Cumberland, and more fully in Ridpath's "Border History." In the notes to Walter Scott's poems are many particulars relating to these deplorable conflicts.

This county contains four royal boroughs, Dumfries, Annan, Sanquhar, and Lochmaben, several small towns and villages, and is divided into 42 parochial districts, containing in all 52,329 inhabitants. Dumfrieshire contains many elegant seats, of which Drumlanrig, the seat of the duke of Queensbury, is the chief: Comlongan-castle, the seat of the earl of Mansfield; Barjarg, the residence of Mr. Hunter; and Amisfield, the seat of the earl of Wemyss; are also fine mansions. Few counties in Scotland possess more valuable, or more numerous minerals than Dumfrieshire. The hills, which border on Clydesdale, contain valuable lead mines, some of which are very rich in silver; and many other parts of the county possess mines of the same metal. Coal and lime-stone are found in several parishes: excellent freestone is also abundant. In the parishes of Penpont, Kirk-michael, and Canoby, are indications of iron; in Langholm copper is wrought; and in Westerkirk, on the estate of sir James Johnstone, a valuable mine of antimony has been lately discovered. Much of the lime-stone receives a polish equal to the finest marble, and many of the springs contain a small quantity of lime, giving them a petrifying quality. Besides the mineral springs of Moffat and Hartfell Spaw, there are many wells, which contain metallic or mineral impregnation. The rivers abound with trout and salmon, and on the shores of the Solway Frith the polype or animal flower is frequently found. In addition to the animals common to other parts of Scotland, it may be mentioned, that at Drumlanrig are still to be seen a few of the wild cattle which anciently inhabited the woods of Scotland. Sinclair's Statistical Account of Scotland.

DUMME, a river of Germany, in the circle of Upper Saxony, and marquisate of Brandenburg, which runs into the Jetze at Wulstro.

DUMMER, a township of America uninhabited, in Grafton county, New Hampshire, incorporated in 1773, S.W. of lake Umbagog, on the waters of Upper Ammonoosuck.

DUMMER SEE, *the, or Dummer Lake*, is a lake of Germany, in the former bishopric of Munster, which at present constitutes a part of the new kingdom of Westphalia. It is five miles in length, and two miles and a half in breadth, and adjoins the county of Dipholtz, and the former bishopric of Osnabruck.

DUMMERSTOWN, a township of America, in Windham county, Vermont, N. of Brattleborough, containing 1692 inhabitants.

DUMMOUDA, a river of Hindoostan, which runs into the Hoogly; 28 miles below Calcutta.

DUMNA, in *Ancient Geography*, an island placed by Ptolemy and Pliny in the northern ocean. Ortelius conjectures, that it is either the present isle of Hoy, or that of Waws.

DUMNII. See DAMNII.

DUMNONII. See DAMNONII.

DUMONT, JOHN, in *Biography*, baron Carlescron, an historical and political writer, flourished at the end of the 17th and beginning of the 18th centuries. After various changes in life, in France and in Holland, he became historiographer to his imperial majesty. He died about the year 1726. His principal works are, "Memoires Politiques pour servir a l'Intelligence de la Paix de Ryfwick," 4 tom. 12mo. "Voyages en France," &c. 4 tom. 12mo. "Corps univerval diplomatique du Droit des Gens," 3 tom. folio. This contains all the treaties of alliance, peace, and commerce, from the peace of Munster to 1709. "Lettres Historique depuis 1652," jusqu'en 1710.

DUMONT, N., a French painter of some merit; surnamed *the Roman*. He died at Paris, in a very advanced age, in 1781.

DUMOSÆ, in *Botany*, the nineteenth natural order in the *Philosophia Botanica* of Linnæus, and the forty-third of the *Predilections*. In the *Philosophia Botanica* it consists of the following genera, Viburnum, Tinus, Opulus, Sambucus, Ronceletia, Bellouia, Maurocœnia, Cassine, Rhus, Cotinus, Celastrus, Eonymus, Ilex, Tomex, Prinos, Calli-carpa, Lawsonia. In the synoptic table of the *Predilections*, p. 499, the genera stand thus. Sideroxylon, * Bumelia Swartz, Rhamnus, Phyllica, Ceanothus, Bättneria, Chryso-phyllum, Achras, Prinos, Ilex, Calli-carpa, Eonymus, * Rochefortia Swartz, Celastrus, Cassine, Viburnum? β. Sambucus? γ. Rhus, Schinus, Fagara. Those marked with an asterisk are inserted by the editor Dr. Giseke. The rest agree with Gen. Plant. except that Bättneria is added and Tomex omitted. By comparing these two lists we find a strong confirmation of Linnæus's own declaration in Gen. Plant. that he was not satisfied with this order, and that it required further examination. The name was taken from *dumus*, a thicket, because the plants are chiefly shrubs, or low bushy trees, such as form thickets. They are generally of a purgative, dangerous, or highly virulent nature, particularly some species of Rhus. The order having been confessedly left in so uncertain a state by its author, it is in vain to seek for any technical characters by which to define it, and unnecessary to shew how ill, in some points, it is afforded.

DUN, in *Geography*, a small town or France, in the department of the Creule, chief place of a canton, in the district of Guéret, with a population of 1057 individuals; its canton has a territorial extent of 295 kilometres, 13 communes, and 13,176 inhabitants.—Also, a small town of France, in the department of the Meuse, chief place of a canton, in the district of Montmedy, situated on the river Meuse, 9 miles S. of Stenay. It has only 988 inhabitants; but its canton contains 18 communes, and a population of 8388 individuals upon a territorial extent of 192½ kilometres.

Dun sur Auron, a small town of France, in the department of the Cher, called, till the year 1792, Dun le Roi, Dunum Regis. It is the chief place of a canton, in the district of St. Amand, on the river Auron, 21 miles S. E.

of Bourges, 30 miles S. W. of Nevers, and 192 miles S. of Paris. The number of its inhabitants amounts to 2710; its canton has an extent of 305 kilometres, and 13 communes, with a population of 7868 individuals.

Dun, in the *Manege*, a colour partaking of brown and black.

DUNA, in *Geography*, a river of Russia, named "Sapadnaia Dvina," and by the Lithuanians Daugava, derives its origin from a lake in the government of Tver, at Biala, not far from the sources of the Volga, pursues its course through this and the government of Plevove, constitutes the boundary between the government of Polotzk and Riga, the republic of Poland, and the duchy of Courland, and falls not far from Riga, at Dunamuende, into the Baltic. In its course, it receives several smaller rivers, as the Torop-tza, the Evelt, the Oger, and the Yagel, and from Courland the Bulder-Aa. The Duna is navigable through its whole course from the uppermost regions, facilitating the commerce from several governments, and from Poland and Courland, to an uncommon degree. It has, however, one inconvenience, that near Dunamuende, it has many shoals, which increase every year, and vary their positions, and those occasion much difficulty in the navigation. Besides, in the Dunaburg circle there are several falls, the shooting of which is attended with great difficulty and danger. Of these falls some reckon as many as fourteen. The constant defection of the water in summer renders the voyage still more difficult and dangerous, and on the early access of autumnal frosts utterly impossible. At Riga, the Duna is 900 paces broad. Here annually, in April, a bridge of pontoons is thrown across it, and fastened by poles, except the part that opens to let the ships go through, which is fixed to anchors. In November the river is generally covered with ice, which, in March or April, again breaks up. The frost not unfrequently makes the river passable on foot in the space of 48 hours. The bridge is then taken away, and safely laid by in a small arm of the river, called the "Soedgraben." Through the whole summer, the great number of ships of all nations, that lie close to the bridge on both sides, exhibits a fine sight. The Duna is the port of Riga. In the spring season the ice, which drives hither from Lithuania, stops the current about the town and towards the sea; and the outlet being thus stopped, and the accumulation continually augmenting, the most destructive inundations occur. The salmon of the Duna are the best and dearest in Livonia. This river has, in general, a sandy and clayey shore, and a discoloured water.

DUNABURG, or **DUNEBURG**, a small town of that part of Poland which fell to the share of Russia, at the final partition of Poland in 1795. It was one of the principal places in the Livonian palatinate, called, in the Polish language, Woiewodztwo Inflantskie. The provincial diets used to be held in this town.

DUNAMASE, in the Queen's county, Ireland, about four miles from Maryborough, forms a very conspicuous object from a great distance. Its name, which imports *the fort of the plain*, evinces it to have been considered and used as a place of strength in the earliest ages: the plain is what is called the *great heath*, nearly surrounding it. This rock is an elliptical conoid, and inaccessible on all sides, except to the east, which, in its improved state, was defended by the Barbican. D. Ledwich gives two plates, and a minute description of this place, in his "Antiquities of Ireland," for the purpose of illustrating the fortification of that day. It was for a long time a great check on the Irish, but from the time of Edward II. when lord Mortimer resided there, to the final subjugation of Ireland, it was often dis-

mantled

mantled and rebuilt. It was effectually destroyed by colonels Hewson and Reynolds in 1650, and has continued in ruins since that time. Ledwich.

DUNAMUNDE, a small town of Russia, in the government of Riga, about 10 miles from that place, at the mouth of the river Duna, with a strong castle, where the ships, which come from the Baltic into the river, pay a toll. It was taken by the Russians from the Swedes in 1710.

DUNAN POINT, a cape on the S. W. coast of the island of Skye. N. lat. 57° 3'. Long. 3° 5'. W. of Edinburgh.

DUNANE, in the Queen's county, province of Leinster, Ireland, a place where there is an extensive colliery, the coals of which are preferred to those of Castle-comer. The coal is of the kind called Kilkenny coal, the *coal-glance* of Jameson. Dunane is amongst the Sliebh-margy mountains, about 6 miles west from Carlow, and about 40 miles S. W. from Dublin. Beaufort.

DUNAVEZ, or **DUNAVITZ**, *Dunavetz*, *Dunajetz*, a small town of Austria, on the limits of Galicia and Hungary, situated on the river Dunavetz, which flows from the Carpathian mountains into the Vitula. It is on the road from Presburg to the famous salt mines of Wieliczka in Galicia, and it is the largest town in that part of the country. Articles of every kind are exposed in the street for sale on Sundays, and give it the appearance of a fair.

DUNAX, in *Ancient Geography*, a mountain of Thrace, according to Strabo; called Donuca by Livy; it is the most elevated part of Mount Rhodope.

DUNBAR, **WILLIAM**, in *Biography*, an eminent Scottish poet, was born, according to Mr. Warton, in 1470, but according to Mr. Pinkerton, in 1465, at Salton, a village on the coast of the Forth in East Lothian. He entered as a travelling novice of the Franciscan order; but he afterwards became dissatisfied with this condition, and relinquishing it, settled in Scotland about the year 1490. Here he acquired celebrity as a poet; but he does not appear to have gained any benefice, though he seems to have desired it. The course of his life, which is unknown, was terminated in the year 1530. His poetical pieces were numerous; they were partly serious and partly comic, and manifest readiness of invention, great energy, and richness of description. One of his chief poems is the "Thistle and Rose," which is a kind of vision, abounding in imagery, and written on occasion of the marriage of James IV. of Scotland with Margaret, daughter of Henry VII. of England. His "Golden Terge," is a moral allegory, exhibiting the shield of reason resisting the attacks of the amorous passion. One of his large pieces is the "Daunce," which is a vision of heaven and he'll in a comic style. Many more of his pieces are printed in the collection of ancient Scottish poems, by sir David Dalrymple, in 1770. Dunbar is said to have derived his poetic taste from the works of Chaucer, Gower, and Lydgate, but to have improved upon their manner. His language is the Scots dialect of those times, much resembling the English. Biog. Brit.

DUNBAR, in *Geography*, a parish and royal borough in the county of Haddington or East Lothian, Scotland. The former comprehends an area of about nine miles in length from E. to W. by two miles from N. to S. The ground rises gradually from the sea coast, and the land is esteemed some of the most fertile in Scotland, which induced Mr. Pennant to call this district the Northamptonshire of North-Britain. It is well cultivated, and produces large crops of wheat, barley, and beans; with smaller crops of oats, clover, rye-grass, turnips, and potatoes. Two large roperies are established on the coast. This parish is famous from containing the

encampment which was occupied by general Leslie and the Scots army, who were defeated by Cromwell.

The borough is seated on a rock near the sea, which here forms a small bay or harbour. The east pier of this was begun during the protectorship of Oliver Cromwell, who gave 300*l*. towards defraying the expence. Since that time it has been much improved; it is safe but small, and its entrance narrow. It is defended by a battery of 12 guns. The chief trade of this place is the exportation of corn, of which there are on an average about 10,000 quarters annually shipped off. Here is a small dry-dock; and several fishing boats are annually fitted out from this town. Attached to the port are 18 vessels of 2180 tons burthen employed in the coasting trade, besides 12 fishing boats.

The ruins of the castle are still considerable. It stands on an elevated rock impending over the sea. It has been a fort of great strength, and the scene of many important transactions. "In 1567 it was in the possession," says Pennant, "of the infamous earl Bothwell, who here committed the simulated outrage on the person of the fair Mary Stuart. Here also the earl retreated after being given up by his mistresses at the capitulation of Carberry-hill." Edward II. took shelter within its walls in his flight from Bannockburn. In 1336, it was most courageously defended by Agnes, countess of March; who in the absence of her husband was besieged by lord Montague and his troops, but they were obliged to raise the siege and leave the country. Here are still preserved some of the famous Scotch pikes, six ells long.

Between the harbour and castle, is a surprising stratum of stone, which, in some respects, resembles that called the Giant's-caufeway in Ireland. It consists of great columns of red grit, either triangular, quadrangular, pentangular, or hexangular: their diameter from one to two feet, their length, at low water, thirty feet, and they dip, or incline a little to the south. They are jointed, but not so regularly, or so plainly, as those of the Giant's caufeway. This range of columns faces the north and extends about two hundred yards in front. The breadth is inconsiderable; the rest of the rock consists of shapless masses of the same sort of stone irregularly divided by thick septa.

Beneath the castle is a vast cavern, partly natural and partly artificial; and near it are two "natural arches through which the tide flowed."

Dunbar is now a respectable, well built town, and is supplied with good water conveyed in pipes from springs about two miles distant. The borough is governed by a provost, three bailiffs, a dean of guild, treasurer, and 15 counsellors. It joins with Haddington, North-Berwick, Lauder, and Jedburgh, in sending one member to parliament. It is nearly equidistant from Edinburgh and Berwick; being 27 miles from each. In the town are two convents; one for Mathurines, and the other for Carmelites. In the church is a magnificent monument, to the memory of sir George Home, earl of Dunbar, "the worthiest and best Scotch minister of James VI." He died Jan. 29, 1610. Sinclair's Statistical account of Scotland, and Pennant's Tour in Scotland, vol. 1.

DUNBARTON, a township of America, in Hillsborough county, New Hampshire, incorporated in 1765, and containing 1222 inhabitants; nine miles S. of Concord, and 35 W. of Portsmouth.

DUNBEATH, a river of Scotland, in the county of Caithness, which runs into the German ocean, eight miles N. E. from the end of Caithness.

DUNCAN, **DANIEL**, in *Biography*, an eminent physician, born at Montauban, in Languedoc, in 1649, was the son of Dr. Peter Duncan, professor of physic in that city, and grandson

grandson to William Duncan, an English gentleman, of Scottish origin, who removed from London to the south of France about the beginning of the 17th century. Having lost both his parents in his early infancy, he was taken under the protection of his mother's brother, Mr. Daniel Paul, a councillor of the parliament of Thoulouse, though a firm and professed Protestant. Instructed in the first elements of grammar, polite literature, and philosophy at Puy Lauren, where the university of Montauban then subsisted, he was removed by his uncle to Montpellier, and placed under the immediate instruction of Dr. Charles Barbeyrac, whose physical lectures and practice were in high reputation. Under this excellent master, who distinguished him by his esteem and friendship, he pursued his studies for eight years, and at the age of 24 he was admitted to the degree of M. D. in that university. He afterwards resided seven years at Paris; and here he published his first work, upon the principle of motion in the constituent parts of animal bodies, entitled, "Explication Nouvelle et Mécanique des Actions Animales," Paris 1678. In the following year he visited London, for the purpose of transacting some family concerns, and of obtaining information concerning the effects of the plague in London, in 1665. He also availed himself of this opportunity for collecting vouchers for the respectable rank which his family had borne in Scotland and in England; with a view of justifying his claim to the letters of noblesse, which had been conceded to him in France, at a time, *viz.* in 1677, when, by favour of the great Colbert, he was appointed physician general to the army before St. Omer's, commanded by the duke of Orleans. During his stay of two years in London, he printed a Latin edition of his "Theory of the Principle of Motion in Animal Bodies." His inclination to settle in London was diverted by a summons which he received from Paris in 1681, to attend his patron Colbert, whose health was then beginning to decline. He does not seem, however, to have entertained a very high opinion of the mode in which the practice of medicine was then conducted in London; as we may conclude from a MS. upon "the prevailing abuses in the established practice of Physicians and Apothecaries in different parts of the World." Soon after his return to France, he published in three parts a popular work, entitled "Chymie Naturelle, ou Explication Chymique et Mécanique de la Nourriture de l'Animal," a second edition of which appeared at Paris in 1687. In this year he published also his "Histoire de l'Animal, ou la Connoissance du Corps; animé par la Méchanique et par la Chymie." Upon the death of Colbert, in 1683, he left Paris, and went to Montauban, in order to settle his affairs, and to prepare for taking up his final abode in England. His friends, however, prevailed upon him to continue in his native city. But the persecution which raged against the Protestants with great violence in 1690, obliged him to retire first to Geneva, and afterwards to settle for about eight or nine years at Berne, where his medical practice was considerable, and where he had the charge of a professorship of anatomy and chemistry. In 1699 he was sent for to Cassel by Philip, landgrave of Hesse, and remained as his domestic physician for three years. Under the hospitable roof of this prince, he wrote his treatise upon the "Abuse of hot Liqueur," with a particular view to the case of the princefs of Hesse, who had indulged in the excessive use of tea, coffee, and chocolate, and who was then in so feeble a state as to incline to a consumption. Although he condemned excess, he allowed the prudent use of them, particularly to persons of a phlegmatic constitution. This work, which was at first circulated in MS., was afterwards, by the persuasion of his friend Dr. Boerhaave, printed

first in French, under the title of "Avis salutaire à tout le Monde, contre l'Abus des Liqueurs chaudes, et particulièrement du Café, du Chocolat, et du Thé;" Rotterd. 1705. In the following year it was printed in English, at London. During his abode at Cassel he contributed to the relief of those Protestants, who were obliged to abandon France on account of the persecution they suffered, and to seek an asylum in Brandenburg. The fame of his liberality reached the court of Berlin, and he was invited thither by the reigning prince; but though he met with great encouragement as professor of physic and physician to the royal household, a regard to his health and to economy obliged him to remove, in 1703, to the Hague. He continued here about 12 years, during which period he was induced by Dr. Boerhaave, to publish a Latin improved edition of his Natural Chemistry, entitled "Chymia Naturalis Specimen, quo planè patet nullum in Chymicis officinis processum fieri, cui similis, aut analogus in Animalis Corpore non fiat." Amstel. 1707. At this time he commenced a correspondence with Dr. Mead, on a variety of subjects immediately connected with his profession. In 1714 he accomplished the purpose which he had always in contemplation, of settling in London: but just before he left the Hague, he sustained a stroke of the palsy, which alarmed his friends, though it was attended with no permanent injury to himself. As it had been his declared intention, if providence extended his life to the age of 70, to devote the remainder of his days to the gratuitous service of those who sought his advice, he attained that age in 1719, and fulfilled his intention during the last 16 years of his life. To the rich who consulted him, from whom he peremptorily refused to take a fee, he used to say with a smile, "The poor are my only paymasters now; they are the best I ever had; their payments are placed in a government fund that can never fail; my security is the only KING that can do no wrong;" alluding to the loss he sustained in 1721, of a third part of his property by the South-sea scheme. He left behind him a great number of MSS., mostly physical, some upon religious subjects, and one containing many curious anecdotes of the history of his own time. Among his physical MSS. the most considerable is a Latin treatise upon contagious distempers, to which is prefixed a very ample dissertation upon the plague, &c. which appears to have been written in the year 1679. Dr. Duncan was in his conversation easy, cheerful, and interesting; in his disposition ingenious and benevolent; and in his religious profession, a sincere Christian and a zealous protestant. He died at London, April 30, 1735, aged 86. His only son, the Rev. Dr. Daniel Duncan, was the author of some religious tracts, and died in June, 1761, leaving behind him two sons, both clergymen; one of whom, *viz.* Dr. John Duncan, has "sustained the honour of his family, in the respectability of his character, in the liberality of his mind, and in his ingenious and valuable publications, both as a poet and divine." Biog. Brit.

DUNCAN, WILLIAM, was born at Aberdeen in the year 1717, where he received the greater part of his education. When he had finished the ordinary course of philosophy and mathematics, he was admitted to the degree of M. A. He now studied very diligently theology under the professors at Aberdeen, with a view, probably, of engaging in the Christian ministry, which, upon more mature deliberation, he afterward thought proper to abandon. He then removed to London, and was employed in many literary undertakings, particularly in translations from the French language. He is supposed likewise to have had a large share in the translation of Horace, which was published under the name of Watson. His talents as a translator were

highly appreciated; and the expectation of the public was fully answered in his version of the Select Oration of Cicero accompanied with notes. He next published "The Elements of Logic," which have obtained a high reputation, and which were originally written for Doddley's Preceptor, published in 1748. In the year 1752 he published a translation of Caesar's Commentaries, which was at first given to the public in the folio size, but has since appeared in 8vo. This work is at once faithful and elegant, and is rendered more valuable by an introductory treatise on the Roman art of war. About the same time Mr. Duncan was appointed by the king professor of philosophy in the Marischal college of Aberdeen. The duties of this office were confined chiefly to the illustration of the principles of natural and experimental philosophy. In this department, though not the favourite pursuit of his life, he highly distinguished himself. The labour was, however, more than adequate to his strength, and he began rapidly to decline in health. He died in 1760, in the forty-third year of his age; leaving behind him an excellent character as a man of learning, and exemplary in all the duties of life. Biog. Brit.

DUNCAN'S Bay, in *Geography*, a bay on the N. coast of the island of Jamaica. N. lat. 18° 31'. W. long. 77° 31'.

DUNCANNON, a fort in the county of Wexford, near the entrance of Waterford harbour, and 20 miles south from New Ross. It is at present used as a barracks.

DUNCANSBOROUGH, a township of America, in Orleans county, Vermont, on the west side of lake Memphremagog, containing 50 inhabitants.

DUNCANSBY HEAD, a cape of Scotland, at the N. E. extremity of Great Britain, in the county of Caithness. N. lat. 58° 33'. E. long. 0° 19'.

DUNCARD'S BOTTOM, a tract of fine lands in America, on the E. side of Cheat river, in Virginia, about 22 miles from its mouth, and 49 W. S. W. from Fort Cumberland.

DUNCHURCH. See **DIMCHURCH**.

DUNCOMBE, WILLIAM, in *Biography*, was born in London in the year 1690. After the usual school education, he was entered at the age of sixteen as a clerk in the navy office. His taste for polite literature was first known to the public by the appearance of a translation of an Ode of Horace. He next published a version of the "Carmen Seculare," which was soon followed by one of "Racine's Athaliah." In 1725, he quitted the navy-office, and devoted himself wholly to a life of literary leisure. In the following year, he married the sister of Mr. Hughes, the poet, and spent the remainder of a long life in virtuous and innocent pursuits, and in friendly intercourse with some of the most respectable characters, among whom were the earl of Cork and archbishop Herring. He died in 1760. His principal works were the tragedy of "Brutus" altered from Voltaire: and with the assistance of his son, an entire version of Horace, with notes, in two volumes, but which came out in 1764 in four volumes, 1. mo. Biog. Brit.

DUNCOMBE, JOHN, son of the preceding, was born in 1729; and at the age of sixteen entered himself at Corpus Christi College, Cambridge, where he was distinguished by the regularity of his conduct, and by his great proficiency in polite literature. He became fellow of his college, and afterwards took orders, and obtained valuable preferments in the church. He was a good poet, and was the author of many pieces which have appeared in the collections of Doddley, Pearch, and Nichols, and f. me in a separate form. Of these the best known is "The Femaleiad," a commemoration of feminine excellence. He furnished papers and essays, in a variety of periodical publications. He published three Sermons, and some antiquarian papers in the Bibliotheca

Topographica, and was editor of "Sir Hugh's Correspondence;" "The earl of Cork's Letters from Italy;" and "Archbishop Herring's Letters." He died in 1788. Biog. Brit.

DUNDALK, in *Geography*, a market and post town of the county of Louth, in Ireland. It is a large ancient and thriving town, with a wide street, nearly a mile long, and a good market house. It is also the county town. In the reign of Edward II. it was, for a short time, the residence of Edward Bruce, who was there crowned king of Ireland. It is advantageously situated for an extensive inland trade; and the port is very safe for shipping. The only cambrick manufacture in Ireland is carried on in this town. It returns one member to the Imperial parliament. Dundalk is on the great northern road, 40½ miles N. of Dublin. Long. 6° 23' W. Lat. 53° 59' N.

DUNDAS, a county of Upper Canada, bounded on the E. by the county of Stormont, on the S. by the river St. Lawrence, and on the W. by the easternmost boundary line of the late township of Edwardburgh, running N. 21° until it intersects the Ottawa, or Grand river; thence descending that river till it meets the north-westernmost boundary of the county of Stormont. This county comprehends all the islands near it in the river St. Lawrence. The boundaries were settled by proclamation July the 26th, 1792. It sends one representative to the provincial parliament. Morfe.

DUNDEE, a town in the county of Forfar or Angus, situated on the north bank of the Tay, not far from its confluence with the German ocean. The town of Dundee is well built, and, like most other Scotch towns, chiefly of free-stone; it also contains some handsome public buildings. The etymology of its name has been said to be taken from the Latin words *donum Dei*, an appellation said to have been given by a brother of William I. of Scotland to a church which he erected here upon his return from a crusade. But this seems at least very doubtful, for the Roman names of many towns in Britain, occupied by their legions, while in possession of the island, terminate in *donum*, and to this day, whether derived from this source or not, the syllable *dun*, with which so many of the names of the Scottish towns commence, means in the Gaelic a fort, castle, or town. The distinction between these, in rude times, was probably not much attended to, as all the towns, during the prevalence of the feudal system, were more or less fortified. The castle of Dungalas in Dumbartonshire, which is generally supposed to have formed the last Roman post at the western extremity of the wall of Adrian, signifies the *grey castle*, and from analogy it is not unreasonable to suppose that the fort, town, or castle of the Tay, may have been the original meaning of the word Dundee, more especially as the letter D is generally founded by the Highlanders, as well as the Germans, like that which the English give to the letter T. Indeed one of the Roman names of this town is said to have been Tawdunum.

The harbour of Dundee is very good, and capable of containing a great number of vessels, and a considerable tonnage belongs to the town. But Dundee cannot properly be considered, either at present, or likely to become, an extensive commercial place. Although the situation of the Tay is favourable for the trade of the Baltic and northern part of Europe, it is by no means so for that of America, or the West Indies. Besides this, it has few articles of manufacture to export, excepting sail-cloth and the coarse linens, known by the name of Osnaburghs, and these articles are manufactured in the very countries to which it is most contiguous. Many of the Osnaburghs manufactured in Dundee are indeed exported to the West Indies for the purpose

of clothing the negroes; but these, instead of being directly sent, are generally sold to the merchants of London, Liverpool, and Glasgow, who are more immediately interested in supplying these colonies.

Hence the ships which have traded from Dundee to the Baltic, have been generally sent for the purpose of importing flax and hemp for the use of their manufacture, and as the country produces nothing which she can export in exchange for those articles, the ships have most commonly been cleared out in ballast, and the returning cargoes paid for by bills on London. A considerable number of vessels, however, are employed in the coasting trade, and five or six ships are annually dispatched to the Greenland whale fishery. The salmon fishery in the river Tay forms a considerable trade to Dundee. These fish were formerly caught by the hauling net, or *seine*, considerably farther up the river, and nearer to the town of Perth than Dundee, but they are now intercepted in their passage up by large nets fixed to stakes in convenient situations, and sent to London packed in ice, excepting in very hot weather, when they are pickled to preserve them.

It has been already stated, that the chief manufacture of Dundee consists of coarse linen goods, as sail-cloth, Osnaburghs, and pack sheet for cotton wool, and other purposes. The sail cloth made at Dundee is chiefly sold by government contracts for the supply of the navy, those for the merchant service being mostly made in England. Hence this branch of their trade has flourished chiefly in time of war, and during long intervals of peace has frequently experienced a total stagnation. The Osnaburghs are a species of coarse linen manufactured in imitation of those made in Germany, and this trade is encouraged, and indeed supported by government, partly by heavy duties on the German linens imported into the British colonies, but chiefly by a bounty of three halfpence *per yard*. As the cloth, which is about 25 inches broad, does not exceed sixpence *per yard*, average value, the bounty may be estimated from 25 to 30 *per cent. ad valorem*.

How far such a premium may be right, or wrong, cannot be discussed in this article, and, indeed, it cannot be decided by any power, except the legislature of the united kingdom.

The soil between Dundee and Perth, known by the name of the Carle, or Kerle, of Gowrie, has always been esteemed the most fertile in Scotland. The remarks of an intelligent correspondent will convey an idea of that recent improvement, which fortunately prevails every where in this island. "Agriculture has improved, in a prodigious degree, within these few years, in this neighbourhood. Heavy wheat-crops are now raised upon soils, and in situations which our forefathers thought scarcely fit for any thing. Considerable quantities of wheat and barley are now sent, coast-ways, to England. Rents, as the leases expire, are doubled, or trebled."

The town of Dundee is governed by a provost, bailies, and council, like the other royal boroughs in Scotland, and, in conjunction with Forfar, St. Andrew's, Cupar (of Fife), and Perth, returns a member to parliament. The present member for the boroughs is Sir David Wedderburn, and for the county of Forfar is the Hon. William Maule of Paumu, brother to the earl of Dalhousie.

The population of Dundee, taken under the authority of the act of 1801, is estimated at 22,500.

Dundee formerly gave the title of viscount to the unfortunate and accomplished nobleman who fell at the battle of Killecrankie, in 1689. Since his death the title has not been revived.

1 DUNDIVER, in *Ornithology*, the name of a water-fowl, esteemed a distinct species of bird, not only by the vulgar,

but by the generality of authors; but supposed by others to be the female merganser, or goosander, a species of the *Mergus*; which see.

DUNDRUM, in *Geography*, a village of the county of Down, province of Ulster, Ireland, that gives name to a very extensive bay, which is, however, shallow and accessible only to small vessels. The outer bay abounds with sea-trouts and lobsters, and other species of white and shell fish, which afford employment to a number of boats. Dundrum is a small pleasant village, prospering by this fishery. Above the village are the ruins of an old castle, once a strong hold of considerable importance. It is 68 miles north from Dublin.

DUNDUKOVA, a settlement of Russian Siberia, in the government of Tobolsk; 300 miles N.N.E. of Turuchanfk. N lat. 70° 16'. E. long. 95° 14'.

DUNES, a small town of France, in the department of Lot and Garonne; three miles from the Gironne, between the rivers Giers and Baise.

DUNFANAGHY, a small post-town in the county of Donegal, province of Ulster, Ireland. It is not far from the promontory of Hornhead; 133 miles N.W. from Dublin.

DUNFERMLINE, a town in the western part of Fife-shire, and formerly a place where the parliament of Scotland occasionally met, previous to the union. The town of Dunfermline is pleasantly situated on the ridge of a hill, and many parts of it command an extensive view of the frith of Forth. The passage from Edinburgh, and the eastern district of Scotland, is the Queen's-Ferry, from which it is about six miles distant. The town of Queen's-Ferry is situated on the southern bank of the Forth, and on the Fife-shire side is a small village, called the North Queen's-Ferry, chiefly inhabited by ferry-men, who ply between the two shores, which are much frequented, being the most ready access between the northern and southern districts of Scotland upon the eastern coast. The shores of the Forth present the appearance of two bold promontories, at the Queen's-Ferry, and the passage is about two miles, although the Forth is much broader farther up, opposite to the sea-port town of Borrowstoness, and even at Grange-mouth, where the great canal connecting the Forth and Clyde begins, and terminates at Bowling bay, in the county of Dumbarton. The narrow passage at the Queen's-Ferry occasions a considerable current, by the flux and reflux of the tide, which is increased by a small island, called Inch-Garvie, situated in the middle of the channel. Upon this island are the ruins of an ancient castle, and it has been lately fortified, and batteries of cannon have been placed upon it, as a defence for the upper part of the Forth. The fares for the passage at the Queen's-Ferry are regulated by the magistrates, like those of the watermen upon the Thames.

Dunfermline was anciently a residence of the kings of Scotland. The abbey church is still preserved in such order, as to serve for a place of public worship. The palace has been long in ruins; and a few years ago a part of it fell, by which several horses, stalled in a stable built contiguous to the wall of the place, were killed, but fortunately, as it occurred during the night, no other accident happened.

The church and palace are said to have been built by Malcolm Canmore.

The county of Fife, contiguous to Dunfermline, is generally fertile, the soil being a rich clay; and the agriculture has rapidly improved of late. Coals are found in great abundance in the immediate vicinity. Of these, the works of Sir John Henderford, of Fordell, bart. are, perhaps, the most extensive. A very curious colliery has lately been

executed by sir Robert Preston, of Valley-field, bart. The mine is situated on a small island in the Forth, near the village of Torryburn, about four miles west from Dunfermline. The island was frequently covered by the tide at high water; but sir Robert, having formed an embankment, at an immense expence, and erected a steam-engine to draw the water, actually succeeded in sinking a pit and procuring coal. The situation of the island certainly affords every convenience for loading coal, but the quality is said not to be equal to that of many of the neighbouring proprietors. The coal trade here is a matter of considerable importance, as many of the northern parts of Scotland, where coal has not been found, are supplied either from hence, or from Newcastle-upon-Tyne.

The country is also plentifully supplied with lime, from the works of the earl of Elgin, at Charlestown, and other lime-works. A considerable quantity of lime is also carried coast ways, to supply the north-east coast of Scotland, from Charlestown.

The chief manufactures at Dunfermline is that of table-linen, although many weavers are also employed in the cotton-manufacture. The latters are chiefly employed by the manufacturers of Glasgow; though that city, by the way of Sterling, is about 50 miles distant from Dunfermline.

The damask and diaper manufactures have proved very productive sources of wealth to this town, and the numerous villas, with which its environs are adorned, afford a pleasing proof of the skill of its artizans, and the success of their employers.

Dunfermline, like the other royal burghs of Scotland, is governed by a provost, magistrates, and town-council, and returns a member to parliament, in conjunction with Sterling, Culrois, Inverkeithing, and the Queen's Ferry. The election for these boroughs has of late been frequently very hotly contested. The present member is major-general Campbell, of Mouzie. The member for the county of Fife is lieutenant general Wemyss, of Wemyss castle.

Not far from Dunfermline are the extensive distilleries of Kennet-Pans and Kibragie, which are said to pay an annual excise duty of not less than half a million sterling.

The population, under the act of 1801, is taken at 5192.

The title of earl of Dunfermline perished in the attainer, subsequent to the rebellion in 1715, and has since been extinct.

DUNG, in *Agriculture*, &c. All kinds of dung contain some matter, which, when mixed with the soil, ferments therein, and, by that fermentation, dissolves the texture of the earth, and divides and crumbles its particles very much. This is the real use of dung in agriculture; for, as to the pure earthy part of it, the quantity is so very small, that after a perfect putrefaction, it bears an extremely inconsiderable proportion to that of the earth it is intended to manure.

The fermenting quality of dung has been supposed to be principally owing to the salt it contains; and yet those, or any other salts, applied immediately to the roots of plants, always destroy them. This proves that the business of the dung is not to nourish, but to divide and separate the terrestrial matter, which is to afford the nourishment to vegetables through the mouths of their roots. And the acrimony of the salts of dung is so great, that the nicest managers of vegetables we have, the florists, have wholly banished the use of it from their gardens. The use of dung should be also forbid in kitchen-gardens; for it is possible to succeed full as well without it; and it gives an ill taste to all the roots and plants that are to stand in the earth, in which it is an ingredient. The water of a cabbage raised in a garden manured with dung, if boiled, is of an intolerable stink; but this is not so much owing to the

nature of the plant, as of the manure used to it; for a field cabbage being boiled, the water has scarce any smell, and what it has, is not disagreeable.

It is also a well-known fact in the country, that a carrot raised in a garden has nothing of that sweet flavour, that such as grow in the fields have; but instead of this natural relish, the garden one has a compound taste, in which the matter of the manure has no small share. And there is the same sort of difference in the taste of all roots nourished with such different diet. Dung not only spoils the flavour of the esculent vegetables, but it spoils the drinkables into the original composition of which it enters: they are obliged to use dung to the poor vineyards of Languedoc; and the consequence is, that the wine is nauseous. The poor, who only raise a few vines for the wine they drink themselves, and cannot be at the expence of this manure, have the less of it, but then it is better, by many degrees, than the other; and it is a general observation, which the French express in these words, that the poor people's wine in Languedoc is the best, because they carry no dung into their vineyards. (Tull's *Horse-hoeing Husbandry*, p. 20.) Another disadvantage attending the use of dung is, that it gives rise to worms. It is for this reason, that garden carrots are generally worm-eaten, and field carrots found; and the same observation will hold good in other vegetables, in the field and in the garden. Vegetable and animal dung are, in fact, only the putrefaction of earth, after it has been altered, by passing through vegetable or animal vessels. Vegetable dung, unless the vegetable be buried alive in the soil, makes a much less ferment in it than animal dung does: but the dung, or putrid matter of vegetables, is much more eligible and wholesome for the esculent roots and plants than that of animals is. Venomous animals are found to be very fond of dung, and are brought into gardens by the smell of the dung used in them as manure. The snakes usually frequent dung-hills, and lay their eggs in them; and gardens, where dung is much used, are always frequented by toads; whereas the fields where roots are planted, are much less infested by them.

However unnecessary and prejudicial dung is in gardens, it is, however, very necessary in the corn-fields; and little can be done without it in the old method of husbandry. Dung is not so injurious in fields as in gardens, because it is used in much smaller quantities in proportion to the quantity of soil; and cabbages, turnips, potatoes, and other things growing in fields, and intended only for the food of cattle, will not be injured by dung, tillage, and hoeing all together; for the crops will by this means be the greater, and the cattle will like the food never the worse. Dung is very beneficial in giving very large crops of wheat; and it is found by experience, that the country farmer, at a distance from a large town, can never have so good crops by all his tillage, as those who live in the neighbourhood of cities, where dung is produced in great plenty, and easily had. The dung used in fields, besides its dissolving and dividing virtue, is of great use in the warmth its fermenting gives to the young plants of the corn in their weakest state, and in the most severe seasons; the lasting of this ferment is not easily determined, because the degrees of heat are very difficult to be judged of when they become small.

The farmers usually understand by the term dung, not only the excrements of animals, with the litter, but every thing that will ferment with the earth; such as the green stalks and leaves of plants buried under ground, and the like, and every thing they add to it, except fire.

The uses of the dungs of several animals are sufficiently proved every day. They are used to repair the decays of exhausted and worn-out land, and to cure the several defects

fects in different natural bad soils; the faults of which are as different as the nature of the different dungs used to improve them. Some land is too cold, moist, and heavy; and the other too light, and dry; and to improve and meliorate these, we have some dung hot, and light, as sheep's, horse's, pigeon's, &c. and other fat and cooling, as that of oxen, hogs, &c. There are two remarkable qualities in dung; the one is to produce a sensible heat, capable of bringing about great efforts; the other is to fatten the soil, and render it more fertile. The first of these is seldom found in any but the dung of horses or mules; the great effects of which, when newly made, and a little moist, are seen in the kitchen-garden, where it invigorates, and gives a new life to every thing, supplying the place of the sun; and to this, in a great degree, we owe all the vegetable delicacies of the spring. Besides, horse dung is the richest of all improvements that can be had in any quantity for poor hungry lands; yet, when either too new, or when used alone, it is very prejudicial to some lands; and if spread too thin on dry lands in summer, it becomes of very little service; the sun soon exhaling all its riches, and leaving it little more than a heap of stubble or dry thatch. Horse dung is always best for cold lands, and cow dung for hot ones; but being mixed together, they make a very good manure for most sorts of soils, and for some they are very properly mixed with mud.

Sheep's dung, and deer's dung, differ very little in their quality, and are esteemed by some the best of all dung for cold clays; for this purpose some recommend the beating them to powder, and spreading them thin over the autumn or spring crops, at about four or five loads to an acre, after the same manner as ashes, malt-dust, &c. are strewed. And in Flanders, and some other places, they house their sheep at night in places spread with clean sand, laid about five or six inches thick, which being laid on fresh every night, is cleared out once a week, and with the dung and urine of the sheep, is a very rich manure, and sells at a very considerable price. It is principally used for stubborn lands; but Mr. Quinteny is of opinion, that it is the best of all manure for land in general.

Hog's dung is by many recommended as the fattest and richest of all dung; and is found, by experience, to be better than any other kind for fruit trees, apples, pears, and the like. It is also a very rich dung for grass, and is said to do as much good in one load, as any other dung whatever in two.

The dung of pigeons, hens, and geese, are great improvers of meadow and corn land. That of pigeons is unquestionably the richest that can be laid on corn land; but before it is used, it ought to be exposed for some time out of the dove-house to the open air, to take off its fiery heat. It is in general very proper for cold clay lands; but then it always should be well dried before it is laid on, because it is apt to clod in the wet. It is best also to mix it with some dry earth, to break its parts that it may be spread the more regularly; and it is in itself so very rich and hot, as to bear such an admixture without greatly impoverishing it. This dung is also by some recommended as better than any other for asparagus and strawberries, and for the propagation and culture of the tender garden-flowers. The dung of pigeons is also particularly recommended by M. Gentil for those trees whose leaves are apt to turn yellow, if they grow in cold soils; but for this use, it should first lie three years in a dung-hill, and then be applied sparingly in autumn, laying about an inch thickness of it at the root of the tree, and suffering it to remain there till the March following.

The dung of poultry being hot, and full of salts, tends much to facilitate vegetation, and is abundantly quicker in

its operation than the dung of animals which feed on the leaves of plants. It is an observation of Sir Hugh Plat, that one load of grains will enrich ground more than ten loads of common dung; and it is easy to infer from hence, that the same grain must needs be of greatly more virtue, when it has passed through an animal body. Human dung is a so great improver of all cold and sour lands, but succeeds best when mixt with other dungs or earths, to give it a fermentation.

But for all stubborn clayey soils, there is no manure so good as the cleaning of London streets; the parts of tough land will be more expeditiously separated by this than by any other compost; and where it is to be bad, it is of the greatest value both for field and garden land. Miller's Gard. Dict.

DUNG Drag, is a sort of crooked fork with only two lines or teeth, which is often employed in setting out dung in heaps, upon land for drawing out of the cart.

DUNG, Goose. This is a very valuable manure, and as useful to the farmer as pigeon's dung, or that of any other fowl. The ancients thought otherwise, and condemned it as prejudicial both to corn and grass; and many are of the same opinion still, but without any foundation in fact. Indeed, where corn is high, and when grass is ready to be mown, these birds, if they get among it, will do great damage, by treading it down with their broad feet; but their dung, instead of being hurtful to the land, does it great service. Near Sutton, in Nottinghamshire, there is a barren piece of land given by the town for a goose-pasture; the geese have been kept in it many years, and their dung has so enriched it, that it is one of the most fruitful pieces of ground in the whole county. There has been an opinion also, that cattle feeding on grass, where these creatures had much dunged the ground, would suffer by it; but it appears from trial, that cattle are most fond of all those parts of pastures where the geese have dunged most, and that they suffer no alteration by it, except the growing fat upon it. The dung of fowls in general is very enriching to land; and Fowley Island, in Lancashire, a place so called from the abundance of wild fowl continually found on it, is so enriched with their dung, that it fattens sheep in a surprising manner. See COMPOST and MANURING.

DUNG-meers, or *dung-hills*, in *Husbandry*, places where soils and dungs are mixed and digested together. For this purpose, it is usual to dig a pit sufficient to hold the stock of soil the husbandman is capable of making, and to prepare it at the bottom with stone and clay, that it may hold the water and moisture of the dung; and it should be so situated that the drips of houses or barns may run into it. Into this pit they cast refuse fodder, litter, dung, weeds, &c., where they lie and rot together till the farmer has occasion for it. Where such a pit is wanting, it is necessary to cover the dung with turf, or other stuff, to prevent the sun and wind from drawing off its virtues. Compost dung-hills, which are formed by a mixture of earth with dung, lime, and other manure, are made with least expence on the field for which they are intended.

DUNG-worms, a species of fly-worms, of a short and somewhat flat body, found in great plenty among the cow-dung in the months of September and October. These have all their metamorphoses into the fly state performed within a shell of their own skin.

The fly produced from this worm is one of Reanmur's first class of the two-winged flies; it has a trunk with lips, and has no teeth; it is of the class of those with the ellipsoid bodies; but its body is remarkable long for one of those, and is composed of six rings: its head is very round, and
nearly

nearly of a spherical form, and is large in proportion to its body; it has antennæ of the lenticular or battle-dore form; its reticular eyes are of a deep chestnut brown, and its three small eyes are placed in the common manner. Its corselet is of a fine gilded green; and its back is not easily to be described as to colour, for it is changeable, and seems composed of a violet colour, and of a deeper and a paler copper colour. The under part, or belly, is of a pale yellow, and the legs and balancers of a yet paler yellow. Reaumur's *Hist. Insect.*, vol. iv. p. 350.

DUNGA, in *Ancient Geography*, a town of India, assigned by Ptolemy to the Ariaces Sadmorum.

DUNGALA. See **DONGOLA**.

DUNGANNON, a market and post-town of the county of Tyrone, province of Ulster, Ireland. It is an ancient borough, and has a barrack for a troop of horse. It was formerly the chief seat of the O'Neils, kings of Ulster, and was accordingly the scene of many warlike transactions, being repeatedly dismantled and repaired. At a later period, it was made remarkable by the assembly of the Ulster delegates from the volunteers in 1782. This body corresponded with the duke of Richmond, lord Effingham, Dr. Price, and other friends of parliamentary reform, and in consequence of the resolutions they entered into, and the discussion thus occasioned, a meeting of delegates, from every part of Ireland, met in Dublin, and brought the measure before parliament, but without success. Dungannon has a good linen market, and in its neighbourhood are good collieries, from which is a canal to the Blackwater. Dungannon is 73 miles N. by W. from Dublin, and 10 west from Armagh. Beaufort Wilson's Directory.

DUNGARVAN, a market, post, and sea-port town of the county of Waterford, in the province of Munster, Ireland. This is an old town, the streets of which are narrow and dirty, but it is pleasantly situated, the sea flowing up to the old walls. On the north side is a quay, sufficiently capacious for the loading and discharging of small vessels. Forty or fifty coaling boats belong to this place, which are principally employed in the fishery, which is one of the most extensive in the kingdom. The inhabitants are celebrated as excellent curers of hake. The duke of Devonshire, who, as heir of the oldest branch of the Boyle family, is the chief proprietor, is taking measures to improve it, by building several new houses; and a bridge is also to be built over the arm of the sea, which separates it from the part of the country towards the city of Waterford, and which has hitherto been crossed by a ferry, or, at low water, by a ford. Here are a good market and session-house, and a barrack for two companies, situated within the walls of an ancient castle, now in ruins, which was built by king John, and afterwards repaired and possessed by the Desmond family. There are ruins of an Augustinian priory on the other side of the water, opposite to the town. Dungarvan is much frequented in the summer season for the purpose of sea bathing. It is a borough which returns a member to the imperial parliament, and is 100 miles S. by W. from Dublin. Long. $7^{\circ} 39' W.$ Lat. $52^{\circ} 5' N.$

DUNGENESS POINT, a cape in the eastern entrance of the Straits of Magellan. S. lat. $52^{\circ} 28'.$ W. long. $68^{\circ} 28'.$

DUNGENESS, a cape of England, on the coast of Kent, in the English chan. el. N. lat. $50^{\circ} 52' 20''.$ E. long. $0^{\circ} 50' 45''.$

DUNGEON. **DONJON**, in *Fortification*, the highest rampart of a castle built after the ancient mode, serving as a watch-tower, or place of observation; and also for the retreat of a garrison, in case of necessity; so that they may capitulate with greater advantage.

The word comes from the French *donjon*, which signifies

the same, and which Faucet derives from *domicellum*, because the dungeon, being the strongest part of the castle, was usually the lord's apartment. Menage derives it from *dominions*, or *dominions*, which in some ancient writings we find used in the same sense. Du Cange derives the appellation from *dano* or *celle adificatum*, *dan* in Celtic denoting hill, which the barbarous writers have altered into *dunjo*, *dungeo*, *danzio*, *danzio*, *domgio*, and *domnio*.

In some castles, as that of Vincennes, &c. the donjon serves as a prison for persons they would have the most securely kept; whence the general use of our word dungeon for a dark close prison under ground.

DUNGING, in *Dyeing*. See **RISING**.

DUNGIVEN, in *Geography*, is a market and post town in the county of Londonderry, province of Ulster, Ireland, on the road from Armagh to Londonderry, at the foot of the Cairntogher mountains; 99 miles N. by W. from Dublin, and 16 from Londonderry.

DUNGLO, in the county of Donegal, province of Ulster, Ireland, is a small village on the western coast opposite to the isle of Arran, which is of no small relative importance on account of its situation. It is on an arm of the sea, and is the place from which the inhabitants of the islands are supplied with all necessaries. It has a parish church, a mill, &c. It is 135 miles N. W. from Dublin, and 36 W. from Lifford.

DUNI, EGIDIO RIMUÁLDO, in *Biography*, a natural, graceful, and facile Italian composer, long settled in France. He was one of the first who a little reconciled the French to Italian melody at the comic opera, by applying it to French words, previous to the arrival and subsequent feuds concerning the merit of Gluck and Piccini.

Duni was born near Otranto, in the kingdom of Naples, 1709: his father was a maestro di cappella, and had six sons and three daughters. At nine years old he was sent, much against his will, to a conservatory at Naples, where he studied under the celebrated Durante.

It will appear in the article **PERGOLESI**, that Duni engaged at Rome to compose the opera of **NERO**, had great success, while the Olimpiade of Pergolesi was almost hissed. This success by no means flattered the vanity of the young Duni, who, ashamed of his victory, said to Pergolesi: "O my friend! *nesciunt qui faciunt!*"

Intruded with an interesting negotiation at Vienna, by cardinal C. . . ., Duni availed himself of this opportunity of displaying his talents, and acquired some reputation there. On his return to Naples, he was nominated by the king maestro di cappella to the church of St. Nicolo di Bari. Some years after his return to Naples he composed an opera for S. Carlo, which had great success. He composed one likewise for Venice, and went again to Paris in 1733 to seek relief for perpetual palpitation, with which he was tormented; when he became so pleased with France, that he resolved to spend there the rest of his days; he however went into England to compose some operas requested of him, (rather songs, we never heard of his operas in England,) but he was in so bad a state of health, that the English physicians advised him to go to Holland, in order to consult Boerhaave.

The new regimen which he prescribed to him was to ride every day, and in a few years he found himself quite recovered; but, soon after, he was in so perilous a situation that he lost his health for ever.

Having returned to Italy to visit his mother, whom he tenderly loved, he was attacked by robbers near Milan, and upon the point of being murdered. The revolution in his health, occasioned by this fright, renewed the hæmorrhage

to which he was subject, and the constant suffering with which he was afflicted to the end of his days.

While marshal Richelieu commanded at Genoa, Duni, in spite of his sufferings, composed an opera, which was so fortunate as to please the French, Italians, and Spaniards, who engaged him to compose another, which was equally successful. This good fortune occasioned his being noticed by the infant, Don Philip, who carried him to Parma, and appointed him music-master to princess Elizabeth, his daughter, first wife of the emperor Joseph. It was at Parma that he first composed to French words, and he succeeded so well there that they sent him, from Paris, the comic opera "Le Peintre Amoureux" to set.

The education of the princess being finished, he obtained leave to go to Paris, and retired thither on a pension, where he was present at the successful performance of his drama, "The Amorous Painter," in 1757, which finally determined him to remain in France.

He resided at Paris till 1775, when a malignant fever beheaded his wife and son of a kind husband and affectionate father.

Duni composed for the theatre Italian at Paris, besides "The Amorous Painter," in 1757; "The Irresolute Widow," in 1758; "La Fille Malgracée," in 1759; "Nina and Lindor," in 1761, and "L'île des Foux;" in 1762, "Le Milicien;" in 1763, "Les Chasseurs & La Laitiere," "Le Rendezvous;" in 1765, "L'Ecolle de la Jeunesse," "La Fée Urgelle;" in 1766, "La Colchette;" in 1768, "Les Moissonniers, les Sabots;" in 1770, "Thémis;" and, the same year, "L'Heureuse Espieglerie." All these had a certain degree of success, and many of them remained several years in favour. Laborde.

DUNIUM, in *Ancient Geography*, a town of Britain, belonging to the Durotriges, supposed by Camden to have stood where DORCHESTER now stands. Mr. Baxter places it on the summit of an adjacent hill, where are a ditch and bulwarks, now called Maiden castle; while Mr. Horsley thinks it was situated at Eggerston hill.

DUNK, in *Geography*, an island on the N.E. coast of New Holland, which forms a boundary of Rockingham bay, and lies so near the shore as not to be easily distinguished from it. S. lat. 17° 20'. E. long. 145° 30'.

DUNKARD'S TOWN. See EPHRATA.

DUNKELD, a small town in the county of Perth, Scotland, has been a place of great note in the annals of Scottish history, and is now noted for the salubrity of its climate, and the picturesque features of the neighbourhood. The latter have been greatly improved by the numerous plantations raised by the duke of Athol, who has a seat in the town. This town is said to have been the capital of ancient Caledonia; and about the dawn of Christianity, a Pictish king made it the seat of religion, by establishing a monastery of Culdees. This was converted by king David I., A. D. 1130, into a bishopric, and was then ranked the first in Scotland. The cathedral, though formerly a large handsome building, is much dilapidated; but its choir is used as the parish church. It was erected in 1350 by bishop Sinclair, whose corpse was interred within its walls. On the north side of the choir is the chapter-house, built by bishop Lauder in 1469; the vault of which is now used for interment of the Athol family. At the west end of the north aisle is a very elegant tower, which has a crack from top to bottom, nearly two inches wide.

The poet Gray visited this place in 1766, and has given an interesting description of the scenery, &c. in a letter to the earl of Oxford. (See his works published by Macon.)

In the town are two tan-yards, two distilleries, and four linen manufactories. Dunkeld is 15 miles N.W. of Perth, and contains 1016 inhabitants. It is seated on the north side of the river Tay, the banks of which are bold, rocky, and romantic. Near the duke's seat is a fine cascade, called the *Rumbling brigs*, which falls about 150 feet. Sinclair's Statistical Account of Scotland.

DUNKELSPUHL. See DINKELBUHL.

DUNKERS, or TUNKERS, in *Ecclesiastical History*, a religious sect at Ephrata or Dunker-town, near Lancaster, in Pennsylvania, which took their rise about the year 1719, and consisting mostly of Germans. They sprung from about 20 families, who in that year landed in Philadelphia, and dispersed themselves through various parts of Pennsylvania. They are of the denomination, called General Baptists, and maintain the doctrine of general redemption. Besides the congregation at Ephrata, there were, in 1770, 14 others in various parts of Pennsylvania, and some in Maryland. The whole number, exclusively of the latter, amounted to upwards of 2000 persons. Their name is said to be derived from their mode of baptizing new converts, which is by dipping, after the manner of the Baptists. Others say, the appellation of *Tunkers* is derived from *tanken*, to put a morsel in fauce, and was first applied to this sect by way of derision. Their habit is a kind of long coat or tunic, made of linen, for the summer, and woollen for the winter, reaching down to the heels, with a sash or girdle round the waist; and a cap, or hood, hanging from the shoulders, resembling the dress of the Dominican friars. The men have neither the head nor beard. The men and women have distinct habitations and governments: they have for this purpose erected two wooden buildings; in each of which there is a banqueting-room, and an apartment for public worship; so that they never meet together even at their devotions. They live chiefly on roots and vegetables, and eat no flesh, except on occasion of their love-feasts, when the brethren and sisters dine together. The Dunkers allow of no intercourse between the brethren and sisters, not even by marriage; a regulation not very favourable to their subsistence and increase: and if any break through this restraint, and marry, they are removed from communion with the unmarried, to a place about a mile distant, called Mount Zion. The principal tenet is said to be, that future happiness is only to be obtained by penance and mortification in this life; and that, as Jesus Christ, by his meritorious sufferings, became the Redeemer of mankind in general, so each individual of the human race, by a life of abstinence and restraint, may work out his own salvation.

DUNKESFIELD, in *Geography*, a small town of the kingdom of Württemberg, on the river Wernitz; 45 miles S.W. of Nuremberg; with a thriving manufacture of woollen cloth and hardware.

DUNKIRK, or DUNQUERQUE, in Flemish and English *Dunkirk*, in Latin *Dunikerka*, *Dunckerka*, *Dunckerca*, in German *Dunkereb*, a considerable maritime town of France, in the department of the North, chief place of a canton, in the district of Bergues; 18 miles N.E. of Gravelines, 30 miles N.E. of Calais, 27 miles S.W. of Ostend, and 27 miles, or 316 kilometres, N. of Paris. E. long. 2° 7'. N. lat. 51° 2' 4". The temperature of Dunkirk, on a mean of 10 years, as given by Pere la Cotte (Meteorol. p. 360.), was 54° 9'. It was originally a hamlet of a few fishermen's huts: but a church having been built, as it is said, by St. Eloi, who first preached Christianity among the inhabitants of Flanders, on the Sand-hills, Dunes, Downs, in its neighbourhood, the place increased and derived its name from the situation

DUNKIRK.

situation of its church, Dunkirk, the *church on the Downs*.

In the tenth century, Baldwin earl of Flanders surrounded Dunkirk with a wall. Being commodiously situated for trade, it engaged in a profitable commerce, which soon enabled it to build even ships of war. In the twelfth century, Dunkirk fitted out a small fleet against the Norman pirates, who infested the Channel and the North sea: the services which this fleet rendered were considered so important, that Philip earl of Flanders granted the town several privileges.

In the thirteenth century, Dunkirk was sold to Godfrey of Condé, bishop of Cambrai, who enlarged the town and improved the harbour. His heirs restored Dunkirk, in the year 1288, to Guy earl of Flanders; whose son, Robert de Bethune, dismembered it from the earldom of Flanders, and in the year 1320, conferred it as a particular lordship on his son Robert de Cassel. The latter built, in 1322, a castle for the defence of the town; but this castle was afterwards demolished, during a rebellion of the Flemish people. In the year 1343, Yolanda, daughter of Robert de Cassel, brought Dunkirk as her marriage portion to her husband, Henry IV. count of Bar. It devolved, in 1375, to her cousin, Robert of Bar, earl of Marle, who, in the year 1400, raised round the town a strong wall; the remains of which are reported to be still traced on the side next the harbour.

In 1435, Dunkirk came by marriage from the house of Bar to that of Luxembourg; and in 1487, from the latter to the house of Bourbon, on the marriage of Mary of Luxembourg with Francis of Bourbon, count of Vendôme. But Dunkirk being only a fief, the sovereignty of which belonged to the house of Austria, the emperor Charles V. erected a strong castle, in the year 1538, for the defence of the harbour.

The French, under marshal de Thermes, took Dunkirk by storm in 1558; but it was soon retaken by the Spaniards. At the peace of Cateau-Cambrésis, Anthony of Bourbon, king of Navarre, cousin and heir to Mary of Luxembourg, obtained Dunkirk, and some other places, as a fief, of Philip II. king of Spain and earl of Flanders. The town was rebuilt, and improved in wealth, chiefly by fitting out privateers against the Dutch. The fortifications of the harbour were strengthened, 15 ships of war built, and a canal of communication opened with the town of Bergues.

This state of prosperity suffered, however, some interruption, from frequent disturbances in the Netherlands. In 1646, Dunkirk was besieged and taken by the French, under the prince of Condé. In 1652, it was retaken by the archduke Leopold, governor of the Netherlands.

In 1655, the alliance of England and France induced the inhabitants of Dunkirk to fit out privateers against both these powers: but the French, assisted by Cromwell, attacked and took Dunkirk, which was put into the hands of the English, to recompense them for the loss of 250 ships, that had been carried into Dunkirk by its privateers during the war.

The English immediately improved the fortifications of Dunkirk, and strengthened it by the addition of a citadel; but they did not keep possession of it above four years.

In 1662, Charles II. of England, two years after his unexpected restoration to the throne of his father, not considering the value of such an acquisition to his country, or unable to judge of its importance, sold Dunkirk to France for the paltry sum of five millions of French livres, or about 209,000*l.* sterling. On the 29th of November, 1662, the comte d'Éstrades, in the name of Louis XIV., took possession

of the town, and of the villages in its district, viz. Mardyck, Great and Little Saintes, Arenbouts's Chapel, Coudekerk, Teteghem, Uxem, Chyved, Lessenhoucke, and Zuytcoete.

Under the superintendance of the celebrated Vauban, Dunkirk was rendered an almost impregnable fortress. The harbour was improved with two jetties, and defended by two castles, le Chateau Verd and le Chateau de bonne Espérance. Other fortifications were successively added. In 1689, the fort called Cornichon, or Batterie de Revers, and some other works, were finished; and in 1701, the whole was completed by the erection of Fort Blanc. Every ship that entered the harbour had to pass between these forts; and at the entrance of the basin was a sluice of 45 feet in width, that the ships within might constantly be afloat.

This protected and strengthened, Dunkirk enjoyed again a most flourishing trade. In 1706, it contained 1639 houses, and 14,274 inhabitants. During the war which terminated in the peace of Utrecht, its privateers took 1614 English prizes, valued at 1,334,375*l.* sterling. This loss was of such a magnitude, that England would not consent to enter into any treaty with France, unless it should contain, as one of its principal stipulations, that the fortifications, harbour, basin, sluices, and canal of Dunkirk were to be immediately destroyed, demolished, and filled up, at the expense of France; and that the latter power should solemnly engage never to attempt the repairing of those works. In consequence of this declaration, a clause to this effect was inserted in one of the articles of the treaty of Utrecht, which was signed on the 28th of April, 1713.

But the demolition of the forts and harbour of Dunkirk did not take place before the month of September, 1713, when two English commissaries, colonels Armstrong and Clayton, were sent from England to Dunkirk, to watch over the execution of the treaty. They witnessed the destruction of the fortifications, the levelling of the jetties with the strand, the filling up of the harbour and canal, and the building of a large dam or bar across the entrance of the basin. Yet all this was no sooner accomplished, than Louis XIV. constructed a new canal at Mardyck, by which the harbour was rendered nearly as commodious as it had been before.

However, in the year 1717, France was once more compelled, by a treaty concluded at the Hague between England, Holland, and France, to render the new canal of Mardyck unserviceable; and it was expressly stipulated, that no harbour, sluice, or basin, should ever be made either at Mardyck or Dunkirk, or within two French leagues round the town. But in 1720, a violent storm, during which the sea broke up the bar built across the old harbour, restored its use in some degree. This advantage was improved upon by Louis XV. in the year 1740, whilst England was engaged in a war with Spain. The jetties were rebuilt, and new forts erected in the place of those which had been destroyed in 1713.

In the mean time, Louis XV. joined the Spaniards; and at the conclusion of the war with England, it was for the third time agreed upon, in the treaty of Aix la Chapelle, signed in 1748, that all the works near Dunkirk towards the sea should be destroyed. France, however, not only never completed this demolition, but even commenced some new works under-hand, notwithstanding the repeated remonstrances of the English court. At the beginning of the seven years' war, Dunkirk was in as good a state of defence towards the sea as it had been at any time during the war, which was concluded by the treaty of Aix la Chapelle.

The same stipulations were renewed at the peace of Paris,

in 1762, but with no better effect. The trade of Dunkirk continued to flourish: its principal commerce, during the interval of peace from 1762 till the beginning of the American war, was with England, Ireland, and Scotland, Spain, Portugal, Sweden, Holland, and Denmark. In 1766, Dunkirk had 46 ships, or a tonnage of 2300 tons in the herring fishery. In 1767, it had in all 170 merchant vessels, manned by 2348 sailors; and besides its own vessels, there entered the harbour of Dunkirk,

228	French ships
176	English
115	Dutch
34	Swedish and Danish
21	Spanish
8	Hambro' vessels, and
300	Smugglers

In all 882 Vessels.

And during the American war, it fitted out several privateers. Before the French revolution of 1789, Dunkirk had also five ships in the slave trade. It is the native city of the famous Jean Bart.

In the year 1801, or rather during the short suspension of hostilities which took place between England and France, in consequence of the peace of Amiens, Dunkirk had 20 ships in the trade with America and the French colonies. In ancient times, it had been in alliance with the Hanseatic towns, and its commerce in French wines and brandies was always considerable. It has been rated at 12,328 hogsheads of wine, and 8580 pipes of brandy annually. From the year 1170 till 1794, or, more exactly, till the seventh Ventose of the third year of the French republic, Dunkirk had been a free port.

The road of Dunkirk lies at the distance of $1\frac{1}{2}$ mile northwards of the town, within the Brak, a sand-bank which extends parallel to the shore near 5 miles in length, and has from three fathoms to one foot of water at low water. There is a safe anchorage about three-fourths of a mile N.N.E. from the jetty, in six or eight fathoms of good clay ground, mixed with sand. The tide at Dunkirk rises 12 feet.

Dunkirk is one of the six maritime districts into which all France is divided. It superintends all the ports and coasts of the Channel and North sea, from the last Dutch port to Dunkirk included. As chief place of this maritime district, Dunkirk has a maritime prefect, who superintends the maritime quarters of Antwerp, Malines, Brussels, Gand, l'Ecluse, le Sas de Gand, Ottend, Bruges, and Nieupoort; each of which has its subdivisions, called *lyndicates*.

With respect to the temperature of Dunkirk, its greatest heat commonly is $23^{\circ} 2'$, the least $6^{\circ} 6'$; medium $8^{\circ} 7'$. The highest elevation of the mercury in the barometer is 28 inches 8.3 lines, the lowest 27 inches 1.4 lines; medium 28 inches 1.1 line. There are annually 126 rainy days, and the prevailing wind is the south-east wind.

The whole population of Dunkirk amounts to 21,158 individuals: but the town is divided into two parts, East and West, each of which is a separate canton; the former having 9792 inhabitants, and comprising 6 communes, with a population of 13,761 individuals; the latter having 11,366 inhabitants, and containing 5 communes, with a population of 13,742 individuals. The two cantons together have a territorial extent of 155 kilometers.

Considered as a town, there is nothing particularly remarkable at Dunkirk, excepting the quay, the principal street, the roperies, and the sailors' barracks. The houses

have only one or two stories; the lower classes live in cellars, which opening into the street, are rather a nuisance: however, it is asserted, that these vaults are not unhealthy, being dug in a very dry sand.

The principal manufactures of Dunkirk are those of tobacco, starch, glass, and leather, besides several rope-walks, distilleries, and sugar-houses. Herbin, Statistique de la France.

DUNKIRK, a post-town of America, in King and Queen county, Virginia; 116 miles from Washington.

DUNLAVIN, a market-town of the county of Wicklow, Ireland, on the road from Blessington to Timolin, in which are a good inn, a handsome market-house, &c. It is 10 miles S. from Naas, and about 22 S. by W. from Dublin.

DUNLEER, a market and post-town of the county of Louth, Ireland, on the great northern road from Dublin. It is 30 miles N. from Dublin, and 7 from Drogheda.

DUNLIN, in *Ornithology*, the English name of the *SCOLOPAX pusilla*; which see.

DUNLOPE, in *Geography*, a fort of America, on the west bank of little Miama river, about 12 miles above Columbia, in the state of Ohio.

DUNLUCE, on the northern coast of Ireland, in the county of Antrim, is the ruins of an old castle, formerly belonging to the Antrim family, near Bushmills. The only passage into the castle lies along the top of a narrow wall, built in the form of a rude arch, from the main land to the rock on which the castle stands; an approach to which is attended with much terror to persons of weak nerves. Underneath is a curious cave in the rock. It is 120 miles N.W. from Dublin.

DUNMANUS-BAY, a bay of the Atlantic, on the south-west coast of Ireland, in the county of Cork. It is about 14 miles in length, and from one to three broad, and is separated from Bantry bay by a narrow mountainous district which terminates in the promontory of *Sheep's head*. This is a safe harbour, but is one of the many on the western coast which have yet been applied to no use. At present there does not appear to be even a fishing village on its shores. W. long. $9^{\circ} 40'$. N. lat. $51^{\circ} 30'$, at its mouth.

DUNMANWAY, a town of Ireland, in the county of Cork. It is a cheerful thriving town, where Sir Richard Cox, formerly lord chancellor of Ireland, established the linen manufacture. It is on the Bandon river; and the country from it to Bandon is a fine well-improved vale, consisting of a light gravelly soil. The country on every other side is rocky. Dunmanway is 151 miles S.W. from Dublin, and 27 miles W. from Cork, on the road to Bantry.

DUNMORE, a small post-town in the northern part of the county of Galway, Ireland, which contains 85 houses, a market-house, and a parish church, built on the site of an old abbey. Near it is Dunmore castle, a large venerable ruin, pleasantly situated on the banks of the river Dunmore. It is 91 miles W. from Dublin, and 7 miles from Tuam. Wilson's Directory.

DUNMORE-BAY, a bay of the Atlantic, on the west coast of Ireland, in the county of Clare. It is not a good harbour, but is frequented for sea-bathing. W. long. $9^{\circ} 35'$. N. lat. $52^{\circ} 44'$.

DUNMORE-HEAD, a cape on the west coast of Ireland, in the county of Kerry. W. long. $10^{\circ} 20'$. N. lat. $52^{\circ} 6'$.

DUNMOW, GREAT, a market-town and parish in the hundred of Dunmow, in the county of Essex, England, is situated on an eminence near the river Chelmer, and consists principally of two streets. The town is of great antiquity, and is supposed to have been the site of the Roman station *Cesaromagus*: which opinion has originated from the dis-

covery of various Roman coins in the town and its vicinity, and also by its situation on a Roman road to Colchester. The parish is very extensive, comprehending seven manors. The church, dedicated to the Virgin Mary, is a large ancient structure, consisting of a nave, chancel, and aisles, with an embattled tower at the west end. Over the entrance into the latter are various shields of arms, carved in stone; among which are those of the noble families of Mortimer, Bohun, Bouchier, and Braybrooke, who are supposed to have contributed towards the erection or repairs of the edifice. Dunmow was incorporated under a charter granted in the reign of Philip and Mary, and afterwards confirmed by Elizabeth. The government is vested in a bailiff and twelve burgesses. The number of houses, in the return of 1501, was 392; of inhabitants, 1828. The poorer classes derive their chief employment from the manufacture of baize and blankets. Dunmow is 37 miles N.E. from London; has a weekly market on Saturdays (by grant from Henry III. A. D. 1253); and two annual fairs.

DUNMOW, *Little*, a village about two miles distant from Great Dunmow, in the same hundred, is noted for an ancient priory of Augustine canons, and also for a singular custom or tenure annexed to the manor. The priory was founded in the year 1104, by lady Juga, sister of Ralph Baynard, who held the manor at the time of the Domesday survey; and from whose family Baynard's castle in London obtained its name. On the suppression, Henry VIII. granted the site of the priory, and the manor to Robert earl of Suffex. The monastic buildings were situated on a rising ground, south west of the church, but are now entirely razed; and some part of the site is occupied by the present manor house. Under an arch in the south wall of the present church is an ancient tomb, supposed to contain the body of the foundress, lady Juga. Near this spot are some well executed monuments of the Fitz-Walters, by whom this lordship was possessed for eleven generations. To one of this family is attributed the well known custom of giving a *slice of bacon* to any married couple, who had not repented of their marriage for a year and a day. The earliest delivery of the bacon on record was in the 23d of Henry VI.; two other instances occurred previous to the suppression of religious houses; and three times it has been delivered since that period. The last persons who received it were John Shakehanks, woolcomber of Wethersfield, and Anne his wife, who established their right on the 20th of June, 1751. *Morant's History of Essex*, 2 vols. folio.

DUNNAGE, in *Sea Language*, a quantity of faggots, boughs of trees, or other loose wood, laid in the bottom of a ship, either to raise the heavy goods which might make her too stiff, or to keep the cargo sufficiently above the bottom, that it may receive no damage from the water, if the ship should prove leaky.

DUNNET, in *Geography*, a town of Scotland, in the county of Caithness, situated on the east side of a bay to which it gives name. The number of inhabitants, in 1791, was about 1400. The bay affords excellent flounders and haddocks, and is sometimes frequented by shoals of herrings in July and August; 5 miles E. of Thurio. N. lat. 58° 32'. Long. 0° 1' W. of Edinburgh.

DUNNET HEAD, a cape on the north coast of Scotland, and county of Caithness. It consists of several hills, with some bold rocks towards the sea, from 100 to 400 feet in height; 3½ miles N. of Dunnet.

DUNNOSE, a cape or promontory on the S.E. coast of the Isle of Wight, in the English channel; about 17 leagues W. from Beachy-head. N. lat. 50° 33'. W. long. 1° 14'.

DUNOIS, JOHN D'ORLEANS, *Count of*, in *Biography*,

the natural son of Louis duke of Orleans, was born in 1403. His father being assassinated by the duke of Burgundy, his dukes declared that he alone of the sons of the duke was capable of avenging his death. He was from an early age a youth of high martial spirit, and of great service to his country. When France was almost reduced to the state of conquest by England, he began to change its fortune by a victory in 1427, of which the consequence was raising the siege of Montargis. He afterwards threw himself into the city of Orleans, which he defended with so much valour and intrepidity, when it was besieged by the duke of Bedford, that he even resolved, rather than surrender, to let fire to the city, and make his way through the enemy. At this critical moment appeared the celebrated Joan of Arc, by whose means the siege was raised. Dunois directed with prudence the enthusiasm which he inspired; and after her unhappy death, rendered the handsomest testimony to her memory. After this he achieved many glorious deeds for his country; and from the title of "Baldard of Orleans," by which he had been known, he was permitted to take the title of count de Dunois. In addition to this, the king, sensible of the obligations he was under to him, caused him to be legitimated, and to be entitled "The Restorer of his Country;" and, to maintain his rank, lands were presented him, and the office of great chamberlain was bestowed. In the following reign, Dunois joined the insurrection called the "League for the public Good;" and was afterwards placed at the head of thirty-six notables, appointed to reform the state. He died in 1468. *Moreri. Hist. of France.*

DUNRODUNUM, in *Ancient Geography*, a town situated in the northern part of the isle of Albion, and belonging to the Carnovæcs.

DUNROSSNESS, in *Geography*, a town of Scotland, situated in the southern part of the isle of Shetland; 28 miles S. of Lerwick.

DUNS, in *Antiquities*, are the remains of a peculiar kind of buildings, which abound in the northern parts of Scotland, and in the Orkney and Shetland isles; though not exclusively so, as it has been generally stated. They are of two kinds: the first, which are most prominent in their appearance, are circular castles, such as the castles of Moura and Glenbeg, in the shire of Inverness; or circular pyramids, like the spires of Brechin and Abernethy. These towers, which generally stand upon some eminence, vary as to their internal structure, but bear a great similarity in their external appearance; though some of them have additional works of defence. Thus the burg of Moura was surrounded by a wall, which now forms round it an heap of stones. Others are guarded by fosses, both wet and dry ditches of considerable magnitude. The second kind consists of numerous subterraneous buildings, either entirely under ground, or nearly so: in the latter case, they exhibit the external appearance of numerous tumuli, or what in the highlands are called *Here cairns*, i. e. long burrows. Some of them are much larger than others; and a dun of this kind consists of strong circular walls without cement, surrounding a large oval area, which appears to have been divided into several divisions, leaving a large internal space in the centre, round which the other apartments ranged. The incumbent roof of earth appears to have been supported by one or more wooden columns, with cross beams, resting upon the walls. The interior space was probably the dwelling, while the surrounding rooms served for the purpose of laying up provisions, and other necessary stores. The hillock over the upper flooring was raised to keep the habitation dry; and with the same view, many of them were surrounded with a deep ditch, over which the entrance was

made by a ridge of earth, left unexcavated; and in some instances, flanked by two dry walls.

They are not confined to one particular part, but are found in the lowlands, as well as the highlands; in the interior parts of the country, as well as in the isles. Nor are they peculiar to Scotland. Specimens of both kinds exist in Ireland, Wales, and Cornwall; a fact which certainly goes far towards demonstrating their Celtic origin. Although it has been confidently asserted, that "they are confined to the countries once subject to the crown of Norway," and out of our own kingdom, observes a Scottish writer, no buildings similar to these are to be found, except in Scandinavia. On the mountain Swalburg in Norway is one, the Sürbifstop at Upsal in Sweden is another, and Umeborg in the same kingdom is another.

The names, fabricators, and designation of these singular buildings have equally claimed the attention of antiquaries. They are called in the Orkneys *burgs*, or *broughs*, evidently a Saxon term for a fortification. On the main land, they have divers appellations, as *castles*, *bowies*, Celtic terms for cavernous fortresses; and *Pict's houses*, as the supposed habitations of that ancient people. The general term, *duns*, is from *dun* or *din*, a Celtic word, simply signifying small hills, or fortified mound of earth; and here applied to designate the shape of the smaller, and situation of the larger kind. When the highlanders in the three of Inverness are asked to whom they belonged? the constant answer is, that they were the houses of the *Drinnich* or *Trinnich*, the Gaelic name for *labourers*; a term which they invariably apply to the Picts.

By some writers they have had a Danish or Norwegian origin assigned to them. Ware and Ledwich, in treating of Irish antiquities, contend for their Danish origin; and Dr. Borlase, in treating of *Castell Chru*, in the parish of Morvah, is of opinion, that such kind of buildings must be attributed to the Danes. But this mode of denomination is directly contrary to the analogy of tradition: for not only in Scotland, but in England, it is almost universally found, that the works of an early age are not usually attributed to the people to whom of right they belong, but successively to the different bodies of victorious armies, who have occasionally figured on the page of history. Thus it has been common for tradition, and those historians who implicitly believe, without having made previous inquiry, to describe camps as Danish or Saxon, which originally were the fortified heights of Britons; and subsequently, the strong holds occupied by the Roman legions. But setting aside the fabulous story of Kenneth Macalpin, which has been the foundation of much unprofitable controversy, it would be very difficult to counteract the force of arguments, adduced by the learned and profound adept in the school of antiquarian research, whose name alone is itself an hoel, the late erudite Mr. King; one of which is, "They are to be seen in parts of the kingdom, where the Danes never penetrated." And that he might not make an assertion without advancing proof, which has been hapless too common a case in this national contention, he refers to what is called *Black castle*, in the Parish of Mouline, Perthshire; to one of these buildings in the hill of Drummin; and to several others in different parts of the Glen Lion; which shew how numerous these structures were in what was denominated the country of the Picts. Mr. Chalmers, in his history of Caledonia, observes, that many of these edifices "in the Orkney and Shetland islands, and in Caithness, have been erroneously called Pictish castles, Pictish towers, and Pict's houses, from a fabulous story which attributes to Kenneth Macalpin the impolicy of driving many of the Picts into the northern extremity of our

island; whence they fled to the Orkney and Shetland isles." But the learned author himself does away the force of this reason for the denomination, by stating in another part of his work, that "it was asserted by ignorance, and believed by credulity, that Kenneth made so bad an use of the power which he had adroitly acquired, as to destroy the whole Pictish people in the wantonness of his cruelty." Caled. p. 333. And he is confident enough to infer, from conformity in the appearance of many of these buildings with others, which have generally been attributed to the northern nations, that their origin must be acknowledged Scandinavian. And in addition, he urges, that "not one of these *strengths* bears any appellation from the Pictish or British language; and that they have no similarity to any of the *strengths* of the genuine Picts, or British tribes of North Britain." Ibid. p. 343, 344.

For their *Scandinavian* origin, there is a degree of feasibility; because, from the accounts given by travellers of undoubted intelligence and veracity, it appears that, even at the present period, the houses of the Icelanders, allowed to be the least unmingled Gothic colony, exhibit a striking resemblance to these buildings. But the ground on which Mr. King rests his judgment, and with a much greater degree of probability, is, that "the Pictish buildings, or those so called, resemble the British remains in Cornwall and South Wales." And the writer of this article has seen a variety of remains of circular buildings, of a similar description, in different parts of North Wales, particularly in Caernarvonshire, of the origin of which the inhabitants are almost traditionally unacquainted. They are in some places called "round-about," and in others "Arthur's round tables;" *Buarth caeden*, *Buarth Arthur*, &c.

It is a curious circumstance attached to these monuments of antiquity, that they have been made the criterion of systematic inquiries diametrically opposite. While Mr. King and Mr. Chalmers lay down the same general principle, as a powerful argument of the Celtic derivation of the Picts; it is singular that the one should attempt to prove they are of Celtic, and the other as strenuously contend that they are of Scandinavian origin. Upon a review of the arguments adduced by both, the hypothesis of Mr. King appears to stand the best supported, from similar structures acknowledged the retreats of the ancient inhabitants of the island, from the etymons of their names, and from the traditions and comparative history of the country.

Of their designation and use equally different opinions have been advanced. Of the first kind, or circular buildings, which appear above ground, no doubt can be entertained. They were evidently *watch towers*, and occasional fortresses for defensive warfare. Of the second sort, a latitude is afforded for variance in judgment. These have been considered as fortified recesses. But reasoning from analogy, they are evidently the remains of the *hybernacula*, or winter habitations of the aboriginal inhabitants; who, principally employed with their flocks on the hills, or cultivating the open fields in the plains, during the summer months, there erected their ætival tabernacles; and when the ungenial season arrived, they retired with their ingatherings to their brumal habitations. Thus, like the other British tribes, they had their *hucfollys* and *gofen*, their summer and winter residences; and similarity of customs is a powerful argument for affinity of origin. See Pennant's Tour in Scotland. Statistical Account of the Highlands. King's Munimenta Antiqua. Chalmers's History of Caledonia.

DUNS, JOHN, commonly called *Duns Scotus*, in *Biography*, one of the scholastics who flourished about the close of the 13th and commencement of the 14th centuries. He

was born, probably, at Dunfance, near Alnwick in Northumberland. In his youth he was admitted to an institution belonging to the Franciscan friars at Newcastle, and sent by them to complete his education at Merton college in the university of Oxford, where he became a fellow, and distinguished himself by his proficiency in scholastic theology, civil and canon law, logic, metaphysics, mathematics, and astronomy. About the year 1301, he occupied the chair of theology in this university; and his fame drew together a great number of scholars to attend upon his lectures. About the year 1304, he was admitted to the highest honours in the university of Paris, whither he was sent by his superiors; and appointed professor and regent in the theological school. Having in this situation acquired singular reputation by his subtlety in disputation, he was denominated "the most subtle doctor;" but his ingenuity was principally displayed in embarrassing, with chimerical abstraction and puzzling distinctions, subjects already sufficiently perplexed. Thus, instead of promoting the knowledge of important and useful truth, he applied his talents and learning to purposes that were injurious to rational investigation and inquiry. In the commencement of his literary career, he was a follower of Thomas Aquinas; but differing from this "angelical doctor," in his opinion concerning the efficacy of divine grace, he formed a distinct sect; and hence proceeded the two denominations of *Thomists* and *Scotists*, which see. Duns Scotus was a zealous advocate for the immaculate conception of the Virgin Mary; a notion which some say was first propounded by him; and which, however, was strenuously maintained by him and his sect, in conjunction with the Franciscans, and as vehemently opposed by the Thomists and the Dominicans. In the year 1308, Duns Scotus was deputed by the fraternity of Minors, of which he was a member, to teach theology at Cologne; where he was received with great pomp and sanguine expectations; but a sudden death, probably by an apoplexy, disappointed the views and hopes of his adherents. This event took place, as some say, in the 43, but according to others, in the 34th year of his age. But the precise time both of his birth and death has not been ascertained. His works in dialectics and scholastic theology are numerous; most of them were printed separately, and the most complete collection of the whole, together with the life of the author, was published by Lucas Waddingus, at Lyons, in 1539, in 12 vols. folio. *Cave's Hist. Lit. vol. ii. sub. sęc. Wicklev. Mss. Eccl. Hist. sęc. 14. Brucker's Hist. Phil. Enfield, vol. ii. p. 379.* See *SCHOLASTICS* and *SCOTISTS*.

DUNSE, in *Geography*, a considerable town and parish in the county of Berwick, Scotland; is encompassed on the west, north, and east by the Lamm-merri hills, a plain of twenty-five miles extent lying towards the south. The ancient site of the town was on the summit of a hill called

The words and syllables in this manner fall on the right notes.

Dunstable seems to have acquired a great reputation on the continent; for he is not only cited by Franchinus, but John Tinctor, a writer somewhat more ancient, who gives to the English the invention of the new art of counterpoint, and places John Dunstable at their head. Speaking of counterpoint he says, "Cujus ut ita dicam novæ artis fons et

Dunse-Law, which rises, from a base of about two miles and a half in circumference, to an elevation of 630 feet above the level of the sea. The town was afterwards rebuilt at the foot of the hill. About half a mile distant is Dunse-castle, a large, venerable building, commanding an extensive prospect southward as far as the Cheviot hills, and surrounded by several hundred acres of thriving plantations; it is now the family residence of Hay of Drummelzier. In the year 1747 the celebrated mineral well, called Dunse-fpa, was discovered; it affords a strong chalybeate water, similar to that of Tunbridge in England. In the vicinity is an extensive bleach-field, a tan-yard, and a very considerable woollen manufactory. The population of the town is about 2400; it has a weekly market; and four annual fairs, chiefly for horses, sheep, and black cattle. The parish extends eight miles in length and five in width: improvements in agriculture proceed here with great rapidity. The river Whittader, which rises in Lamm-merri, runs through the parish, and contains excellent salmon. Cockburn Law is a useful land mark for ships navigating the German ocean, as it rises 900 feet above the sea. On this hill are the ruins of a very ancient structure called Woden's or Eden's Hall. The celebrated theologian and metaphysician Johannes Duns Scotus, as some say, was born in Dunse A. D. 1274. The house in which he was born is said still to remain. Sinclair's Statistical account of Scotland.

DUNSKERRY, a small island near the north coast of Scotland; 4 miles E.S.E. of Farout Head.

DUNSTABLE, JOHN, in *Biography*, an English musician, who at an early stage of counterpoint, acquired on the continent the reputation of being its inventor. He was the musician whom the Germans, from a similarity of name, have mistaken for saint Dunstan, and to whom, as erroneously, they have joined issue with others in ascribing to him the invention of counterpoint in four parts. He was author of the musical treatise "De Mensurabil Musica," which is cited by Franchinus, Morley, and Ravenicroft. But though this work is lost, there is still extant in the Bodleian library, a Geographical Treatise by this author; and, if we may believe his epitaph, which is preserved by Weaver, he was not only a musician, but a mathematician, and an eminent astrologer. Of his musical compositions nothing remains but two or three fragments in Franchinus, and Morley. He is very unjustly accused by this last writer of separating the syllables of the same word by *rests*. But I believe master Morley was so eager to make a wretched pun on the name of Dunstable, that he did not sufficiently consider the passages which he censured; the errors in which seem to be only those of the transcriber or printer: for the last syllable of Angelorum belongs to the last note of the first musical phrase, *before* the rests, and not to the first note of the second group.

origo, apud Anglos, quorum Caput Dunstable exiit fuisse perhibetur." It was in a MS. Latin tract, in the possession of Padre Martini, that I saw this curious passage, which probably has done us some credit with those who have believed and transcribed it; but he could not have been the inventor of that art concerning which several treatises were written before he was born. However this is but one proof more of what has been already remarked, that when a mistake or a falsehood has

once had admission into a book, it is not easily eradicated; and this assertion concerning John Dunstable's invention of counterpoint, as if it were not sufficiently false in itself, has been aggravated by the additional blunder of mistaking his name for that of St. Dunstan. Not only M. Marpurge, but the editors of the Supplement to the Encyclopædia, art. Contrepoint, have lately copied this error unexamined.

Dunstable, whom Stow calls "a master of astrononie and music," was buried in the church of St. Stephen, Walbrook, 1453.

DUNSTABLE, in *Geography*, a post town of America, in the state of New Hampshire and county of Hillsborough, on the west side of Merrimack river, below the town of Merrimack, and separated by the state line from Pepperell and Dunstable in Middlesex county, Massachusetts: incorporated in 1746, containing 862 inhabitants, and lying about 40 miles N.W. of Boston.—Also, a township of Massachusetts, in the northern part of Middlesex county, on the southern bank of Merrimack river; containing 485 inhabitants, and situated 37 miles north westerly of Boston.

DUNSTABLE. See DUNSTAPLE.

DUNSTAN, St. in *Biography*, was born of noble parents at Glastonbury in Somersetshire in the year 925. Under the patronage of his uncle Aldhelm, archbishop of Canterbury, he was well instructed in the literature and accomplishments of those times, and in consequence of his recommendation invited by king Athelstan to court. By his own address and the interest of his uncle the king presented him with some lands near Glastonbury, where he is said to have spent some years in retirement. Edmund, the successor of Athelstan, appointed him abbot of a monastery, which he founded in that place. To this prince, however, he was represented as a man of licentious manners; and dreading the ruin of his fortune, by suspicions of this nature, he determined to repair past indiscretions by exchanging the extreme of superstition for that of licentiousness. Accordingly he secluded himself altogether from the world; and he framed a cell so small, that he could neither stand erect in it nor stretch out his limbs during his repose; and here he employed himself perpetually in devotion or manual labour. In this retreat his mind was probably somewhat deranged, and he indulged chimeras, which, believed by himself and announced to the credulous multitude, established a character of sanctity among the people. He is said to have fancied that the devil, among the frequent visits which he paid him, was one day more earnest than usual in his temptations; that Dunstan, provoked by his impertinency, seized him by the nose with a pair of red-hot pincers as he put his head into the cell; and he held him there, till the malignant spirit made the whole neighbourhood resound with his bellowsings. The people credited and extolled this notable exploit; and it ensured to Dunstan a degree of reputation, which no real piety, much less virtue, could, even in the most enlightened period, have ever procured for him. Supported by the character gained in his retreat, Dunstan appeared again in the world; and gained such an ascendancy over Edred, who had succeeded to the crown, as made him not only the director of that prince's conscience, but his counsellor in the most important affairs of government. The prince, deluded by an appearance of sanctity, which covered the most violent and most insolent ambition, gratified him by re-building Glastonbury church and monastery in a very sumptuous and magnificent style. He was placed at the head of the treasury; and being possessed of power at court, and of credit with the populace, he was enabled to attempt with success the most arduous enterprises. Taking advantage of the implicit confidence reposed in him by the king, Dunstan imported into England

a new order of monks, who, by changing the state of ecclesiastical affairs, excited, on their first establishment, the most violent commotions. Finding also that his advancement had been owing to the opinion of his austerity, he professed himself a partizan of the rigid monastic rules; and after introducing that reformation into the convents of Glastonbury and Abingdon, he endeavoured to render it universal in the kingdom. (See CELIBACY.) This conduct, however, incurred the resentment of the secular clergy; and this exasperated the indignation of many courtiers, which had been already excited by the haughty and over-bearing demeanour which Dunstan assumed. Upon the death of Edred, who had supported his prime minister and favourite in all his measures, and the subsequent succession of Edwy, Dunstan was accused of malversation in his office and banished the kingdom. But his cabal had obtained an influence over the minds of the populace which it was not easy to supplant, and during his absence his sanctity was extolled and served to excite insurrections against the government of Edwy. The moral and religious character of the king and queen was attacked, chiefly on the ground of their mutual attachment and endearment, and pretences of various kinds were directed for collecting together a great number of malcontents, who placed Edgar at their head and determined to exclude the reigning family. Edgar soon made himself master of the kingdom, and the death of Edwy made way for his accession to the throne. As soon as Edgar's power was established, Dunstan was recalled and promoted first to the see of Worcester, then to that of London; and about the year 959 to the archiepiscopal see of Canterbury. For this last advancement it was requisite to obtain the sanction of the pope; and for this purpose Dunstan was sent to Rome, where he soon obtained the object of his wishes and the appointment of legate in England, with very extensive authority. Upon his return to England, so absolute was his influence over the king, he was enabled to give to the Romish see an authority and jurisdiction, of which the English clergy had been before in a considerable degree independent. In order the more effectually and completely to accomplish this object, the secular clergy were excluded from their livings and disgraced; and the monks were appointed to supply their places. The scandalous lives of the secular clergy furnished one plea for this measure, and it was not altogether groundless; but the principal motive was that of rendering the papal power absolute in the English church, for, at this period, the English clergy had not yielded implicit submission to the pretended successors of St. Peter, as they refused to comply with the decrees of the popes, which enjoined celibacy on the clergy. Dunstan was active and persevering, and supported by the authority of the crown, he conquered the struggles which the country had long maintained against papal dominion, and gave to the monks an influence, the baneful effects of which were experienced in England until the era of the reformation. Hence Dunstan has been highly extolled by the monks and partizans of the Romish church; and his character has been celebrated in a variety of ways, and particularly by the miracles, which have been wrought either by himself or by others in his favour. During the whole reign of Edgar, Dunstan maintained his interest at court; and upon his death, in 975, his influence served to raise his son Edward to the throne, in opposition to Ethelred. Whilst Edward was in his minority, Dunstan ruled with absolute sway both in the church and state, but on the murder of the king in 979, and after the accession of Ethelred, his credit and influence declined; and the contempt with which his threatenings of divine vengeance were regarded by the king are said to have mortified him to such a degree,

ª degree, that he returned to his archbishopric, and died of grief and vexation in the year 988. Cave's Hist. Lit. vol. ii. p. 102. Rapin's Hist. Engl. vol. i. Hume's Hist. vol. i.

Dunstan is mentioned by several German writers not only as a great musician, but as the inventor of music in four parts: a mistake that has arisen from the similarity of his name with that of Dunstible, one of the earliest writers on counterpoint in this country; at least it is certain, that music in four parts was not only unknown here, but throughout Europe, in the tenth century, during which Dunstan flourished. Dunstan died 988, aged 64. Indeed, almost all the Monkish writers thought it necessary to make a conjurer of this turbulent prelate. Fuller, (Church History, 1666,) who has consulted them all, tells us, that he was an excellent musician, which, according to this writer, was a qualification very requisite to ecclesiastical preferment; for, he informs us, that, "preaching, in those days, could not be heard for singing in churches." However, the superior knowledge of Dunstan in music was numbered among his crimes; for being accused of magic to the king, it was urged against him, that he had constructed, by the help of the devil, (probably before he had taken him by the nose,) a harp, that not only moved of itself, but played without any human assistance. With all his violence and ambition, it may be supposed, that he was a man of genius and talents; since it is allowed, by the least monkish among his historians, that he was not only an excellent musician, but a notable painter and statuary, which, says Fuller, "were two very useful accomplishments for the furtherance of faint-worship either in pictures or in statues."

Indeed, it is expressly said, in a MS. life of this prelate, (Vit. St. Dunstan. MSS. Cott. Brit. Mus. Faustini. b. xiii.) that among his sacred studies, he cultivated the arts of writing, harping, and painting. It is likewise upon record, that he cast two of the bells of Abingdon abbey with his own hands. (Monast. Anglic. tom. i. p. 104.) And according to William of Malmesbury, who wrote about the year 1120, the Saxons had organs in their churches before the conquest. He says, that Dunstan, in the reign of king Edgar, gave an organ to the abbey of Malmesbury; which, by his description, very much resembled that in present use. "Organa, ubi per æreas fistulas musicis mensuris elaboratas, dudum conceptas follis vomit anxius auras." William, who was a monk of this abbey, adds, that this benefaction of Dunstan was inscribed in a Latin diltch, which he quotes, on the organ-pipes. Vit. Aldhem. Whart. Ang. Sac. ii. p. 33. Ob. Vit. S. Dunst.

DUNSTANG, in *Geography*, a town of Lithuania, in the palatinate of Wiina; 28 miles N. E. of Wilkomierz.

DUNSTAPLE, a market town and parish in the hundred of Manshead and county of Bedford, England, is situated on a chalky soil at the entrance of the Chiltern hills, where the Roman Watling street is crossed by the Ickneild-street. It was constituted a borough and market town by king Henry I. who, to defeat the depredations of robbers who infested that part of the country, encouraged a settler here, and built a royal mansion for himself. The name of the town is by some supposed to be derived from Dun, a chief of the robbers, but is with greater probability attributed to the market or staple on the downs. In the year 1131, the king bestowed the town with all its rights and privileges on a priory of Black Canons which he had founded near his palace. The town and priory were the scenes of many royal visits and solemnities in that and several succeeding reigns. In 1290 the corpse of Eleanor, Edward I.'s queen, was deposited here one night, which was commemorated by the erection of a cross in the market

place. This remained till 1643, when it was destroyed by the parliamentary forces. The priors of Dunstaple enjoyed very considerable rights and liberties; having the power of life and death vested in them. At the dissolution in 1554 the site of the priory was granted to Dr. Leonard Chamberlayne; it is now the property of Col. Maddison. The only remains of the conventual buildings, except what is now the parish church, are a few rooms roofed with vaulted and groned stone. In the present parish church, which contains only the nave of that of the old priory, different styles of architecture are displayed. The inside is part of the original structure. At the west end is a stone gallery, which has pointed arches; the windows are more modern. The decorations of the west front externally are of the early pointed style. The great western door has a semicircular arch, richly ornamented, but is now in a mutilated state. The town consists of four principal streets, answering to the cardinal points. At the fourth end are a respectable charity school endowed in 1712, and several alms-houses. But few of the privileges conferred by Henry I. are now retained by the townsmen; the government is vested in four constables. The chief manufactures are of various articles, useful and ornamental, in straw, particularly hats, which are known throughout the kingdom by the name of *Dunstaples*, the making of which affords subsistence to a great number of women and girls. King Henry I. granted two markets, held on Sundays (no unusual thing in ancient times) and Wednesdays; the latter only is now in use, with four annual fairs. Dunstaple is 33 miles N.W. from London; and contains, according to the returns under the late population act, 243 houses and 1296 inhabitants. Among the natives of this town, was Elkanah Settle, well known for his dramatic and political writings, which were published towards the close of the 17th century. The first attempt at theatrical representations in this kingdom is supposed to have been made in this town.

About a mile west of Dunstaple are the remains of an ancient fortification, called *Maiden Bower*. It is a circular earth-work, about 2500 feet in circumference, consisting of a single vallum and ditch.

Two miles north-west of the town, on the brow of a hill, is situated Totternhoe-castle, a work of great strength, consisting of a lofty circular mount, with a slight vallum round its base, and a larger one of an irregular form at some distance. On the fourth-east side is an encampment about 500 feet long and 250 wide; of which three sides are guarded by a vallum and ditch; the fourth being on the edge of a precipice has no vallum. Lysons's *Magna Britannia*, vol. i. Britton's *Archæological Antiquities*, vol. i.

DUNSTER, a town of England, in the county of Somerset, having a weekly market on Friday; 20½ miles W. of Bridgewater, and 15¾ W. of London.

DUNTER GOOSE, a species of the wild goose, found in Zealand. Phil. Trans. N^o 473. § 8. See *Cubæri Ducæ*.

DUNUM, Bav of, in *Ancient Geography*, is supposed to have been the mouth of the river Tees.

DUNWICH, in *Geography*, now a small borough and market town, in the hundred of Blything, in the county of Suffolk, England, was, during part of the Anglo-Saxon dynasty, a bishop's see, in which eleven prelates presided. In the year 955, this bishopric was united with that of Elmham in Norfolk, and both were soon afterwards transferred to Thetford, and thence, in 1088, to Norwich. Spelman states, that the town at one time contained 52 churches; but he must certainly mean the see. Dunwich, at present, consists of 42 houses, and 184 inhabitants. It sends two members to parliament; who are elected by a few free-men residing within the borough, and who do not receive

alms.

alma. The corporation consists of two bailiffs and 12 capital burgesses. In the town are the remains of an old church, which some antiquaries endeavour to prove was the Saxon cathedral. Here are also some remains of an ancient chapel, and a building called the palace. Here is a small market on Monday, and one annual fair. See Gardner's History of Dunwich.

DUNWICH, a township of America, in the county of Suffolk, in Upper Canada, W. of Southwold, having the river Thames for its north, and lake Erie for its south boundary.

DUNZ, or DUNS, JOHN, in *Biography*, painter of portraits and flowers. He was born at Berne, in Switzerland. Possessing an affluent fortune, he never painted for money; but was, nevertheless, indefatigable in his art. He was a great encourager of the arts and artists of his own time, and was much respected for his virtues. Died 1736. *Vie des Peintres Flamands, &c.*

DUO, in *Music*, a song, or composition, to be performed in two parts only; the one sung, and the other played on an instrument; or by two voices alone. See *Duet*.

DUO is also when two voices sing different parts, accompanied with a third, which is a thorough base. Unisons and octaves are rarely to be used in duos, except at the beginning and end.

DUOBUS, *Pilula ex*, in *Medicine*. See *PILLS*.

DUOBUS, *Sal de*. See *SULPHAT of Potash*.

DUODENALIS, in *Anatomy*, a term applied to such parts as belong to the duodenum; as the arteries, veins, &c.

DUODENUM, the first portion of the small intestine which communicates at its origin with the stomach, through the pylorus, and is continuous, at its termination with the jejunum, or second division. See *INTESTINE*.

DUPAGE, in *Geography*, a circular lake on the S. E. side of Plein river in America, or rather an enlargement of that river; 5 miles from its mouth. Plein and Theakiki there form the Illinois.

DUPATY, in *Biography*, a distinguished magistrate, and man of letters, was born at Rochelle, and became advocate-general to the parliament at Bourdeaux, and afterwards president à mortier. He acquired great honour by his firmness and eloquence at the revolution in the magistracy which took place in 1771, and successfully defended three persons of Chaumont, who had been condemned to be broken on the wheel. He published "Historical Reflections upon the Criminal Laws," which display an humane and enlightened mind, and was long occupied in promoting a reform on this subject, contending with a zeal worthy the cause against the obstacles, which prejudice and powerful influence threw in his way. He spent the latter part of his life at Paris, and made himself known, as a man of letters, by "Academical Discourses," and "Letters on Italy." He was thought too close an imitator of the manner of Diderot, by which his style did not appear to advantage. He died in 1788. *Gen. Biog.*

DUPHLY, a musical professor on the harpsichord, who composed some agreeable pieces in the French style of the time, (30 or 40 years ago,) which were printed in England by Walfsh, and which, as well as their author at Paris, were in high favour here, and thought well calculated to form the hand. Duphly was employed by Rousseau in drawing up the article *Dolce*, fingering; but his method is not what would be called good now, nor did it agree with the method of Couperin, good at the beginning of the last century, and in many particulars still excellent.

DUPIN, LOUIS ELLIS, a celebrated ecclesiastical historian, was born at Paris in 1657, where he was educated.

In the year 1672, he was admitted to his degree, on which occasion he particularly recommended himself to notice, by the able manner in which he performed the customary exercises. Having fixed upon theology as a profession, he studied at the Sorbonne, and then applied himself with the utmost diligence to the history of the councils, and the works of the fathers. In the year 1680, he was licensed to officiate as a priest, and, in 1684, he received the honour of doctor of the Sorbonne, and then employed his time and talents on his great work, entitled "Bibliothèque universelle des Auteurs Ecclesiastiques," &c. or, "History of Ecclesiastical Writers, containing an Account of the Authors of the several Books of the Old and New Testament; and the Lives and Writings of the primitive Fathers," &c. &c. This work was well received, and has maintained a high reputation to the present time, as well for the information which it conveys, as for its impartiality. It has gone through many editions in France, Holland, and this country. He next published, "An Account of the Writers of the first Three Centuries." This work appeared in 1686, and was followed by a succession of volumes, published at different periods, from that time to 1719. Before M. Dupin had completed his "Account of the Writers of the first Eight Centuries," the freedom of his opinions called forth the remarks of some monks, which obliged him to justify what he had written. These were not the only enemies with whom he had to struggle; the celebrated Bossuet, in his zeal for the catholic faith, collected a number of propositions from the volumes of Dupin, which he asserted were of a highly dangerous tendency. The historian retracted, and was allowed to proceed without farther interruption. Notwithstanding the labour of research which this work required, the author, during the time of publishing it, presented to the world many other volumes on different subjects, and he sustained at the same time the office of commissary in the concerns of the faculty of the Sorbonne, discharged the duties of professor of philosophy in the college royal; furnished important contributions to the "Journal des Sçavans;" supplied numerous applicants with memoirs, prefaces, advice on literary and other subjects; and yet, by his industry, and a methodical distribution of his time, found leisure to indulge in the society, and conversation of his friends. In the dispute concerning the opinions of Janfenius, he took that side which exposed him to the resentment of the pope, and of the court of France, and was, accordingly, deprived of his professorship in the year 1703, and likewise banished: nor was he permitted to return to Paris before he retracted the measures which he had taken; and even then he was not reinstated in his professorship. This was not his only trouble; he was harassed under the regency, on account of the correspondence which he held with Dr. Wake, archbishop of Canterbury, relative to a project for uniting the churches of England and France. In the beginning of the year 1719, his papers were seized, by order of government, and innumerable calumnies propagated to his prejudice; but as no charge could be made out against him, he was permitted to spend his few remaining days in peace. He died in a very short time after at Paris, in the 62d year of his age, regretted by his friends, and by his enemies, who were now ashamed of their conduct towards him. His works were very numerous, of which an account will be found in Moreri, and also in the *Gen. Biography*.

DUPINO, or DURLIN, in *Geography*, a town of Poland, in the palatinate of Pofnania; 44 miles south of Posen.

DUPLÉIX, SCIPIO, in *Biography*, a French historian, was born at Condon in 1569. Queen Margaret of Navarre brought him to Paris in 1605, and made him her master of requests. After this he was appointed historiographer of France, and laudably employed many years in researches into the ancient records of his country. Hence he published “Memoirs of the Gauls,” 1619, 4to., which, on account of the facts contained in them, were highly esteemed. It might also be regarded as the first part of his “History of France,” which is brought down to the year 1645. The last two reigns were revised by cardinal Richieu, which will account for the adulation paid to that minister. He intended to have re-written a part of the work after the death of the cardinal, but did not live to effect it. He was author of a “Roman History,” and a “Course of Philosophy,” and other pieces of no great note. In the decline of life he composed a work on the liberties of the Gallican church, which he presented in MS. to the chancellor Seguier, requesting permission to print it, but the chancellor unfeelingly threw it in the fire before his face. The poor old man was so affected with this circumstance that he never again looked up, and died soon after, in 1661, at the age of 92. *Moreri*.

DUPLÉIX, JOSEPH, a celebrated French naval commander in the East Indies, was brought up to a mercantile life, and sent out in the year 1730 to direct and support the declining settlement of Chandernagore, which, by his activity and great address, he restored to a most prosperous condition. He extended his country's commerce through the great mogul's territories as far as Tibet, and established a maritime trade with the Red sea, the Persian gulf, the Maldives, and Manilla. And in 1742 his great services were recompensed with the government of Pondicherry. In 1746 La Bourdonnais asserted the honour of the French flag, by dispossessing the English of Madras: this excited the jealousy of Duplex, who broke the capitulation, and sent charges against Bourdonnais to the French court, which caused him to be confined in the Bastille. In 1748 the English attacked Pondicherry, but Duplex was successful in its defence, and exhibited so much skill and heroism on the occasion, that he was rewarded with the title of marquis, and the red ribbon. From this time his ambition was almost boundless, and to him is to be ascribed the system of entering into the quarrels of the native powers, and sifting them alternately against each other, so as to render them at length tributaries and subjects, and almost the slaves of European settlers. He was at first very successful in his projects, and procured for himself the nabobship of the Carnatic, of which he was extremely proud, and indulged his vanity in assuming the state of a sovereign prince. But fortune soon turned against him: the English under Lawrence and Clive became triumphant, and expelled the French from their usurpations. Duplex was recalled in 1754, and the mortifications which he experienced at home preyed so much upon his mind, that he died soon after his return. *Hist. of France. Modern Univ. Hist.*

DUPLICATE, a second instrument, or act in writing; or a transcript, or copy of another.

The word is formed from the Latin *diploma*, or *diplum*, double.

It is usual to send a duplicate, when it is apprehended the first dispatch, &c. is lost.

DUPLICATE, in *Chancery*, is particularly used for a second letter patent granted by the lord chancellor, in a case where he had formerly done the same. See PATENT.

DUPLICATE *Ratio*, the ratio between the squares of two quantities. Thus the duplicate ratio of a to b is the ratio of aa to bb , or of the square of a to the square of b .

In a series of geometrical proportions, the first to the third is said to be in a duplicate ratio of the first to the second; or as its square is to the square of the second. Thus in 2, 4, 8, 16, the ratio of 2 to 8, is duplicate of that of 2 to 4, or as the square of 2 to the square of 4: whereas, duplicate ratio is the proportion of squares; as triplicate is of cubes, &c. and the ratio of 2 to 8, is said to be compounded of that of 2 to 4, and of 4 to 8.

DUPLICATE *Root*, among *Batanists*, one composed of two coats. See ROOT.

DUPLICATION, DOUBLING, in *Arithmetic*, or *Trigonometry*, the multiplying of a quantity, either discrete, continued, by two.

DUPLICATION of a *Cube*, is the finding of the side of a cube that shall be double in solidity to a given cube; which is a famous problem cultivated by the geometrists two thousand years ago.

It was first proposed by the oracle of Apollo at Delos; which, being consulted about the manner of stopping a plague then raging at Athens, returned for answer that the plague should cease when Apollo's altar, which was cubical, should be doubled. Upon this, they applied themselves in good earnest, to seek the duplicate of the cube, which henceforward was called the *Delian problem*. The problem is only to be solved by finding two mean proportionals between the side of the cube, and double that side; the first whereof will be the side of the cube doubled, was first observed by Hippocrates Chius.

Thus let x and z be two mean proportionals between a and $2a$: then $a : x :: x : z :: z :: \frac{z^2}{a}$; and $x : \frac{z^2}{a} :: \frac{z^2}{a} : 2a$; therefore $x^2 = 2a^2$. Supposing the side of the given altar a to be 10, then the cube root of $2a^3$, or 2000, found by approximation, will be the side of the altar required, &c.

Eutocius, in his comments on Archimedes, gives several ways of performing this by the melolabe. Pappus Alexandrinus, and his commentator, Commandine, give three ways: the first, according to Archimedes; the second, according to Hero; and the third, by an instrument invented by Pappus, which gives all the proportions required.

The sieur de Comiers has likewise published an elegant description of the same problem, by means of a compass with three legs; but these methods are all only mechanical.

Re-DUPLICATION. See REDUPLICATION.

DUPLICATION, a term in the French plain-chant. An intonation by duplication is made by a kind of period, or leading notes, doubling the penultima note of the word which terminates the intonation; and which can only happen when this penultima is below the terminating note. The duplication then serves to prepare and mark the clef in the manner of a *note sensible*, or sharp 7th of the key. See PERICLES.

DUPLICATUM ARCANUM. See ARCANUM.

DUPLICATION, in *Anatomy*, a term applied to folds of membrans or other soft parts, in which other organs are contained. Hence all duplicatures consist of two layers. Thus the lips and eyelids consist of duplicature

The skin the cartilage of the ear is enclosed in a duplicature of the same part; the intestines, with the mesenteric vessels, &c. are inclosed in a duplicature of the peritoneum, &c.

DUELIN, in *Geography*, a county of America, in the state of North Carolina and district of Wilmington, bounded E. by Clow, and S.W. by Sampson. The number of inhabitants is 6796, of whom 1364 are slaves. The farmers generally cultivate wheat and rice, but more commonly eat bread made of Indian corn. Cotton and sweet potatoes are raised in considerable quantities. The court-house is 55 miles N.W. of Wilmington, and 566 from Philadelphia.

DUEODES. See **GAMBEZON**.

DUONDIDIUS, in *Antiquity*, a weight of two pounds; or a duodecy of the value of two asses. See **AS**.

As it was, at first, weighed a just pondus, or libra, the dupondius then weighed two. And hence the name.

And though the weight of the as was afterwards diminished, and of consequence that of the dupondius also, yet they still retained the denomination. See **POUND** and **LIBRA**.

DUPUDI, or double asses, were coined both in the former and last period of the commonwealth. The dupondius was half the *Sestertius* (which see), and worth one penny sterling. Prior to Augustus, and before the *Oichalcus*, or yellow rals, appeared in the Roman coinage he generally as it did afterwards, this coin was struck in copper just double the size of the as. There are indeed dupondii of Julius in yellow rals, weighing half an ounce, with a head of **VENUS VICTRIX** on one side, and **CÆSAR DICT. TER.** reverse a female gure, with serpents at her feet, **C. CLOVI. PRÆF.**; others bear a victory on the reverse, with **Q. OPPIUS PR.** From the time of Augustus the dupondius was struck in yellow rals; as Pliny informs us it was in his time; and it is known that no change took place between that and the Augustan age. When this mode first began, the dupondiarus, used by Pliny, seems to have been adopted, expressing that the coin was not dupondius, or double the weight of the as, but of a dupondiar value. The word dupondius, however, was never confined, in its literal acceptation, to double weight, for Vitruvius and Varro use it as double length or measure, in the instance of *dupondius pes*, that is two feet, and the like. Hence, in the imperial times, it did not mean a coin double the weight of the as, but of double the value. The *sestertius* weighed an ounce, and the dupondius was the half of it; the as being of copper, as Pliny informs us; and it is inferred from him and from the whole coins that remain, that it stood at half an ounce, till the gradual decline of the *sestertius*, hardly perceivable before the time of Alexander Severus, brought the as along with it. The dupondius, being the half of the *sestertius*, kept pace with it through all its stages. (See **SESTERTIUS**.) It was one of the most common coins in the Roman empire, and it was also common in the Byzantine empire. Although the dupondius was of the same size with the as, it was commonly of much finer workmanship, as its metal was esteemed superior in value. The *sestertius* and the dupondius continued to be of yellow brass to the termination of the *sestertius* under Alaricus; and the as was always of copper. Pinkerton's *Essay on Medals*, vol. 1.

DUPORT, in *Biography*, a powerful performer on the violoncello. Till our *Crofdil*, stimulated, perhaps, by his example, had vanquished all the difficulties of finger-board and bow, incident to the instrument, we should readily have joined with M. Laborde, in calling him the most admirable performer on the violoncello that has ever been heard. When in England with his younger brother, it was thought that he could only be excelled by the elder.

DUPPA, BRIAN, a respectable English prelate, who

flourished in the 17th century, was born at Lewisham, in Kent, in the year 1588. The first part of his education he had at Westminster school, from whence he was removed to Christ-church, Oxford, in the year 1605. Here he took his first degree; and in 1612, he was chosen fellow of All-Soul's college. Two years after, he took his degree of M. A.; and having entered into orders, he travelled on the continent for farther improvement. In 1619, he was made a proctor to the university of Oxford; and in 1625, he took the degree of doctor in divinity. At this time he was chaplain to the prince Palatine, and likewise to the earl of Dorset; by the interest of the latter, he was appointed to the deanery of Christ-church, in the year 1629. He was, in the year 1632, chosen to the office of vice-chancellor of the university of Oxford; and in 1634, he was appointed chancellor of the church of Sarum, and chaplain to king Charles I., who, in 1638, gave him the office of tutor to Charles, prince of Wales, and his brother, the duke of York: in the same year he was nominated to the bishopric of Chichester, and in 1640 translated to the see of Salisbury, though, owing to the confusion of the times, he drew no emolument from it. He was a great favourite with the king, attended him closely in the scenes of his affliction, and is said to have assisted him in the composition of the "Eikon Basilike." After the death of his royal master, bishop Duppa retired to Richmond, in Surrey, where he spent the greater part of his time in solitude, until the restoration opened to him brighter prospects. On the accomplishment of that event, the loyalty of the bishop was rewarded by a translation to the rich bishopric of Winchester, to which he was nominated in 1660; he was also made lord almoner, and received other marks of royal distinction. In the following year, he began to build, at his own expence, an hospital for the poor of Richmond, and projected other works of piety and benevolence; but death, in 1662, stopped his hand. Charles II. so much respected his faithful tutor and steady friend, that he paid him a visit only a few hours before his decease, and, it is said, knelt down by his bed-side, and sought the blessing of the dying prelate, which he, no doubt, bestowed with true zeal and devotion. The bishop died, as he had ever lived, honoured and beloved by all who knew him, and leaving behind him a character exemplary for piety, candour, humility, meekness, generosity, and every useful virtue. He was author only of a few occasional sermons. Burnet, in his history, assumes, that bishop Duppa was unequal to the task of educating the young princes; but the biographers of the prelate have given good reason to believe he was admirably qualified for the office, as well by his talents as his strict integrity. Biog. Britan.

DUPRE, DE ST. MAUR, NICHOLAS, was born at Paris about the close of the 17th century; by his education, he was intended for the law, and obtained a place of master of the accounts. He acquired great reputation as a man of letters, and was one of the first of his countrymen who possessed a taste for English literature, and who endeavoured to promote it among his countrymen. He translated Milton's *Paradise Lost*, which, perhaps, was as well done as the nature of the thing would allow, and on account of it, he was admitted into the French academy, in 1733. He wrote also an "Essay on the Monies of France," 1746, 4to.; "Inquiries into the Value of Monies, and the Price of Corn," 1761, 12mo. And he communicated to Buffon "Tables on the Duration of Human Life," which are to be found in his *Natural History of Man*. M. Duprè died in 1775, at a very advanced age, leaving behind him a number of MSS. on the same kind of topics as those which he had discussed during his life. Gen. Biog.

DUPLEIX, SCIPIO, in *Biography*, a French historian, was born at Condon in 1569. Queen Margaret of Navarre brought him to Paris in 1605, and made him her master of requests. After this he was appointed historiographer of France, and laudably employed many years in researches into the ancient records of his country. Hence he published “Memoirs of the Gauls,” 1619, 4to., which, on account of the facts contained in them, were highly esteemed. It might also be regarded as the first part of his “History of France,” which is brought down to the year 1545. The last two reigns were revised by cardinal Richieu, which will account for the adulation paid to that minister. He intended to have re-written a part of the work after the death of the cardinal, but did not live to effect it. He was author of a “Roman History,” and a “Course of Philosophy,” and other pieces of no great note. In the decline of life he composed a work on the liberties of the Gallican church, which he presented in MS. to the chancellor Seguier, requesting permission to print it, but the chancellor unfeelingly threw it in the fire before his face. The poor old man was so affected with this circumstance that he never again looked up, and died soon after, in 1661, at the age of 92. *Moreri*.

DUPLEIX, JOSEPH, a celebrated French naval commander in the East Indies, was brought up to a mercantile life, and sent out in the year 1730 to direct and support the declining settlement of Chandernagore, which, by his activity and great address, he restored to a most prosperous condition. He extended his country's commerce through the great mogul's territories as far as Tibet, and established a maritime trade with the Red sea, the Persian gulf, the Maldives, and Manilla. And in 1742 his great services were recompensed with the government of Pondicherry. In 1746 La Bourdonnais asserted the honour of the French flag, by dispossessing the English of Madras: this excited the jealousy of Dupleix, who broke the capitulation, and sent charges against Bourdonnais to the French court, which caused him to be confined in the Bastille. In 1748 the English attacked Pondicherry, but Dupleix was successful in its defence, and exhibited so much skill and heroism on the occasion, that he was rewarded with the title of marquis, and the red ribbon. From this time his ambition was almost boundless, and to him is to be ascribed the system of entering into the quarrels of the native powers, and smiting them alternately against each other, so as to render them at length tributaries and subjects, and almost the slaves of European settlers. He was at first very successful in his projects, and procured for himself the nobility of the Carnatic, of which he was extremely proud, and indulged his vanity in assuming the state of a sovereign prince. But fortune soon turned against him: the English under Lawrence and Clive became triumphant, and expelled the French from their usurpations. Dupleix was recalled in 1754, and the mortifications which he experienced at home preyed so much upon his mind, that he died soon after his return. *Hist. of France. Modern Univ. Hist.*

DUPPLICATE, a second instrument, or act in writing; or a transcript, or copy of another.

The word is formed from the Latin *duploma*, or *duplum*, double.

It is usual to send a duplicate, when it is apprehended the first duplicate, &c. is lost.

DUPPLICATE, in *Chancery*, is particularly used for a second letter patent granted by the lord chancellor, in a case where he had formerly done the same. See PATENT.

DUPPLICATE Ratio, the ratio between the squares of two quantities. Thus the duplicate ratio of a to b is the ratio of a^2 to b^2 , or of the square of a to the square of b .

In a series of geometrical proportions, the first term to the third is said to be in a duplicate ratio of the first to the second; or as its square is to the square of the second: thus in 2, 4, 8, 16, the ratio of 2 to 8, is duplicate of that of 2 to 4, or as the square of 2 to the square of 4: wherefore, duplicate ratio is the proportion of squares; as triplicate is of cubes, &c. and the ratio of 2 to 8, is said to be compounded of that of 2 to 4, and of 4 to 8.

DUPPLICATE Root, among *Batanists*, one composed of two coats. See ROOT.

DUPPLICATION, DOUBLING, in *Arithmetic*, and *Geometry*, the multiplying of a quantity, either discrete, or continued, by two.

DUPPLICATION of a Cube, is the finding of the side of a cube that shall be double in solidity to a given cube; which is a famous problem cultivated by the geometers two thousand years ago.

It was first proposed by the oracle of Apollo at Delphos; which, being consulted about the manner of stopping a plague then raging at Athens, returned for answer, that the plague should cease when Apollo's altar, which was cubical, should be doubled. Upon this, they applied themselves in good earnest, to seek the duplicate of the cube, which henceforward was called the *Delian problem*. The problem is only to be solved by finding two mean proportionals between the side of the cube, and double that side; the first whereof will be the side of the cube doubled, as was first observed by Hippocrates Chius.

Thus let x and z be two mean proportionals between a and $2a$: then $a : x :: x : z :: \frac{x^2}{a} :: \frac{z^2}{2a} :: 2a$; therefore $x^2 = 2a^2$. Supposing the side of the given altar a to be 10, then the cube root of $2a^2$, or 2000, found by approximation, will be the side of the altar required, nearly.

Eutochius, in his comments on Archimedes, gives several ways of performing this by the mesolabe. Pappus Alexandrinus, and his commentator, Commandine, give three ways: the first, according to Archimedes; the second, according to Hero; and the third, by an instrument invented by Pappus, which gives all the proportions required.

The sieur de Comiers has likewise published an elegant demonstration of the same problem, by means of a compass with three legs; but these methods are all only mechanical.

RE-DUPPLICATION. See REDUPPLICATION.

DUPPLICATION, a term in the French plain-chant. An intonation by duplication is made by a kind of periclesis, or leading notes, doubling the penultima note of the word which terminates the intonation; and which can only happen when this penultima is below the terminating note. The duplication then serves to prepare and mark the clef in the manner of a *note sensible*, or sharp 7th of the key. See PERICLESIS.

DUPPLICATUM ARCANUM. See ARCANUM.

DUPPLICATURE, in *Anatomy*, a term applied to the folds of membranes or other soft parts, in which other organs are contained. Hence all duplicatures consist of two layers. Thus the lips and eyelids consist of duplicatures of the

The skin; the cartilage of the ear is enclosed in a duplicature of the same part; the intestines, with the mesenteric vessels, &c. are enclosed in a duplicature of the peritoneum, &c.

DUPLIN, in *Geography*, a county of America, in the state of North Carolina and district of Wilmington, bounded E. by Onslow, and S.W. by Sampson. The number of inhabitants is 6799, of whom 1364 are slaves. The farmers generally cultivate wheat and rice, but more commonly eat bread made of Indian corn. Cotton and sweet potatoes are raised in considerable quantities. The court house is 55 miles N. of Wilmington, and 566 from Philadelphia.

DUPLODES. See GAMBESON.

DUPONDIIUS, in *Antiquity*, a weight of two pounds; or a money of the value of two asses. See AS.

As the as, at first, weighed a jult pondio, or libra, the dupondius then weighed two. And hence the name.

And though the weight of the as was afterwards diminished, and of consequence that of the dupondius also, yet it still retained the denomination. See POUND and LIBRA.

Dupondii, or double asses, were coined both in the former and later period of the commonwealth. The dupondius was half the *Sestertius* (which see), and worth one penny sterling. Prior to Augustus, and before the *Oichalcus*, or yellow brass, appeared in the Roman coinage so generally as it did afterwards, this coin was struck in copper just double the size of the as. There are indeed dupondii of Julius in yellow brass, weighing half an ounce, with a head of VENUS VICTRIX on one side, and CÆSAR DICT. TER. reverse a female figure, with serpents at her feet, C. CLOVI. PRÆF.; others have a victory on the reverse, with Q. OPPIUS PR. From the time of Augustus the dupondius was struck in yellow brass; as Pliny informs us it was in his time; and it is known that no change took place between that and the Augustan age. When this mode first began, the dupondiarus, used by Pliny, seems to have been adopted, expressing that the coin was not dupondus, or double the weight of the as, but of a dupondary value. The word dupondius, however, was never confined, in its literal acceptation, to double weight, for Vitruvius and Varro use it as double length or measure, in the instance of *dupondius pes*, that is two feet, and the like. Hence, in the imperial times, it did not mean a coin of double the weight of the as, but of double the value. The *sestertius* weighed an ounce, and the dupondius was the half of it; the as being of copper, as Pliny informs us; and it is inferred from him and from the whole coins that remain, that it stood at half an ounce, till the gradual decline of the *sestertius*, hardly perceivable before the time of Alexander Severus, brought the as along with it. The dupondus, being the half of the *sestertius*, kept pace with it through all its stages. (See SESTERTIUS.) It was one of the most common coins in the Roman empire, and it was also common in the Byzantine empire. Although the dupondius was of the same size with the as, it was commonly of much finer workmanship, as its metal was esteemed superior in value. The *sestertius* and the dupondius continued to be of yellow brass to the termination of the *sestertius* under Gallienus; and the as was always of copper. Pinkerton's Essay on Medals, vol. i.

DUPORT, in *Biography*, a powerful performer on the violoncello. Till our *Croft*l, stimulated, perhaps, by his example, had vanquished all the difficulties of finger-board and bow, incident to the instrument, we should readily have joined with M. Laborde, in calling him the most admirable performer on the violoncello that has ever been heard. When in England with his younger brother, it was thought that he could only be excelled by the elder.

DUPPA, BRIAN, a respectable English prelate, who

flourished in the 17th century, was born at Lewisham, in Kent, in the year 1588. The first part of his education he had at Westminster school, from whence he was removed to Christ-church, Oxford, in the year 1605. Here he took his first degree; and in 1612, he was chosen fellow of All-Souls college. Two years after, he took his degree of M. A.; and having entered into orders, he travelled on the continent for farther improvement. In 1619, he was made a professor to the university of Oxford; and in 1625, he took the degree of doctor in divinity. At this time he was chaplain to the prince Palatine, and likewise to the earl of Dorset; by the interest of the latter, he was appointed to the deanery of Christ-church, in the year 1629. He was, in the year 1632, chosen to the office of vice-chancellor of the university of Oxford; and in 1634, he was appointed chancellor of the church of Sarum, and chaplain to king Charles I., who, in 1638, gave him the office of tutor to Charles, prince of Wales, and his brother, the duke of York; in the same year he was nominated to the bishopric of Chichester, and in 1640 translated to the see of Salisbury, though, owing to the confusion of the times, he drew no emolument from it. He was a great favourite with the king, attended him closely in the scenes of his affliction, and is said to have assisted him in the composition of the "Eikon Basilike." After the death of his royal master, bishop Duppa retired to Richmond, in Surrey, where he spent the greater part of his time in solitude, until the restoration opened to him brighter prospects. On the accomplishment of that event, the loyalty of the bishop was rewarded by a translation to the rich bishopric of Winchester, to which he was nominated in 1660; he was also made lord almoner, and received other marks of royal distinction. In the following year, he began to build, at his own expence, an hospital for the poor of Richmond, and projected other works of piety and benevolence; but death, in 1662, stopped his hand. Charles II. so much respected his faithful tutor and steady friend, that he paid him a visit only a few hours before his decease, and, it is said, knelt down by his bed-side, and sought the blessing of the dying prelate, which he, no doubt, bestowed with true zeal and devotion. The bishop died, as he had ever lived, honoured and beloved by all who knew him, and leaving behind him a character exemplary for piety, candour, humility, meekness, generosity, and every useful virtue. He was author only of a few occasional sermons. Burnet, in his history, assumes, that bishop Duppa was unequal to the task of educating the young princes; but the biographers of the prelate have given good reason to believe he was admirably qualified for the office, as well by his talents as his strict integrity. Biog. Britan.

DUPRE, DE ST. MAUR, NICHOLAS, was born at Paris about the close of the 17th century; by his education, he was intended for the law, and obtained a place of master of the accounts. He acquired great reputation as a man of letters, and was one of the first of his countrymen who possessed a taste for English literature, and who endeavoured to promote it among his countrymen. He translated Milton's Paradise Lost, which, perhaps, was as well done as the nature of the thing would allow, and on account of it, he was admitted into the French academy, in 1733. He wrote also an "Essay on the Monies of France," 1749, 4to.; "Inquiries into the Value of Monies, and the Price of Corn," 1761, 12mo. And he communicated to Buffon "Tables on the Duration of Human Life," which are to be found in his Natural History of Man. M. Duprè died in 1775, at a very advanced age, leaving behind him a number of MSS. on the same kind of topics as those which he had discussed during his life. Gen. Biog.

DUPUIS, DR. THOMAS SAUNDERS, late one of the organists and composers of the king's chapel. He was a correct harmonist in his compositions, and a good performer on the organ, with a fancy not very rich or original; but his finger was lively, and he knew the instrument well. He died in 1796, and was succeeded in the chapel-royal by Dr. Arnold.

DUPUIS, ERICUS. Cardinal Bona pretended, that ever since the eleventh century (which was that of Guido), Ericus Dupuis had added a note to the hexachord of Guido, to avoid the difficulties of the mutations in solmifation, and facilitate the study of plain-chant. This assertion cannot be supported, as there remains not the least vestige of any such addition. No one doubts at present of this 7th syllable *fi* having been added to the other six by Le Mare, about the end of the 17th century.

All his merit, however, consists in giving the syllable *fi* to the 7th note, for its utility had long been demonstrated. See the works of Pere Merseune. Laborde. The use of this syllable, however, is not yet general in any part of Europe, except France; nor in any other country do they agree to call it, except when it is the key note.

DUQUE CORNEJO, PEDRO, sculptor, painter, and architect, born at Seville in 1677; disciple of Pedro Roldan, but inferior to his master. His works are very numerous at Seville, and particularly in the cathedral. He was already in high estimation in that city, when Philip V., passing through it, carried the artist with him to Madrid. He there executed several works; but, his royal patron dying, he returned to Seville, where he maintained, and even increased his former reputation. Thence, he accepted an invitation to Granada, to make the statues for the chapel of Nuestra Senora de las Angustias, and afterwards proceeded, on a similar invitation from the chapter of the cathedral at Cordova, to undertake the works of that church, which he had scarcely completed, when he died, at the age of 80, and was sumptuously interred in the cathedral, at the expence of the chapter.

He possessed a ready invention, and great facility in all the arts of design; but his public works are chiefly on sculpture. Diccionario Historico de las Bellas Artes en Espana.

DUQUELLA, in *Geography*, a province of Africa, in the empire of Morocco, which extends to the walls of Saffi. This province is bounded on the north by that of Temfena; to the east by those of Escura, Ramna, and Morocco; to the south by the province of Abda, and to the west by the ocean. It is populous, rich, and commercial; abounds in corn, and produces a great quantity of wool, part of which is sold unwrought, and the rest employed in the manufactures, with which it supplies the southern provinces. This province formerly extended to the river Taniff; but that of Abda has been taken out of it, in order to divide it between two brothers who disputed the government. The inhabitants of Duquella are, in general, of a large size, and robust; they are a trading people, and all more affable and engaging than those of the other southern provinces. The province of Abda, which once made a part of that of Duquella, begins at the city of Saffi, and extends to the river of Taniff; its form is triangular. The inhabitants are addicted to the profession of arms, and many of them are in the service of the court.

DUQUESNE, a river of the island of Grenada, which runs into the sea, in a bay to which it gives name. N. lat. 12° 18'. W. long. 61° 27'.

DUQUESNE Point, a cape on the W. coast of the island of Grenada. N. lat. 12° 17'. W. long. 61° 29'.

DUR, Fr. harsh, in *Music*. Every sound is called *dur*

that is shrill, piercing, and disagreeable. There are coarse voices, harsh instruments, rough harmony. The harshness of B quadrum, made it at first be called *durum*. There are harsh intervals in melody; such are the tritonous and sharp 5th; and, in general, all the major discords. The harshness of extraneous modulation renders the harmony disagreeable, and offends the ear.

DURA, or DURIS, in *Ancient Geography*, a river of Hibernia, according to Ptolemy.—Also, a town of Asia, in Mesopotamia, according to Steph. Byz. and Polybius.—Also, a river of Greece, in Trachinia, a canton of Theffaly.—Also, an episcopal town of Africa, in the Byzacean territory.—Also, a town of Asia, in Cœlefyria, according to Polybius; who says, that it was well fortified, and unsuccessfully besieged by Antiochus, king of Syria. It is thought to be the *Dor* of Scripture, situated between Ptolemais and Cœarea.—Also, *Inam-Mohammed-Dour*, a town of Asia, on the left bank of the Tigris, E. S. E. of Birta.—Also, a town of Asia, in Mesopotamia, on the banks of the Euphrates, called also *Nicanoris*, and situated S. E. of Circetium.

DURA-MATER, or MENINX, in *Anatomy*, is the membrane which lines the inner surface of the cranium. See BRAIN.

DURA-MATER, *tumours of*. Most writers have not understood the diseases, which are now well known by the appellation of fungous tumours of the dura-mater, or outer membrane of the brain. These swellings make their appearance suddenly under the integuments of the head; but they can only protrude externally in this manner, after they have made their way through the bones of the skull, which, one might suppose, would be capable of impeding their progress outward.

M. Louis, one of the greatest of the French surgeons, has written a very interesting memoir on the present subject. It is observed by this gentleman, that the kind of relation, which unintelligent persons generally discern between causes and effects, creates a prejudice, which prevents them from seeing the possibility of the cranium being perforated by a subjacent, soft, fungous excrescence, formed by the vessels of the dura-mater. But the comparative density of the bones, and softness of the tumour, which present, on one hand, a cause to all appearances very weak, and on the other, a resistance which might be thought invincible, can only deceive such persons as are inattentive to the ordinary actions of nature. Numerous phenomena of a similar kind might be pointed out. But, not to quit the human body, do we not frequently see aneurisms of the arch of the aorta occasion an absorption of the sternum and ribs, while the aneurismal sac, on the side towards these bones, suffers the least degree of attenuation?

The symptoms and complaints, which fungous tumours of the dura mater have in common with some other diseases, have been too superficially attended to by many practitioners, who have, therefore, imbibed erroneous opinions concerning the true character of these swellings. M. Louis also very justly imputes some of the slowness, with which surgeons became acquainted with the real nature of the present disease, to those few observers who did know something about it, not extending their investigations beyond one particular fact, which was the exclusive object of their consideration. Their views of the subject being circumscribed, they regarded the case only in the light of a very singular and extraordinary affection; and every one will be of opinion with M. Louis, that our knowledge, which is always too confined, must necessarily be very imperfect, when not drawn from a due number of facts relating to one object, which facts

ought

ought to be most scrupulously examined in every possible point of view.

We think the best way of making the reader acquainted with the nature of fungous tumours of the dura mater is, to present him with the particulars of a case recorded by M. Louis.

This eminent surgeon was requested by M. Pibra to examine the head of a man, 35 years of age, who had died of a disease which had for some time been the subject of conversation among professional men. The patient had had an excellent constitution, and was born of very healthy parents. Towards the end of December, 1761, he slipped, and fell with considerable force on the tuberosities of the ischium, which alone sustained all the violence of the shock. The latter circumstance was ascertained beyond the possibility of doubt. It is also highly deserving of notice, that the person felt so stunned at the instant of the fall, that he could scarcely manage to get up again. The accident was attended with no degree of pain. The sensation of stunning in the head lasted incessantly for four months, and then gradually went off.

After four months ease, a barber, who was shaving the man's head, perceived an odd sensation under the razor, on the right side of the top of the head. It was a sort of crepitation, like that occasioned by the handling of a piece of dry parchment, which lay under the integuments. The hair-dresser expressed his surprize to the patient, who felt his head, and experienced the same sensation. At this period there was no elevation nor depression at the part. The next day, a tumour, about as large as a shilling, made its appearance; it was not very prominent, but it had a pulsatory motion. It is obvious, that the crepitation previously felt had been occasioned by the compression of the razor and fingers on the surface of the parietal bone, which was exceedingly attenuated by the fungus, the upper part of the tumour being merely covered with a plate of bone, so very thin as to be flexible.

The tumour, which was always of an indolent nature, made considerable progress in a few days, and this circumstance led the patient to consult several persons about it. The first one, whose opinion was requested, thought that the swelling was an aneurism, and, consequently, advised the employment of a bandage, for the purpose of making pressure on it. The patient, however, could not endure this plan. The tumour, when compressed, was easily reduced to a level with the opening in the parietal bone; but when this was done, very alarming numbnesses were produced, and it was absolutely necessary to leave off the use of the bandage. The swelling continued to grow larger, and the opening in the parietal bone acquired an increase of size in proportion. Several physicians and surgeons met to give their opinions concerning the disease; only one of them thought the case an aneurism. Some supposed it was a hernia of the brain; but most of them suspended their judgment, not wishing to hazard an opinion on a disease which they regarded as altogether extraordinary. The patient was exempt from all suspicion of having any venereal complaints; but, when he was about 18, he had had some appearances of scurvy, and this circumstance led to the trial of antiscorbutic remedies.

These, however, only impaired the constitution, and, far from retarding the growth of the tumour, it increased more rapidly in size during the exhibition of such medicines than before. It made its appearance externally, being as large as a turkey's egg, painful, and remarkable for this singularity, that when the tumour was compressed the pain ceased. The stupefaction, which was the immediate effect of such compression, made the method intolerable, so that the patient

preferred an habitual pain to the means of getting relieved of it. M. Louis thought this circumstance easily admitted of explanation: the sense of pain was not a part of the character of the disease, but only arose from the irritation which the tumour suffered from the irregular points and inequalities of the edges of the opening in the parietal bone. Gently pushing back the prominent part of the fungus kept the tumour at the instant from being hurt by the inequalities and sharp edges of the preternatural opening in the parietal bone. The patient for the four or five last months of his existence gave himself up to empiric; he died April 17th, 1763.

For the purpose of examining the disease with the utmost care, and not doing mischief with the knife, M. Louis made a circular incision in the soft parts at the base of the skull-cap, so as to be able to saw it and take it away, together with the dura-mater and integuments, while these parts retained the same relations which they had to the tumour, both internally and externally. The tumour arose from the convex surface of the dura-mater, was as large as the fist, and was very regularly circumscribed, being rather less prominent under the cranium than above it. The base of the swelling was more extensive than its upper part; the protuberant part under the cranium was occasioned by a kind of thickening of the dura-mater, and was lodged in a depression, which it had formed for itself in the corresponding portion of the brain. The inner layer of the dura-mater, in the situation of the tumour, was a little thicker than elsewhere, and its vessels were more considerable and large.

The tumour was not at all adherent to the cranium; the preternatural opening in the skull was exceedingly irregular; and on the outside of the parietal bone, round the aperture, there were some bony eminences. Between the two anterior angles of the parietal bone, near the coronal suture, an unequal piece of bone was found, as wide as a quill, and about an inch long, which rose almost perpendicularly from a base very little larger than the rest of this portion of bone. The inner table of the parietal bone was irregularly destroyed around the opening, and to an extent proportioned to the base of the swelling, which the incessant pulsations of the brain tended to force entirely out of the cranium, by beginning to destroy the bony parts, which covered the disease.

Both externally and internally there were numerous inequalities on the surface of the adjacent bones for some way from the opening. The fungous substance of the dura-mater was covered with a membrane which accurately circumscribed its extent. Its consistence was such as common sarcomatous swellings usually have, being attended at no point with either elasticity or fluctuation. The blood, which flowed out when an incision was made, was dark coloured, like what the veins of the above kind of swelling commonly contain.

Paré has recorded a case, which M. Louis concludes was certainly a fungous tumour of the dura-mater; although Paré himself was informed by two surgeons, who examined the head after death, that it was a tumour composed of the substance of the brain itself. M. Louis says, that this must certainly have been a mistake; for, while the cerebrum is covered by the dura-mater and cranium, it cannot overcome the resistance which these parts present. For a hernia cerebri to have taken place the bone must have been previously destroyed in some way or another, and there must have been at the same time a solution of continuity in the dura-mater. Experience has frequently proved, that in wounds of the head, attended with great destruction of the cranium, no hernia, nor fungus cerebri ever occurs as long as the dura-mater covers this viscus. In the same cases, when this membrane has been torn or cut, a protrusion of the brain does not happen, except from a pre-

cular alteration of the very substance of this organ, in consequence of the injury it has sustained.

M. Petit, in his "Traité des Maladies des Os," takes notice of certain tumours, attended with a pulsation on the surface of the cranium, and with caries of the bone. These were obviously, according to M. Louis, fungous swellings of the dura-mater; they also had been mistaken by several practitioners for aneurisms. Petit shews how wrong this opinion was, and explains that the pulsation of the tumours in question was only communicated to them by the brain.

M. Louis, in his valuable dissertation on the present subject, cites a vast number of cases, from which it appears, that fungous tumours of the dura-mater are usually preceded by external violence done to the head. Some examples are also adduced, which were supposed to have proceeded from internal syphilitic causes. However, M. Louis himself was well aware, that the tumours in question might only be an accidental complication, and not at all connected with the venereal disease. Of this fact, we think there can be little doubt.

Fungous tumours of the dura-mater may originate at any part of this membrane; but they are said to be particularly apt to grow on the surface, which is adherent either to the upper part of the inside of the skull, or to its basis. They are firm, indolent, and chronic, seeming as if they were the consequence of a slow inflammation, affecting the vessels which supply the dura-mater, and inoculate with those of the diploe. It is very difficult, one might say impossible, to determine, whether an affection of this kind always begins in the dura-mater, or the substance of the bone itself. The patient, whose case is above quoted from the memoir of M. Louis, had received no blow upon the head, and could only impute his complaint to a fall, in which the head had not struck against any thing. Although this case may tend to shew that fungous tumours of the dura-mater may form spontaneously, yet, it is confirmed by the examination of a vast number of cases, that the disease more frequently follows blows, than any other cause. Hence, a slow kind of thickening of the dura-mater is produced, which ends in a sarcomatous excrescence, the formation of which always precedes the destruction of the bone.

In the memoir, published by M. Louis in the 5th volume of those of the Royal Academy of Surgery, there is a very interesting case, illustrating to what an extent this disease may proceed. The subject is a young man, aged 21, who had on the left side of his head a considerable tumour, which was supposed to be a hernia cerebri. The swelling had begun in the region of the temple, and had gradually acquired the magnitude of a second head. The external ear was displaced by it, and pushed down as low as the angle of the jaw. At the upper part of the circumference of the base of the tumour, the inequalities of the perforated bone, and the pulsations of the brain, could be distinctly felt. Some parts of the mass were elastic and hard; others were soft and fluctuating. A plaster, which had been applied, brought on a suppuration at some points, from which an ichorous discharge took place. Shiverings, and febrile symptoms ensued, and the man died in less than four months. On dissection, a sarcomatous tumour of the dura-mater was detected, together with a destruction of the whole portion of the skull, corresponding to the extent of the disease.

When a fungous tumour of the dura-mater has once formed, it makes its way outward, through all the parts, soft, or hard, which are in its way. Such portion of the skull, as opposes its progress outward, is absorbed, and then the swelling, all on a sudden, and, in general, very unexpected-

ly, rises up externally, confounds itself with the scalp, and presents itself outwardly in the form of a preternatural, soft, yielding swelling, which even sometimes betrays an appearance of a decided fluctuation, or a pulsation; which latter symptom, as we have remarked above, has very frequently led former practitioners to suppose the case an aneurism. When once the swelling has made its exit from the cavity of the cranium, it spreads out on every side under the integuments, which readily make way for its growth. The scalp becomes distended, smooth, and œdematous over the extent of the tumour, and, lastly, it ulcerates. The matter which is discharged from such ulcerations, is thin and sanious. The outer part of the tumour is confounded with the integuments and edges of the skull on which it rests, so that, in this state, it is easy to mistake the tumour for one whose base is altogether external. While the swelling thus increases in size externally, it also enlarges internally. The latter change takes place, in particular, while the opening in the cranium is not large enough to admit the whole mass of the tumour, which then depresses the brain, and lodges in an excavation which it forms for itself. But this cavity quickly diminishes, and becomes reduced almost to nothing, as soon as the tumour has formed an external protrusion. In order to make way for the progress of the swelling outward, a portion of both tables of the skull is absorbed; but, it is remarked, that the internal, or vitreous table, is always found much more extensively destroyed than the external one. Sometimes, as is mentioned in the preceding case, new bony matter is found deposited around the opening in the cranium.

The existence of a fungous tumour of the dura-mater cannot be ascertained, as long as there is no external change. The effects produced may originate from so many causes, that there would be great risk of a gross mistake in referring them to any particular ones. This is not the case when there is an opening in the skull. Then a hard-ness, which is always perceptible from the very first, at the circumference of the tumour, denotes, that it comes from within. When the part of the skull, immediately over the disease, has become exceedingly attenuated, and the outward swelling is just commencing, a crackling sensation is perceived, on handling the part, just such as one may suppose would arise from touching some dry parchment stretched under the skin. When much pressure is made on the disease, considerable pain is excited, and sometimes a numbness in all the limbs, stupefaction, and other more or less alarming symptoms. Pressure makes the tumour recede inward, in a certain degree, especially when the swelling is not very large. However, as soon as the compression is discontinued, it gradually rises up again. In some instances, the disease is attended with pain; in others, this effect is not produced; which circumstances may depend on the manner in which the tumour is affected by the edges of the bone, through which it passes. The pain often admits of being relieved by compression; but recurs as soon as this is discontinued. The tumour has a pulsatory motion, which is communicated to it by the brain, and which, as we have above related, has led many practitioners into an erroneous supposition, that the case was an aneurism. When the tumour is pushed sideways, and the finger is put between it and the edge of the bone through which the disease protrudes, the bony margin may be felt pressing against the base of the swelling, so as to cause a certain constriction of it. When this symptom is distinguishable, and conjoined with a certain degree of firmness and elasticity, and occasionally with a facility of reducing the swelling, it serves as a criterion for discriminating

ing a fungous tumour of the dura-mater, from a hernia of the brain, external fleshy tumours, abscesses, exstufes, and other difeases, which sometimes exhibit fomewhat fimilar appearances to thofe of the prefent affection.

Fungous tumours of the dura-mater are generally attended with a vaft deal of danger, as well on account of their nature, as of the difficulty of curing them in any certain manner, and of the dreadful fymptoms which they are apt to induce. Thofe fungous fwellings of the dura-mater which have a fmall bafe, which are firm in their texture, which are unattended with much difeafe of the furrounding bone, which are moveable, and not very painful, and which allo affect perfons who are, in other refpects, quite well, afford moft room for hope. However, though it is our duty to make fome effort to cure the difeafe, when thus circumftanced, the event muft always be regarded as very uncertain.

Our expectations of fucces must be very inconfiderable, indeed, when the difeafe has exifted a great while, and the functions of the brain are ferioufly impaired by it.

The moft fimple mode of attempting a cure is compreffion. It was this which naturally prefented itfelf to the minds of all thofe former furgeons, who fell into the error of miflaking the difeafe for an aneurifm, or a hernia cerebri. Erroneous opinions have alfo arifen, concerning the efficacy of compreffion, in confequence of the tumour, while below a certain fize, fometimes admitting of being reduced into the cranium, without any bad effects. However, as any one, at all acquainted with the nature of the difeafe, might expect, the reduction was only attended with a very temporary appearance of good being done. It had no effect whatever on the original caufe of the affection, the fymptoms returned, and the fwelling rofe up again, immediately when the preffure was difcontinued.

M. Louis records, in his difertation on the prefent fubject, a fact, which tends to fhew, that a certain degree of relief may fometimes be derived from a prudent employment of preffure. A woman, who had been brought to death's door by the alarming fymptoms arifing from a fungous tumour of the dura-mater, relted, for fome time, on the fame fide of her head on which the difeafe was fituated, the confequence of which act was, that all her appearances of difolution fuddenly vanifhed, and the fwelling difappeared in fo instantaneous a way, that fhe conceived her cure was the effect of a miracle. The tumour was afterwards kept from protruding again, by means of a piece of tin, faftened to the infide of her cap. The preffure, however, was not always maintained in an equal and regular manner, fo that the bad fymptoms occasionally recurred. They then ceafed, after the fwelling was reduced, and had got into a certain pofition.

There cannot be the fmalleft doubt, that the bad fymptoms were produced by the irritation which the tumour fuffered in paffing the inequalities of the edges of the opening in the cranium. The patient lived in this ftate nine years, fubject to occafional fits, in one of which, attended with hiccough and vomiting, the perifhed.

The compreffion being a very uncertain means of relief, it is, perhaps, better to expofe the tumour with a knife. This plan of bringing the fwelling into view is infinitely preferable to that of applying cauftic for the fame purpofe. Every one knows, that the action of cauftic can never be regulated with fufficient precision, befides being confiderably more painful than an incifion, and attended with an unneceffary deftruction of parts. The beft way is to make a crucial divifion of the fcalp, immediately over the tumour, and then difsect up the flaps, and reflect them, fo as to expofe all the bony circumference of the opening, through

which the fungous tumour projects. The furgeon fhould next cautiously remove all the part of the skull immediately furrounding the bafe of the fungus. This object has ufually been effected by applying the trephine as often as neceffary; but, perhaps, the beft instruments for the accomplifhment of the object in view, would be the faws defcribed by Mr. Hey, and now fold by all the makers of furgical instruments.

The fungous fwelling having been difengaged on all fides, is next to be cut off with a fcapel. Some advife the furface, from which the tumour grew, to be next fpinkled with fome of the pulv. hydrarg. nitrat. rub. However, the latter meafure feems by no means certain proper; for, applying eucharotics to one of the membranes of the brain cannot be free from danger. Were we to offer our fentiments on this part of the fubject, they would be in favour of cutting away the very root of the difeafe, in preference to ufing eucharotic applications.

Cutting away fungous tumours of the dura-mater is always a more advifable plan than tying their roots with a ligature, which cannot be executed, without dragging and ferioufly injuring the dura-mater, fo as to occafion the dangerous effects always attending any confiderable inflammation of this membrane. The employment of the knife is alfo preferable to that of cauftics, which are productive of much more pain and irritation, are apt to bring on fatal convulfions, and can never be accurately made to deftroy a certain quantity of fubftance, and no more.

In whatever way the furgeon choofes to operate, the root of the fungus muft be deftroyed, or elfe the excrescence will fhoot up again, and, by its injurious effects on the brain, at length prove fatal. When the knife is ufed, the practitioner muft not be afraid of removing a piece of the inner layer of the dura-mater, if there is any likelihood that the whole of the difeafe cannot be taken away without this proceeding. Cutting the dura-mater is certainly by no means a thing unattended with rifk; but the difeafe, if not fuppreffed, is furely fatal; and of the plans which hold forth the chance of a cure, none feem lefs dangerous and objectionable than that attempted with the knife. The effort to extirpate the difeafe at its very origin is lefs perilous, and lefs certainly fatal, than the unchecked progreff of the fungus, and, upon this principle, is obviously right, and, indeed, the only rational alternative.

Another circumftance, which we wifh to urge, is, that the attempt to extirpate fungous tumours of the dura-mater be always made as foon as the nature of the difeafe is known. In the early period of the diforder, the profpect of a cure muft be more hopeful, as it would not be neceffary to expofe fo much of the dura-mater, as afterwards becomes unavoidable.

Writers have defcribed other tumours of the dura-mater, which chiefly differ from the preceding ones, in only occurring after a perforation has been made in the cranium. They fhould be difcriminated from a hernia of the brain. See FUNGUS.

The inflammation of the dura-mater will be fpoken of in another place. See *Injuries of the HEAD*.

Every one who's defirous of being well acquainted with the fubject we have juft quitted, fhould read the difertation written by M. Louis, entitled, "Memoire fur les tumeurs fongueufes de la Dure-mere," and inferted in the fifth vol. of the Mem. de l'Acad. de Chirurgie, 4to.

DURA-PORIO, is that part of the feventh pair of nerves, which fupplies the face, and is more properly termed the facial nerve. See NERVES.

DURADE, or DURO, in the *Italian Mufic*, fignifies hard, harfh, or, more properly, fharp. This name is given to B natural.

tural, because its sound is sharp, when compared with B mol, or flat.

DURAKA, in *Geography*, a small island of Arabia, in the Red sea, about four leagues from the coast. N. lat. 16° 48'. E. long. 41° 31'.

DURAKOVA, a town of Russia, in the government of Archangel, on the coast of the White sea; 48 miles W. of Archangel.

DURAMPOUR, a town of Hindoostan, in the country of Guzerat; 45 miles S.S.E. of Surat, and 96 N.E. of Bombay. N. lat. 20° 32'. E. long. 73° 14'.

DURANCE, *The* a river of France, which has its source in the mountains north of Briançon, near the high road over Mont Genève, in the department of the Upper Alps. It runs to Briançon, Vailand, and Embrun; thence flowing to the west, and taking up the river Ubaye, it passes by Talard, near Gap, divides the department of the Upper from that of the Lower Alps, the latter of which it crosses from north to south; passes by Sisteron, where it receives the river Buèche, by Man-ſque and Saint Paul; after which, shaping its course to the west, it divides the department of Vaucluse from that of the Bouches du Rhône, flows to Pertuis, in the neighbourhood of which place it takes up the Verdon, and a little lower down the Cavallon, and at last falls into the Rhône, three miles below Avignon. Its whole course is about 180 miles.

The current of the Durance is so rapid, that this river can be crossed only in barks; hitherto, at least, it has been found impracticable to throw a bridge over it below Sisteron. Its frequent inundations make a dreadful havoc; it even alters its bed, and cannot be navigated on account of the many islets and sand-banks by which its course is obstructed. A company or association of Jews offered several years ago to embark the Durance at their own charge, provided all the land saved should be declared their property; to this the land owners objected, but it would now be considered as a very advantageous bargain. The Durance generally overflows its banks in July, after the melting of the snow in the Alps, and after the heavy rains of the month of November. It abounds, however, in fish, chiefly eels and trout. Its numerous islets, abounding with rabbits, are the haunts of snipes and wild ducks.

DURAND DE ST. POURRAIN, WILLIAM, in *Biography*, a learned scholastic divine in the 14th century, was born in the town annexed to his name, in the diocese of Clermont, and educated as a preaching monk of the Dominican order. In consequence of his eminent attainments in philosophical and theological studies, he was admitted to the degree of doctor in divinity, in the university of Paris, in the year 1313; and he afterwards delivered public lectures on sacred literature as master of the sacred palace at Rome. In 1318 he was nominated bishop of Rey, and, in 1326, translated to the bishopric of Meaux, by pope John XXII. By his indefatigable perseverance in the discussion of difficulties in scholastic theology, he obtained the appellation of the "Most resolute Doctor." He was at first a follower of Thomas Aquinas, but afterwards attached himself to the sect of Scotists, and defended their tenets with so much acuteness and zeal, that he offended the Thomists, and incurred their displeasure to such a degree, as to induce one of them, after his death, which happened in 1332, to degrade his memory by the following epitaph:

"Durus Durandus jacet hic sub marmore duro,
An sit salvandus ego nescio, nec quoque curo."

He was the author of "Commentaria super libros 4-Sententiarum," the best edition of which was published in 1571;

also, "Liber de origine Jurisdictionum, seu de ecclesiastica Jurisdictione, et Tractatus de legibus," printed in 4to. in 1571; and other treatises, one of which was never published, and others enumerated in a collection of his works edited under the care of Dr. Merlin in 1515. Cave's Hist. Lit. vol. ii. Sæc. Wicklev. p. 22. Brocker's Hist. Philof. by Enfield, vol. ii. p. 381.

DURANGO, in *Geography*, a town of Spain, in the province of Biscay, about three leagues from the sea-coast, and four east of Bilbao.

DURANGO, the capital of the kingdom of New Biscay, in the Spanish dominions of North America, and the farthest town of any note towards the north. This city is more remarkable for the extent of its bishopric, than for its population, which only consists of 5000 persons, including the companies of militia appointed to defend it against the Indians. The climate is mild and healthy, and the soil extremely fertile in wheat, maize, and fruits, whilst the pastures abound with excellent cattle. It contains four convents and three churches, one of which is situated on a hill without the city. It has an office of the royal treasury, for collecting the duties on the numerous mines in New Biscay. The bishopric was founded in 1620, and extends over all the provinces of New Biscay, viz. Tepeguana, Taranmara, Topia, Batopilas, Culiacan, Cinaloa, Ostimuri, Senora, and Pimeria. The amount of the tythes in the bishopric of Durango for ten years is 1,080,313 pesos. Durango is situated on an inland river, which is lost in a lake. This river seems to be the Guadiana, (another name of Durango,) or the Saucedo of D'Anville. N. lat. 23° 30'. W. long. 103°.

DURANTA, in *Botany*, in honour of Castor Durante, physician to pope Sixtus V., who published several medicobotanical works, amongst others an Italian herbal, which passed through many editions in folio, and some in quarto, illustrated with the smaller wooden cuts used by Matthiolum. Plumier, who founded this genus, called it *Castorea*, but Linnaeus rightly changed it, to accord with the family name of the person commemorated, as in other cases. Linn. Gen. 324. Schreb. 424. Willd. Sp. Pl. v. 3. 380. Mart. Mill. Dict. v. 2. Juss. 109. Gært. t. 57. (Castorea; Plum. Gen. 30. t. 17. Eilisia; Browne Jam. 262. Loefl. It. 104.) Class and order. *Didymania Angiosperma*. Nat. Ord. *Personate*, Linn. *Filices*, Juss.

Gen. Ch. Cal. Perianth of one leaf, inferior, tubular, somewhat abrupt, five-cleft. Cor. of one petal. Tube longer than the calyx, a little curved; limb spreading, rounded, in five deep, nearly equal, segments. Stamens four, enclosed within the tube, two longer than the rest; anthers roundish. Pist. Germen inferior, roundish; style thread-shaped, shorter than the tube; stigma a little swelling. Peric. Berry roundish, clothed with the calyx, and crowned with its teeth, of one cell. Nuts four, convex on one side, angular on the other, each of two cells. Seeds solitary.

Ess. Ch. Calyx inferior, tubular, with five teeth. Corolla tubular, curved, its limb five-cleft, nearly equal. Stamens in the tube. Berry with four nuts, of two cells each.

1. *D. Plumieri*. Linn. Sp. Pl. 888. Jacq. Amer. 186. t. 176. f. 76. Ic. Rar. v. 3. t. 502. Leaves ovato-lanceolate, slightly serrated. Calyx-teeth of the fruit spirally twisted together.—Gathered by Plumier, probably, and certainly by Jacquin, in Hispaniola. The stem forms a small tree, about fifteen feet high, with alternate, erect or drooping, square leafy branches. Leaves opposite, stalked, an inch and half long, lanceolate, inclining to ovate or elliptic, more or less acute, usually with a few shallow serratures towards the upper part, sometimes nearly entire, smooth on both sides, paler

paler and opaque beneath, veiny. In the bosom of each leaf is a small tuft of other leaves, or a downy bud, above which stands a horizontal awl shaped thorn, various in length, and sometimes wanting. *Clysters* of flowers situated in the pice of these thorns, in great abundance towards the upper part of each branch, solitary, simple, many-flowered, three or four inches long, their common stalks, and especially their partial ones, silky, as are likewise the awl-shaped bractees. *Calyx* somewhat bell shaped, rather silky, with five angles, and five small, acute, incurved teeth. *Corolla* blue-ish or lilac, its two uppermost segments rather narrowest, and each marked with a dark longitudinal line. *Fruit* invested with the permanent base of the calyx, which becomes united to it, and orange-coloured, while the teeth are spirally twisted together and crown the top. Such is the plant of the Linnean herbarium, in which are very perfect specimens in flower and fruit. The figure in Plumier's *Icones*, t. 79, is probably the same plant, but its leaves are much too strongly serrated, and there are no thorns; the latter circumstance is, however, said to be variable. We cannot but rely on the repeated assurances of the learned Jacquin, that this species is different from the following, and that the character taken from the calyx-teeth is permanent, especially as there is a difference in the leaves also. Swartz appears to have known but one species.

2. *D. Ellisia*. Linn. Sp. Pl. 888. Jacq. Amer. 187. t. 176. f. 77. Hort. Vind. v. 3. 51. t. 99. Sm. Tour on the Continent, ed. 2. v. 3. 97. (*Ellisia frutescens*, quandoque spinosa, foliis ovatis utrinque acutis ad apicem serratis, spicis alaribus; Browne Jam. 262. t. 29. f. 1.) Leaves ovato-lanceolate, sharply serrated. Calyx-teeth of the fruit erect.—Native of Jamaica. Very like the foregoing in general aspect and characters, except the calyx-teeth, and the deeper serratures of the leaves, which are constant, as represented by Jacquin, in all the specimens that have fallen in our way. We have seen this species cultivated in the open ground near Genoa, so that it seems less tender than most Jamaica shrubs. Its beautiful flowers rival those of our *Veronica Chamædrys*. Jacquin's plate is excellent.

3. *D. Mutifana*. Sm. Intr. to Bot. 381. (*D. Mutifii*; Linn. Suppl. 291. Willd. Sp. Pl. v. 3. 380.) Leaves elliptical, obtuse, entire, shining on both sides. Sent from New Granada by Mutis to Linnæus. This has the general habit of the two preceding, but is stronger, and, notwithstanding the suggestion of the younger Linnæus in the *Supplementum Plantarum*, we cannot but think it clearly and abundantly distinct. The leaves are of an elliptical figure, scarcely above an inch long, and above half as broad, very obtuse, perfectly entire, somewhat revolute, shining on both sides, and very little paler beneath. *Clysters* about as long as the leaves, only stronger, but in other respects much like the last. The branches also are spinous. The fruit we have not seen. S.

DURANTE, FRANCISCO, in *Biography*. This illustrious disciple of Alessandro Scarlatti, whom he succeeded as principal master of the conservatorio of Sant' Onofrio in Naples, deservedly merited the character of the best and most judicious contrapuntist that Italy can boast; not so much for the fugues, canons, or masses which he has composed, as for the number of illustrious scholars which his instruction and example have produced. No better proofs need be instanced than Pergolesi, Terradeglias, Piccini, Sacchini, Guglielmi, Traetta, Anfossi, and Paisiello, with whose admirable productions all Europe is well acquainted. Though Durante can hardly be called a secular composer, having pointed his labours to sacred music, in which no very light or gay melodies can occur with propriety: yet his

masses and motets abound with elegant movements ingeniously and richly accompanied; in which there is learning without pedantry, and gravity without dulness. These are treasured up in the conservatorio, for which they were produced, and where, in 1770, they were still in constant use.

But the cantatas of his master Al. Scarlatti for a single voice, which, after his decease, Durante formed into duets, of the most learned, graceful, and expressive kind, are what the greatest masters now living continue to study, and teach to their favourite and most accomplished scholars.

Several musicians have doubted whether the ground-work of these very elaborate *Stufi* was Scarlatti's, among whom was Pacchierotti; but in turning over different volumes of his cantatas in the presence of this admirable singer, while he resided in London, we found, and shewed him in Scarlatti's own hand-writing, the beautiful movements and recitatives upon which Durante worked with much felicity.

DURANTI, JOHN STEPHEN, was born at Toulouse, and deligned in early life for the bar, at which he afterwards distinguished himself for his eloquence. In the year 1563, he was made first magistrate; afterwards he became advocate-general, and, in 1581, was nominated by the king president of the parliament of Toulouse. He was strongly attached to the royal cause, and when the massacre of the duke and cardinal of Guise, in 1589, had inflamed the rage of the leaguers, especially at Toulouse, he employed all the force of his eloquence to appease the people. He afterwards prevented the parliament from throwing off their obedience to Henry III, and narrowly escaped with his life. His papers were seized and searched, but nothing was found to criminate him; some letters however written by his brother-in-law, Daffis, to the king's commandant at Bourdeaux, imploring assistance, being intercepted, the crime was imputed to Duranti, and the mob went in a body to the Jacobin convent, where he had sought protection, and demanded him to be given up. Taking leave of his wife and children, and commending his soul to God, he went forth, and asked with a tranquil mind of what he had been guilty. For a moment a profound silence ensued, at length a villain fired a musket which brought him to the ground, and immediately he was oppressed by a thousand bloody hands, which instantly put an end to his life. They treated the dead body with every indignity, and, at length, tied it to the pillory, with the king's picture hung at its back. This massacre of an excellent man, who had, in a hundred instances, been beneficial to his country, was perpetrated in February 1589. He was a friend and patron to letters, and had collected a fine library which was dispersed after his death. He is supposed to have been the author of a learned and excellent work, "De ritibus Ecclesie," which was given to Peter Danes, bishop of Lavaur. Moreri.

DURAS, in *Geography*, a small town of France, in the department of Lot and Garonne, chief place of a canton, in the district of Marmande, with a population of 1576 individuals. It is seated on a small river which flows into the Drot, 40 miles N.W. of Agen. Its district was erected into a dukedom in the year 1688, but lost its title with the French revolution of 1789. The canton has an extent of 222½ kilimètres, and contains 18 communes and 11,907 inhabitants.

DURAS, in *Ancient Geography*, a river of Vindelicis, which ran into the Ister, according to Strabo, supposed to be the present *Draua*.

DURASTANTE, LA MARGARITA, in *Biography*, the first capital female singer imported for the Italian opera in

in England. When Handel was commissioned by the directors of the Royal Academy of Music to engage vocal performers in the year 1723, he brought over from Dresden the Durante at the same time as Senefino, Borenstätt and Buschi. The figure of the Durante was somewhat masculine; but she was thought a good actress, and more admired in male than female parts. She seems to have been in great favour at our court; for his majesty, Geo. I., honoured her so far as to command an opera, and be present at her benefit, July 5, 1722; and in the Evening Post, N^o 1810, from Saturday the 4th to Tuesday the 7th of March 1721, we find the following paragraph: "Last Thursday his majesty was pleased to stand godfather, and the princefs and the lady Bruce, godmothers, to a daughter Mrs. Durante, chief singer in the opera-house. The marquis Visconti for the king, and the lady Litchfield for the princefs."

In the British Museum, among the Harleian MSS. there are verses written by Pope on the Durante leaving England.

"Generous, gay, and palant nation," &c. which are parodied by Arbuthnot, "Puppies, whom I now am leaving," &c.

DURATION, an idea we get by attending to the fleeting, and perpetual perishing parts of succession.

The idea of succession we get by reflecting on that train of ideas, which continually follow one another in our minds, while awake. The distance between any parts of this succession is what we call duration; and the continuation of the existence of ourselves, or any thing else commensurate to the succession of ideas in the mind, is called our own duration, or that of the thing co-existing with our thinking. So that we have no perception of duration when that succession of ideas ceases.

Duration, in Mr. Locke's philosophy, is a mode, or modification of space.

The simple modes of duration are any lengths, or parts thereof, of which we have distant ideas; as hours, days, weeks, months, years, time, eternity, &c.

Duration, as marked by certain periods and measures, is what we call properly *time*.

1. By observing certain appearances at regular and seemingly equidistant periods, we get the ideas of certain lengths and measures of duration, as minutes, hours, &c. 2. By being able to repeat those measures of time, as often as we will, we come to imagine duration where nothing really endures, or exists: thus we imagine to-morrow, next year, yesterday, &c. 3. By being able to repeat such ideas of any length of time, as of a minute, year, &c. as often as we will, and add them to one another, without ever coming to an end, we get the idea of eternity.

Time is to duration, as place is to space, or expansion. They are so much of those boundless oceans of eternity, and immensity, as is set out, and distinguished, from the rest; and thus they serve to denote the position of finite real beings, in respect of each other, in those infinite oceans of duration and space.

DURATION of action. See ACTION.

DURATION of an Eclipse. See ECLIPSE.

DURATION, scruples of half. See SCRUPLE.

DURATION of a solar eclipse. See ECLIPSE.

DURATION of sound. See SOUND.

DURATION, in *Vegetable Physiology*, means the determinate period of existence appropriated to each species of plant, whether annual, biennial, or perennial. Annual plants are such as spring up from seed, arrive at perfection, ripen their seed, and totally perish, in the space of one year, or

rather one season, as Mulsard, Radishes, Barley, and various garden flowers. In some instances the existence of such plants is limited to a very few months or even weeks, and is dormant in their seed the greater part of the year. Truly annual plants can never be propagated by cuttings or layers, except indeed some whose decumbent branches of themselves take root, and may therefore be separated from the parent root for that season only, as the common annual meadow-grass, *Poa annua*. The roots of some also are capable of division, and may therefore be increased artificially to a great extent, as is sometimes practised by curious persons on corn by way of experiment.

Biennial plants arrive at only a certain degree of perfection the first season, shewing no signs of flowering, and continuing stationary through the winter. In the following season they bear flowers, perfect their seed, and then perish like annuals. Of this nature are many species of mullein or *Verbascum*, the Fox-glove, *Digitalis purpurea*, the Canterbury Bell, *Campanula Medium*, &c. The tree mallow *Lavatera arborea* is justly esteemed biennial, because though it may survive several winters, if circumstances do not favour its flowering, it soon dies after ripening seed. A biennial plant therefore never fructifies more than once, how long soever its previous existence may be. Wheat is perhaps rather to be reckoned annual than biennial; for though with us it is found most convenient to commit it to the ground in autumn, it may be raised in one season, and does not require one summer to bring its herbage to perfection, and another to form fructification.

Perennial plants live and fructify through many successive seasons, like the generality of trees and shrubs, as well as many herbaceous plants, and may be increased by dividing their roots, or by cuttings, layers, or grafts. Their propagation however by such methods, does not appear to be unlimited. Several herbaceous perennial plants are well known to require frequent renewal from seed, in order to flourish in perfection, and some late experiments and observations on fruit-trees seem to prove that each variety, or, in other words, each individual plant, originally raised from seed, is limited to a certain period, in some kinds longer, in others shorter, beyond which the offspring of their buds or cuttings drag on but a sickly existence, and finally perish. This is best seen in the history of the different varieties of apples, some of which, after flourishing long, are now in decay, witness the golden pippin, while others raised from time to time by seed, either disappear by the effects of canker in a very few seasons, or seem to promise a long future existence. Willows and osiers of various kinds seem, as far as we can observe, to be of very long, or even indeterminate, duration, being increased by cuttings, year after year, without any apparent decay or deterioration. This is perhaps because each species is in its natural original state, without the marks or properties of a variety. Besides, we have had ample opportunities of observing that this genus of plants are frequently renewed spontaneously by seed, and such seedlings, being more vigorous, may often be chosen unconsciously for cuttings by their cultivators. But human life is not long enough fully to determine this question. Gardeners well know that the frequent renewal of plants from seed is the best way to have them in perfection, and they chiefly therefore prefer that method, except where a variety is to be preserved, which is not propagated by seed. This general experience is sufficient to confirm what we have advanced above. S.

DURATON, in *Geography*, a river of Spain, which runs into the Duero, near Peraliel.

DURAVEL, a small town of France, in the department

ment of the Lot, on the river of that name; 3 miles E. of Fumel.

DURAZZO, a sea-port town of European Turkey, in Albania, anciently named *Epidamnus* and *Dyrrachium*, strong and populous, with a good harbour in the gulf of Venice; the see of a Greek bishop; 88 miles S.S.E. of Ragusa. N. lat. 41° 42'. E. long. 19° 16'.

DURBACH, a small town of Austria, in the Saxon country of Transylvania, in the district of Bitritz.

DURBAN, a small town of France, in the department of the Aude, chief place of a canton in the district of Narbonne. It has only 206 inhabitants; but the canton contains 2837 individuals, dispersed in 12 communes, upon a territorial extent of 240 kilometres.

DURBEN, a town of the duchy of Courland; 24 miles S.S.W. of Goldingen.

DURBION, a river of France, which runs into the Moselle, near Chatel sur Moselle, in the department of the Vosges.

DURBUNGA, a town of Hindoostan, in the country of Bahar; 48 miles N.E. of Patna, and 58 S.W. of Amrour.

DURBUY, a small town of France, in the department of Sambre and Meuse, chief place of a canton in the district of Marche, with a population of 312 individuals, situated on the river Ourte, 30 miles S. of Liege, and 40 miles S.E. of Namur. It is also called Durbu. The canton has a territorial extent of 150 kilometres, and contains 19 communes, with 5783 inhabitants.

DURCKHEIM, a small town of France, in the department of Mont-Tonnerre, chief place of a canton in the district of Spire, 15 miles N.W. of Spire, with a population of 3037 individuals. The canton has 19 communes, and 14,520 inhabitants.

DURDUS MONS, in *Ancient Geography*, a chain of African mountains in Mauritania Caesariensis, which extend themselves from the south-west to the north-east.

DURE, DOOR. See *SUTH-Dure*.

DUREL, JOHN, in *Biography*, was born at St. Helier, in the island of Jersey, in the year 1626. He was entered a student at Merton college, Oxford, in 1640, and having continued there about two years, he was, on account of the civil wars, induced to retire into France, and become a member of the college at Caen in Normandy. Here he took his degree of M. A. in the year 1644, and henceforth applied himself assiduously to the study of theology. In 1647 he returned to Jersey, and took active measures in behalf of the royal cause, so that when the island was reduced by the parliament's forces, he was obliged to seek refuge at Paris. Here he was ordained according to the English episcopal forms at the chapel of Sir Richard Brown, king Charles residing at that time in France. He received two invitations to settle as a minister, which he declined, and engaged himself as chaplain to the duke de la Force, father to the princeps of Turne, a situation in which he continued about eight years. On the restoration of Charles II. he came to England, assisted in establishing the French church at the Savoy, London, where he continued to officiate several years. His steady zeal in defence of the royal prerogative obtained for him considerable preferment. In 1663, he was made prebendary in the cathedral church of Salisbury; chaplain to the king; and soon after canon of Windsor, and prebend of Durham. He was afterwards created doctor in divinity by the university of Oxford, in consequence of letters addressed to that body by the chancellor, in which the greatest praise was be-

flowed on his loyalty, fidelity, and important services achieved by him for the king. He had every prospect of being made bishop, but his death, in 1683, put an end to farther promotion. He was the author of several works, but chiefly of the controversial kind; from this general account we must except his "Theormata Philofofophæ rationalis, moralis, naturalis, & fupernaturalis," &c. 4to. 1664. It must be spoken highly in his praise, that as an honest and truly consistent character, he was always a zealous advocate for the constitution of the church of England, even when he was in the most hopeless and desperate condition. As a controversialist he was, by the learned Du Moulin, reckoned candid and open, but by the puritans of England he is differently characterized. Biog. Britan.

DURELL, DAVID, was born at Jersey in 1728, and though the name is differently spelt, it has been thought that he was of the same family as John already mentioned. He studied at Pembroke college, Oxford, where he took his degree of M. A. in the year 1755. At this college he was chosen first a fellow, and in 1753 the principal. In 1764, he published a learned theological work, entitled "The Hebrew Texts of the parallel prophecies of Jacob and Moses relating to the 12 tribes, with a translation and notes, &c. &c." He now took his degree of doctor of divinity, and great expectations were formed of his future services in biblical criticism, from his publication in which he displayed considerable knowledge in the oriental languages, and much industry in elucidating the sense of the sacred scriptures. Dr. Durell was presented in 1767 to a prebend in the church of Canterbury, and soon after to the vicarage of Tyechurch in Suffex. In 1772, he laid before the public "Critical remarks on the books of Job, Psalms, Ecclesiastes, and Canticles," in a 4to. volume. This work will long remain a monument to his erudition, and at the same time it exhibits a superiority to long established prejudices. In his preface, the doctor pleads earnestly for a new translation of the bible, and offers powerful arguments for this measure, in opposition to the objections urged against it. To the great loss of biblical literature, he died in the year 1775, when he was only in the 48th year of his age; he was as distinguished for piety and goodness, as he was eminent for sound and extensive learning. Biog. Britan.

DUREN, in *Geography*. See *DEUREN*.

DURENMETTSTETTEN, a small town of the kingdom of Wirtemberg, which formerly was an independent lordship in Suabia, and which was ceded to Wirtemberg at the peace of Lunville as part of its indemnity for the loss of some provinces on the left shore of the Rhine.

DURER, ALBERT, in *Biography*, a painter and engraver of history, portrait, and landscape, born at Nuremberg, A. D. 1471. He was the son of an eminent goldsmith of that town, by whom, as he has himself left on record, he was instructed in the art of working in gold, as well as in chasing in general. His father appears to have designed him to follow his own business, since, during his childhood, he had not made even the slightest attempt at painting, and it was not until he had reached the fifteenth year of his age, that he received the first instructions in that art from Michael Waizemuth, a painter of Nuremberg, under whose tuition he was then placed for a term of three years.

At the expiration of that term, Albert was sent by his father into Belgium, with what view is uncertain, but he continued there four years, and it is evident that he must, in that period, have made himself master of considerable knowledge in the art of engraving, since the first of his

works that is noticed, on his return to his native city, was a print of three or four naked females; a work which bears the date of 1497, and is remarkable for the supercription which he affixed to it, of O. G. H. said by Sandrart to be designed for the initials of the German words O Gott Huete! or, O God, deliver us from witchcraft!

His engravings of "The passion of Christ," bear the dates of 1507, 1508, and 1512. The last date has on any of his works is that of 1506, on the portrait of Melancthon.

But the display of his talents, however conspicuous in that art, was not confined to engraving. He discovered a general capacity, not only for every branch of design, but for every science that stood in any relation to it, and wrote treatises on proportion, perspective, geometry, civil and military architecture. He crowned his various knowledge by the most eminent skill in painting, in which he so far surpassed all those who had hitherto studied and practised the art in his own country, that he obtained the appellation of "Father of the German school."

The first pictures which are known to have been painted by him, are a portrait of his mother, and another portrait of himself in his thirtieth year, A. D. 1500; placed in the palace of Prague, as were, afterwards, many other of his works. Among the most celebrated in that collection, were the "Magi;" "The Virgin crowned with Roses by Angels;" "Adam and Eve," of the size of life; "The sufferings of the Martyrs;" and the "Christ on the Cross, surrounded with Glory;" in which the painter has introduced, at the foot of the cross, a group of popes, cardinals, and emperors, and a figure representing himself as holding a small canvas, on which is written: Albertus Durer, Noricus, faciebat, anno de Virginis partu 1511.

His style was so generally admired by the artists of his time, that it was imitated by his countrymen to the utmost of their ability, and he received a still more gratifying homage from the professors of the Italian school, many of whom, and those (according to Sandrart) of the highest reputation, thought it no diminution of their fame to adopt not only the attitudes, designs, dresses, and other ornaments of Albert's figures, but the entire figures themselves, and even sometimes painted nearly the whole of large historical compositions from his engravings on wood and copper.

Among the artists of the then flourishing Tuscan school, in whose principles and taste the importation of his works into Italy is said to have effected a change, Andrea del Sarto, and Jacopo da Pontormo, are particularly mentioned; and Raffaele himself is said to have accepted with pleasure some engravings sent to him by Albert, and to have hung them in his own apartment.

His works are at present very numerous throughout Italy and Germany; and in fame he ranks with the highest artists of his time.

His character is thus given by an artist of our own days. "He was a man of extreme ingenuity, without being a genius. In composition, copious without taste, and anxiously precise in parts. In conception, he had sometimes a glimpse of the sublime; but it was a glimpse only. Such is the expressive attitude of his "Christ in the Garden," and such the figure of "Melancholy," as the mother of invention. He studied, and, as far as his penetration reached, established certain proportions of the human frame; but he did not invent or compose a permanent standard of style. He made the nearest approach to genius in his colour, which went beyond the age he lived in, and, in easel pictures, he as far surpassed the oil colour of Raffaele, in juicy-ness,

breadth, and handling, as Raffaele surpassed him in every other part of his art. His drapery is broad, but much too angular in its folds."

The merit of Albert Durer was not lost in obscurity. Having painted a picture of St. Bartholomew, for the church dedicated to that saint at Venice, the fame of the work rose so high, that the emperor Rodolphus II. sent orders to Venice for the picture to be purchased for himself at any price, and to be brought to Prague, (a journey of great length,) not by the ordinary methods of conveyance, for fear of its receiving some damage, but by means of a pole carried on men's shoulders.

With the emperor Maximilian he was a still greater favourite, enjoying his particular patronage, as well as afterwards that of Charles V. Several of his principal pictures were painted expressly for Maximilian's palace. And it is related that, one day, when the emperor came to visit Albert in his room, where he was employed on a picture of large dimensions, the artist being desirous to touch some part of his work at a considerable height from the ground, and his stool not enabling him to reach it, Maximilian ordered one of his nobles who attended him to hold the ladder for Albert, while he went up to the point he wished. The nobleman drew back, and, with the utmost reverence and humility, ventured to represent to his majesty his doubt, how far such an office might be derogatory to his rank: on which, Maximilian is said to have replied, that he considered Albert Durer as a man far above any noble in his suite; for that he could, at any time, make a nobleman of a clown, but that he could not make a painter of a nobleman. In confirmation of these sentiments, he immediately ordered a patent of nobility to be made out for the painter.

In addition to his great celebrity as an artist, Albert Durer established a character no less respectable in private life. In domestic patience he unfortunately experienced very severe trials, which he supported with calmness; and preserved the singular benignity of his disposition unimpaired to the last. The avarice of an ill-tempered wife had discovered itself for a series of years, in continual suggestions of her husband's want of proper assiduity in the lucrative points of his profession; and her reproaches allowed him to little rest, that some of his friends counselled him to leave her for a time: and, agreeably to their advice, he set out secretly for Flanders, and took up his residence in the house of the celebrated painter, Lucas Van Leyden, where the artists drew the portraits of each other, in sign of mutual friendship and esteem. But his abode could not long be concealed from the unremitting curiosity and researches of his wife; and, having once discovered the secret, she, by repeated solicitation, and the most earnest promises of gentle conduct on her part, prevailed on him to return to his home. He returned, and her ill temper returned, and, fatally for the world, triumphed over the strength of his constitution. He is said to have died of this second pericution.

In his behaviour to contemporary artists he was so courteous, that, whenever they brought their works to him to receive his judgment, even the total want of any thing which he could commend in the pictures did not lessen his attention to the authors of them. In conversation he was cheerful, without licentiousness; and, as a firm friend of piety and virtue, he never profaned his talents, by employing them on subjects unworthy of his mind and pencil.

On his return to Nuremberg, he was named one of the members of the council. He died in that city, in 1528, and was buried in the church of St. John; and a monument was raised to his memory, which, falling to ruin, was repaired

paired 153 years afterwards; and the following eulogium inscribed in brass over his grave:

Vixit Germaniæ fuz decus
ALBERTUS DURERUS,
Artium lumen, sol artificum,
Urbis patriæ Nor. Ornamentum,
Pictor, chalcographus, sculptor,
Sine exemplo, quia omnificus,
Dignus inventus exteris,
Quem imitandum censerent,
Magnes magnetum, eos ingeniorum,
Post seculi seculi requiem,
Quia parem non habuit,
Sonus hic cubare jubetur,
Tu flores spargere, viator.
A. R. S. MDCLXXXI.
Opt. Mer. F. Cur.
J. DE S.

Some books written by him in German, on the rules of painting, his "Institutiones Geometricæ," &c. were published after his death.

He used this mark on his works ; and some

of his contemporaries having also assumed it, and particularly Marc Antonio Raimondi, in a series of engravings of the Life of Christ, Albert Durer brought an accusation against the latter before the senate of Venice, who ordered M. Antonio to efface the mark, and forbid any one beside Albert to use it in future. Sandrart, Pilkington, &c. &c.

DURESSE, *Hardship*, in *Law*, is where a person is kept in prison, or restrained of his liberty, contrary to the order of law; or is threatened to be killed, maimed, or beaten.

In which case, if a person so in prison, or in fear of such threats, make any speciality, or obligation, by reason of such imprisonment, or threats, such deed is void in law; and in an action brought on such speciality, the party may plead, that it was brought by duress.

DURETAL, in *Geography*. See DURTAL.

DURFORT, a small town of France, in the department of the Oude.—Also, a small town of France, in the department of the Gard; 9 miles S.W. of Alais.—Also, a small town of France, in the department of the Arrége; 6 miles N.W. of Pamiers.

D'URFY, or D'URFEY, TOM, in *Biography*. We cannot help being a little familiar with this facetious bard, who was himself no respecter of persons. Tom had much wit and humour of a certain kind, but very little delicacy or decorum in expressing it. Tom's muse was hardly of a higher order than an oyster girl, or a cinder-wench, who are not without their wit and humour any more than Tom: only the use these ladies make of the vulgar tongue is in plain prose, and Tom's is embellished with verse.

Tom lived in a merry time, and his writings are well tinged with the mirth in season. As a poet, Tom's measures are as frolicsome as his ideas; and as a musician, his tunes correspond with the comicality of his verses. If Tom had been a little more squeamish in his moments of jocularly, and, in making up his "pills to purge melancholy," had kept out the most offensive ingredients, the recipe itself, being a good one, might have been filed with safety and benefit to the public. To quit the medical metaphor, the collection, had it been purified of its most gross and coarse materials, containing so many original songs, and

grotesque tunes of a much higher date than his own, would have been a curious repository of such words and tunes as it would be difficult to find any where else.

D'Urfy was descended from an ancient family in France. His parents, being Hugonots, fled from Rochelle before it was besieged by Lewis XIII. in 1628, and settled at Exeter, where this their son was born, but in what year is uncertain. He was originally bred to the law; but soon finding that profession too saturnine for his volatile and lively genius, he quitted it, to become a devotee of the muses; in which he met with no small success. His dramatic pieces, which are very numerous, were in general well received: yet, within thirty years after his death, there was not one of them on the muster-roll of acting plays; that licentiousness of intrigue, looseness of sentiment, and indelicacy of wit, which were their strongest recommendations to the audiences for whom they were written, having very justly banished them from the stage in the periods of purer taste. Yet are they very far from being totally devoid of merit. The plots are in general busy, intricate, and entertaining; the characters are not ill drawn, although rather too farcical; and the language, if not perfectly correct, yet easy and well adapted for the dialogue of comedy. But what obtained Mr. D'Urfy his greatest reputation, was a peculiarly happy knack he possessed in the writing of satires and irregular odes. Many of these were upon temporary occasions, and were of no little service to the party in whose cause he wrote; which, together with his natural vivacity and good humour, obtained him the favour of great numbers of all ranks and conditions, monarchs themselves not excluded. He was strongly attached to the tory interest, and in the latter part of queen Anne's reign, had frequently the honour of diverting that princeess with witty catches and songs of humour, suited to the spirit of the times, and written by himself, and which he sung in a lively and entertaining manner. And the author of the Guardian, who, in N^o 67, has given a very humorous account of Mr. D'Urfy, with a view to recommend him to the public notice for a benefit play, tells us, that he remembered king Charles II. leaning on Tom D'Urfy's shoulder more than once, and humming over a song with him. He used frequently to reside with the earl of Dorset at Knowle; where a picture of him, painted by itself, is still to be seen.

He was certainly a very diverting companion, and a cheerful, honest, good-natured man; so that he was the delight of the most polite companies and conversations, from the beginning of Charles II.'s to the latter part of king George I.'s reign; and many an honest gentleman got a reputation in his country, by pretending to have been in company with Tom D'Urfy. Yet, so universal a favourite as he was, it is apparent that towards the latter part of his life he stood in need of assistance, to prevent his passing the remainder of it in a cage, like a singing-bird; for, to speak in his own words, as repeated by the above-mentioned author, "After having written more odes than Herace, and about four times as many comedies as Terence, he found himself reduced to great difficulties by the inopportunities of a set of men, who of late years had furnished him with the accommodations of life, and would not, as we say, be paid with a song." Mr. Addison then informs us, that, in order to extricate him from these difficulties, he himself immediately applied to the directors of the play-house, who very generously agreed to act "The Plotting Sisters," a play of Mr. D'Urfy's, for the benefit of its author. What the result of this benefit was, does not appear; but it was probably sufficient to make him easy, as we find him living and continuing to write with the same humour and liveliness to the

time of his death, which happened Feb. 26, 1723. What was his age at this time, is not certainly specified any where; but he must have been considerably advanced in life, his first play, which could scarcely have been written before he was 20 years of age, having made its appearance 47 years before. He was buried in the church-yard of St. James's, Westminster.

Those who have a curiosity to see his ballads, sonnets, &c. may find a large number of them in 6 vols. 12mo. entitled; "Pills to purge Melancholy," of which the *Guardian*, in N° 29, speaks in very favourable terms. The titles of his dramatic pieces, thirty-one in number, may be found in the *Biographia Dramatica*.

DURGA POOGA, the name of the great autumnal festival of the Hindoos. On this occasion, an effigy of Durga, in combat with the chief of the Rascusses Soomne Soom, is exhibited, amidst a gaudy group of evil geni and auxiliary gods, forming a picture, in also relieve, sufficient to fill the breadth of a large saloon, as shewn as brilliant colours andinsel ornaments can make it. This effigy is removed, on the last day at noon, and conveyed in procession to the Ganges, where Durga and her associates are committed all together to the deep. During this latter part of the festival, which is generally known in Calcutta by the appellation of the *Nautees*, the houses of the most opulent Hindoos are open to European visitors, and constantly attract a prodigious concourse of company. This festival, which is the most famous among the Hindoos, gives occasion also in Bootan to a great display of ingenuity. The festival lasts for ten days, and it is there termed "Mulluum." The grotesque figures that exhibited themselves in the combat formed a very fantastic motley group. Elephants, horses, apes, and a most frightful figure environed with snakes, were among the representations intended to personate rascusses, or evil geni. Virtue appeared in the shape of Durga, with a view to exterminate vice; and some of the group received very hard blows before they would quit the stage; but the force of Durga never failed to maintain its ground in all the triumph of victory. The object of this festival seems to have been the celebration of the arrival of the autumnal, as that of the "Hooli" does the vernal equinox.

Durga Poogah is distinguished also as being the well-known period, when the armies of the native powers in India have always been accustomed to take the field: and till their acquaintance with Europeans taught them the necessity of relinquishing some of their most inveterate prejudices, it was very seldom that any of their troops assembled in the field, till after the celebration of the Duffera, which happens on the first full moon after the equinox. As that has been ever considered as the signal for hostile preparations, so has the Dewali, the following new moon, a festival kept in honour of the dead, when it is usual to make large feasts, to distribute food to the poor, and to make grand illuminations during the night, been commonly the time to set their troops in motion. *Turner's Embassy to Tibet*, p. 162.

DURGAN, in *Geography*, a town of Asiatic Turkey, in the province of Natolia; 48 miles S.E. of Callamoni.

DURGUT, a town of Asiatic Turkey, in the province of Natolia; 18 miles E. of Smyrna.

DURHAM, a county in the northern part of England, bounded to the east by the German ocean, to the north by Northumberland, from which it is separated by the rivers Tyne and Derwent, on the west by the counties of Cumberland and Westmoreland, and on the south by Yorkshire. The area thus enclosed forms a triangular figure, and measures about 36 miles in its greatest extent from north to south, by nearly 45 miles in an opposite direction. Its su-

perficual area includes about 610,000 acres. This space is divided into four wards, all of which derive their names from places of little importance, *viz.* Chester, Darlington, Easington, and Stockt n; besides which there are two other districts, called Northamshire and Islandshire. The county is divided, according to some authors, into 113 parishes, while others say 120, including one city and ten market towns. According to the last report to parliament, this district contained 27,195 houses, and 160,361 inhabitants, of whom 74,770 were males, and 85,591 were females. Four members are returned to parliament; two for the county and two for the city.

This part of England was anciently inhabited by the *Brigantes*, a class of Britons, distinguished by Tacitus as being powerful, brave, and numerous; but who were subdued by the Romans. The latter included Durham within the division of *Maxima Cæsariensis*; and the Saxons made it part of the kingdom of Northumbria. In the year 685, Egfrid, king of this district, granted all the lands between "the rivers Wear and Tyne" to St. Cuthbert, the apostle of the north. From this time the county was invested with great privileges, and has been generally termed the *Bishopric*; and *County palatine*. Edward I., however, seized the power from the bishop, and transferred the liberties of the see to the crown. These were afterwards restored in part; and were augmented or enlarged by different monarchs, till queen Mary re-established them. The bishops of Durham; from time immemorial, have exercised peculiar immunities and power; consisting of all manner of royal jurisdiction, both civil and military, by land and sea. For the exercise of which they had their proper courts of chancery, exchequer, and court of pleas, as well of the crown as of the county. The nature and peculiarity of all these cannot be properly described in this place, but may be found fully explained in Hutehinson's *History of Durham*, 3 vols. 4to. and Gough's edition of *Camden's Britannia*, vol. iii. p. 109, &c.

The general aspect of Durham is hilly and mountainous, particularly towards the western angle, which is a bleak, barren, and naked region, crossed by a lofty ridge called the English Apennines. Several different streams issue from the eastern side of these mountains. On the eastern side, and near the centre of the county, are some fine and fertile vallies, through which various brooks and rivers flow to the sea. Nearly one-third of the land is held by ecclesiastical tenure, under leases for lives, or for 21 years. The cattle of Durham are in great repute, as to shape, weight, produce of milk, &c. The sheep are mostly large, and covered with long wool.

The waste or uncultivated lands of this county are of considerable extent, occupying, according to Mr. Granger, nearly 130,000 acres. According to sir William Appleby, in a communication to the author of the *Agricultural Report*, "Durham, taking its small dimensions into consideration, is not to be equalled by any other county in Great Britain, except Middlesex, for its numerous and important coal, lead, and iron mines; its large cast-metal founderies, and iron manufactories, potteries, glass-houses, coppers works, coal, tar, and salt works, quarries of marble, fire and free-stone; lime, brick, and tile-kilns; grind-stone and mill-stone; linen and woollen manufactories; trade, agriculture, and population." Granger's general View of the *Agriculture of the County of Durham*, 4to.

Towards the east and north-east parts of Durham are several extensive coal-mines. The seams or strata, now worked, are five in number, which extend horizontally for many miles, and are from 20 to 100 fathoms beneath the surface.

surface. Each stratum is from three to about eight feet in thickness. Below these are several other seams of coal. Some steam-engines have been erected, to raise the coal to the surface, and for the purpose of pumping the water out of the mines. In the great sea-fale collieries, several hories are constantly kept under ground, to draw the coals to the mouths of the pits.

In the vicinity of Walsingham, a firm black spotted limestone or marble is procured, and is much used for hearths, chimney-pieces, &c. The same neighbourhood also abounds with stone, much used in making mill-stones. Many quarries of excellent flate have been opened in different parts of the county; and Gatehead-fell is particularly famous for producing what are vulgarly termed Newcastle grind-stones, from being mostly shipped off at that port. Fire-stone, in high estimation for making ovens, furnaces, &c. is obtained in various parts of the county; and large quantities are annually exported. Several lead-mines are worked in Teesdale and Wear-dale. Some extensive works for manufacturing salt from sea-water have been long established at South Shields; but these have been much neglected, in consequence of a singular salt spring having been discovered at Birtley. The water rises at the depth of 70 fathoms, and has produced 20,000 gallons *per day* for some years past. The water is found to be four times stronger than any sea-water.

The manufactures of Durham are numerous and important, and are distributed over various parts of the county. At Chester-le-Street is a very extensive foundery for cannon; and another at Wallington. At Swalwell and at Winton are some very large iron-works; and at Lumley is a manufactory for converting scrap-iron into engine-boiler-plates, and cast metal into malleable iron. At Shortley-Bridge, Derwent-Coal, and Blackhall-Mills, are manufactories of steel for sword-blades. Tammys, carpets, and waistcoat-pieces, are manufactured at Durham; tammys and huckabacks are also made at Darlington; cottons are manufactured at Castle-Eden, Stockton, and Bishops-Auckland; glass-bottles in large quantities are made at Sunderland, &c.

The chief rivers of this county are the Tees, the Wear, and the Derwent. The total return of income, under the influence of the property-tax bill for this county, in 1806, was 1,320 36*4*l. The amount of the poor-rates for 1803, at 2*s*. 4*d*. in the pound, was 71,065*l*.

DURHAM, a city, and the capital of the county of the same name, England, is situated on a singular rocky eminence, rising near the centre of the county, and almost surrounded by the river Wear. From all the neighbouring points of view, its appearance is unique and striking; its public edifices exhibiting a degree of magnificence not to be expected at so remote a distance from the metropolis; and its situation and figure being so peculiar as to have acquired the emphatic appellation of the *English Zion*. Durham derives its name from its situation; the term being a corruption from the Saxon words, *Dur*, a hill, and *holme*, a river island. By the Latins, observes Camden, "it is called *Dunelmus*; and by the common people, Durham or *Dur-fine*." The earliest historical notice of this city is contained in the monkish legend of St. Cuthbert, from whose votaries Dunholme, as it was then called, accumulated all its celebrity and riches. From this legend we collect, that the saint died in 687, and was buried in the church of Landisfarne, at that period an episcopal see, which rank it continued to hold till the year 876, when the Danes, under Halfden, ravaged this part of the country, exercised peculiar cruelty against the clergy: on which bishop Eardulf, and the other members of the church, resolved on immediate

migration; and collecting all their relics, sacred vessels, shrines, jewels, and ornaments, abandoned Landisfarne, and were followed by all the inhabitants. After a long series of temporary residences, Dunholme was the place fixed on for the lasting abode of St. Cuthbert's relics, and the further establishment of the holy fraternity. From these and other correlative circumstances, we are led to date the rise of the town of Durham in the beginning of the eleventh century. In the year 1040, it appears to be strongly fortified, when attacked by Duncan king of Scotland: for the townsmen sustained his assaults for a considerable time; and at length, by a vigorous sally, totally routed the assailants, and beheaded the leaders in the market-place. In 1069, William I. sent Robert Cumin, whom he had created earl of Northumberland, with 700 veteran Normans, to enforce his authority. These warriors committed great enormities, which excited the inhabitants to a desperate resistance; when, after a very sanguinary contest, the earl with his 700 guards (one only excepted, who escaped wounded) were put to death. William, determined on revenge, indulged the malignity of his heart in the spoil and blood of his subjects, and desolated the country in such a manner, that, for 60 miles between York and Durham, he did not leave a house standing; reducing the whole district by fire and sword. Churches and monasteries were not spared. A dreadful famine ensued; and a mortality unequalled in the annals of this country. The bishop, ecclesiastics, and principal inhabitants, evacuated Durham, and again returned to Landisfarne, till the king's departure, and the restoration of some degree of tranquillity enabled them to return to their desolated country. William, on his retreat from an expedition against Malcolm king of Scotland, considering that Durham was a proper barrier against the Scottish incursions, resolved to erect a castle here, which might serve also to keep the neighbourhood in awe; or, as he explained it, "to secure his earl of that province from tumults and insurrections, as also to protect the bishop of the see, and his church." About this time, the Domesday book was compiled; and as Durham does not occur in it, a supposition arises, that the county was so wasted, as not to be worth the expence of a survey. Malcolm king of Scotland now entered the county, and being opposed by Robert, son of king William, a fresh scene of warfare commenced. On the accession of William Rufus, the bishop of Durham, William de Carlepho, fled into Normandy; and his temporalities were seized by the king, who appointed John de Talbois and Enefius de Burone governors of the castle and palatinate. Durham sustained great injury by fire in the time of bishop Flambard, when, in consequence of his flight to Robert duke of Normandy, his possessions were in the hands of the crown. This bishop, to ingratiate himself at court, oppressed the bishopric with taxes, but without success; king Henry having an invincible hatred to the principles of the prelate. In 1112, the bishop founded the hospital of Kepier, which he dedicated to St. Egidius or Giles, and amply endowed it. After his restoration to the see, he improved the fortifications, by extending the walls between the cathedral and castle, removing the houses on the intermediate area, and levelling the ground. He fortified the castle with a moat, improved the banks of the river, and built Framwell-gate bridge. In the reign of Stephen, Durham and its vicinity again experienced the horrors of war, from the incursions of David king of Scotland, in behalf of his niece Matilda. On the establishment of peace, this city was chosen as the place of assembly by the members of that convention, in April, 1139. Henry II. having a dispute with bishop Pudsey, took possession of the castle and city of Durham; and, on various pretexts, de-

prived the bishop of the custody of so strong a pest. This bishop obtained a charter from pope Alexander III. at the council of Lateran, in 1176. He also made many additions to the cathedral, and ornamented the city by several public structures; he built Elvet bridge, and rebuilt the borough of that name, which had been destroyed by Cumyn and his adherents; he constructed the city wall from the Gaol-gate to the Water-gate, part of which is still remaining; and re-edified the castle, which had been destroyed by fire. The *Balloon bulks*, now remaining in the auditor's office, was compiled by his order; and has been admitted as evidence in all cases, to ascertain the ecclesiastical property of the diocese. The castle seems to have remained in the crown: for, when Henry III. consented to the election of Richard Poore to this see, he excepted the possession of the castles of Durham and Norham. This pious prelate made, by an agreement with the convent, several regulations concerning the privileges of the two boroughs of Durham and Elvet, with respect to civil authority, weights, measures, &c. In this reign, it appears that Durham had a royal and palatinate mintage within itself, which Edward I. on his accession, made a point of reforming. This city exhibited a singular scene of festivity in 1333, on the promotion of Richard de Bury or Aungerville to the bishopric. He entertained, in the great hall of his palace, Edward III. and his queen, the queen dowager, the king of Scotland, the two metropolitans, and five bishops, seven earls and their ladies, all the nobility north of Trent, with a vast concourse of knights, abbots, priors. It was in this year that king Edward III. gained the famous battle of Halidown-hill. This monarch again visited the city in 1356, and issued summonses for the military tenants to attend him, previously to the siege of Berwick. Bishop Hatfield, who succeeded De Bury, was a great benefactor to the church and city; in 1377, he granted a toll on certain merchandize brought to Durham, to defray the charges of paving the city and repairing the walls. Letters patent were likewise granted by him to William de Elmedon, gaoler and porter of the castle, with certain profits annexed to the office, among which are fees for sealing the measures to be used in the city. In the 3d of Henry VI. the city was enlivened by the marriage of James king of Scotland with his cousin Jane of Somerset, grand-daughter of John of Gaunt duke of Lancaster: the solemnity was attended by many of the most illustrious persons of both kingdoms. The suppression of the rebellion of the Nevilles, in the reign of Elizabeth, occasioned a scene of horror in Durham; not fewer than 66 persons being executed, to satisfy the brutality of sir George Bowes, who boasted, that in a tract of country 60 miles in length and 40 in breadth, between Newcastle and Wetherby, there was scarcely a town or village wherein he had not sacrificed some of the inhabitants. During the time of the commonwealth, an attempt was made to establish a university at Durham: the plan was strenuously promoted by Oliver, and advanced so far as to excite the jealousy and opposition of the universities of Oxford and Cambridge; when the machine of government fell to pieces, and involved in its ruins this new seminary of learning. It is a singular fact, that George Fox, the founder of the quakers, resorted to himself the consequence, and, as he thought, merited by being the means of suppressing this laudable institution.

The present magnificent cathedral of Durham owes its origin to bishop William de Carlepho, who, having projected a change in the government of this church, which had hitherto been directed by the secular clergy and their provost, obtained, under the authority of the king and the pope, a licence to introduce regular canons. Conceiving also, that

the church built by his predecessors was unsuitable to the increasing dignity of the see, he formed a plan for erecting a structure similar to the superb fabrics he had seen during his exile on the continent. Accordingly, on August 11, 1093, the foundation was laid with suitable solemnity, at which Malcolm, king of Scotland, assisted. The bishop compelled the monks to labour in the holy work constantly; but no considerable progress was made in his life time, which terminated within two years after the commencement of the edifice. His successor, Ralph Flambard, who enjoyed the bishopric twenty-nine years, and was equally zealous in the pious undertaking, finished the building nearly to the roof. This prelate, before his promotion to the see of Durham, had given proof of his ability in architecture, by the erection of the collegiate church of Twinningbourne, or Christ church, Hampshire. The cathedral erected by these bishops was of the form universally adopted by the Norman architects; a long cross, with two turrets at the west end, and between them, a large and richly ornamented entrance: the east end probably terminated in a semicircular form, as the lines of union of the original work, with the chapel of the nine altars, strongly indicate. The side aisles, both of the nave and choir, were vaulted with semicircular arches, groined, and the ribs of the groins carved; but the nave and the choir were open to the timber roof. The nave exhibits the next change of style. Bishop Poore, having already given a specimen of his taste in the construction of Salisbury cathedral, induced prior Melfonby to conform to a more ornamental mode of architecture in the roof, which he was then building. Under his direction the whole vault was accommodated to the pointed arch, though the Norman zig-zag is used along the ribs of the groins. Successive additions have rendered this church as it now appears; not only an enlarged specimen of Norman building, but "a most instructive series of examples, illustrating the gradual change of style which took place during the reigns of the three first Henrys, till, by degrees, the pointed had completely superseded the semicircular arch; and the heavy clusters of the Norman pillars were polished into the light shafts of the early English." "Account of the Cathedral Church of Durham, with Plans, Sections, &c." published by the Society of Antiquaries of London.

To describe the whole of this structure, with its numerous chapels, tombs, connected edifices, &c. would occupy more space than we can consistently appropriate to this article. Those who are desirous of such information, may consult the work just referred to, also the Beauties of England, vol. v., and Hutchinson's History, &c. of Durham. A few additional particulars respecting it may, however, be required. When bishop Flambard deposited the remains of St. Cuthbert in the new church, he erected an elegant shrine, called the *Ferretory*, over them. Bishop Hugh Pudsey began to erect, at the east end of the cathedral, a chapel to the Virgin Mary; but relinquishing this, he appropriated a part of the west end, called the *Galilee*, for the admission and sanctuary of females; as they were not allowed to enter the cathedral. This exclusion was one of the strange prejudices, or infatigations, of the disciples of St. Cuthbert, who, they asserted, had an antipathy to the female sex.

The great central tower, 214 feet in height, was partly built by prior Melfonby, soon after 1233, and completed by priors Middleton and Hugh, before the year 1258. A survey of the cathedral was made in 1776, when it was found to want much repair, &c. which was immediately commenced: and since that period, workmen have been constantly employed on this structure. During the last fifteen or sixteen years a sum amounting to not less than 1500*l.* or

DURHAM.

2000*l.* has been annually expended for this purpose; and a fund is provided to answer future demands. Of this noble structure Dr. Johnson speaks in his usual style, that "it strikes with a kind of gigantic dignity, and aspires to no other praise than that of rocky solidity, and indeterminate duration." The cathedral may be described as consisting of a nave, with two aisles; a transept with an aisle towards the east; a choir, with two aisles; the chapel of the nine altars at the east end, extending north and south; an oblong chapter-house, with semicircular east end; a cloister to the south; a chapel, or Galilee, at the west end; and several apartments on the west and south sides of the cloisters. The entire length of this structure is 461 feet, thus divided: nave 250 by 74 feet, and 69 feet six inches in height; length of transept 170 by 57 feet in width; choir 120 by 74 feet; chapel at east end 130 feet from N. to S. by 51 in an opposite direction; Galilee 50 feet from E to W. by 80 feet from N. to S. There are interior measurements.

From the cathedral on the north extends an open area, called the Place, or Palace Green, on the north side of which is the castle, now the residence of the bishop when he visits Durham. This structure stands on the continuation of the same rocky eminence on which the cathedral is built; and from its upper apartments commands some fine views of the city and surrounding country. The most ancient part of this edifice is the keep or tower, which occupies the top of an artificial mount, and is supposed to have been of Norman construction. The buildings, which now constitute the castle, have been erected at various periods, and have consequently but little uniformity. Some parts, which have suffered by fire, were restored by bishop Pudsey, who acceded to the see in 1153. He is also supposed to have erected the first hall: but this, with other parts of the castle, going to decay, a new and more magnificent hall was built by bishop Hatfield, the original length of which was 120 yards. From this apartment the present hall was formed, which is of extensive dimension; its length being 180 feet, the breadth 50, and the height 36. Contiguous to the keep, on the east, is the great north gateway, a very strong fabric, erected by bishop Langley, and now used as the gaol. The outward, or lower part, was defended by a gate and portcullis; within which is a recess, constructed with Sallyports and galleries; the annoyance of assailants, who might force the first gate: the upper part was secured by double gates. All the other gates of the city have been removed. On the west side of the Place Green is the exchequer, a strong square stone building, erected by bishop Neville about the year 1450. Adjoining it is the bishop's library, built by bishop Cosin, who also greatly contributed towards the erection of the law courts, where the assizes, quarter sessions, &c. are held. The court for the trial of crown causes was much enlarged in 1791. On the opposite side of the green is an hospital, or almshouse, for eight poor men and women, founded by bishop Cosin in 1656; and adjoining it, at each end, a school-house, rebuilt by him about the same period, but originally endowed by bishop Langley. From the Place Green is an avenue leading to the public walks called the Banks, which skirt the river, and were made, and are still kept in repair, by the munificence of the dean and chapter. These walks are much celebrated for their beauty and interesting views. Over the river Wear are three bridges: Framwell-gate bridge, erected by bishop Flambard, about 1120, Elvet bridge, by bishop Pudsey, about 1155; and the New bridge, built in 1772.

Independently of the cathedral, Durham contains six churches, the principal of which is that dedicated to St.

Nicholas, an ancient structure, situated on the south side of the market-place. It consists of a nave and side aisles, with a square tower at the south-west angle. The church of St. Mary-le-Bow, or Bough, is on the east side of the North Bailey, on the same spot, according to tradition, where St. Cuthbert's remains were lodged, in a tabernacle of boughs and wands, when first brought by the monks to Durham. St. Oswald's church is an ancient structure, occupying an elevated situation on the eastern banks of the river in that part of the suburbs called New Elvet: it consists of a nave, chancel, and side aisles. St. Giles's church is of remote origin, having no aisles; it is narrow, long, and lofty. The church of St. Margaret, situated in Crof-gate, and that of Little St. Mary, in the South Bailey, display nothing remarkable. The market-place is a small square, having a Guildhall, or Tolbooth, on the west side, a pent to supply the inhabitants with water, near the centre, and a piazza, where the corn-markets are held on the south.

The original denomination of Durham, after its civil establishment, was that of Borough; and its local polity was exercised by a bailiff, appointed by the bishops. In 1565 the civil jurisdiction was vested, by bishop Pilkington, in an alderman and twelve burgesses. In 1602 bishop Matthew changed it to that of a mayor, twelve aldermen, and twenty-four common councilmen. This mode of government, having sustained several interruptions, was finally re-established in 1780, by a new charter from bishop Egerton, in which the rights of the citizens were explained and confirmed.

Neither the county, nor the city of Durham, was represented in parliament till the reign of Charles II.; a circumstance which may be ascribed to the vast power and influence of the bishop: as returning members to parliament was anciently considered more grievous and inconvenient, than useful or honourable. The extension of learning induced ideas more favourable to liberty: and, in 1673, an act was passed, authorizing the city and county to send each two members; and from that time the returns have been regularly made. The right of election for the city is in the mayor, aldermen, and freemen: the voters are about 1000. Durham is situated 260 miles N. from London; has a weekly market on Saturdays, and three annual fairs; and contained, as returned under the late act, 1024 houses, and 7530 inhabitants.

DURHAM, a township of America, in Cumberland county, Maine, on the S. W. bank of Androscoggin river, which separates it from Bowdoin on the N. E. It was incorporated in 1789, contains 1242 inhabitants, and lies 145 miles north-easterly of Boston. N. lat. 43° 55'.—Also, a post town in Strafford county, New Hampshire, seated on Oyster river, near its junction with the Piscataqua; 12 miles W. of Portsmouth. It was incorporated in 1635, and contains 1126 inhabitants. It was formerly a part of Dover, which adjoins it on the north, and was called Oyster river.—Also, a post town in New Haven county, Connecticut, settled from Guildford in 1698, and incorporated in 1708. It is about 22 miles S. W. of Hartford, and 18 miles N. E. of New Haven. The Indians called it "Cagingchague," which name a small river that rises here still bears. It has 1029 inhabitants.—Also, a township in Bucks county, Pennsylvania, having 405 inhabitants.—Also, a county in Upper Canada, bounded on the E. by the county of Northumberland, on the S. by lake Ontario, until it meets the westernmost point of Long Beach, thence by a line running N. 16° W. until it intersects the southern boundary of a tract of land belonging to the Mississauga Indians, and thence along the said tract, parallel to lake Ontario, until it meets the N. westernmost

N. westernmost boundary of the county of Northumberland. Morfe.

DURIA MAJOR and MINOR, in *Ancient Geography*. See *La DORIA Baltea* and *Riparia*.

DURIO, in *Botany*, (from a Malay word *dury*, which, according to Rumphius, means a thorn, the names of this Spinous fruit, *Duryon*, *Durcin*, or *Durcyn*, in Malacca, Ternate and Ambon, are derived. Linæus, perhaps, considered the word *Durio* as rendered canonical, by an equally correct allusion to the hard coarse rind of the fruit, ("a fructus duritia.") Durion. Linn. Syst. Veg. ed. 13. 581. Schreb. 516. Willd. Sp. Pl. v. 3. 1434. Juss. 244. König in Tr. of Linn. Soc. v. 7. 256. Clais and order, *Polyadelphia Polyandria*. Nat. Ord. *Malvaceæ*, König.

Gen. Ch. *Cal.* Perianth inferior, double, each of one leaf, somewhat coriaceous, smooth within, externally clothed with very minute, shining, silvery, flattened, pellucid scales: the outer one widest, obtusely two-lobed, spreading: the inner longest, nearly an inch in length, urn-shaped, swelling, with five erect, acute, equal, marginal segments. *Cor.* Petals five, above twice as long the inner calyx, inserted into its base, elliptic-lanceolate, entire, recurved, equal, with furrowed claws. *Stam.* Filaments numerous, from twenty-five to forty-five, rather longer than the petals, upright, thread-shaped, equal, united in a somewhat forked manner into five sets, inserted into the bottom of the calyx, opposite to the petals; anthers roundish, composed of numerous aggregate cells. *Pist.* Germen superior, obovate, obscurely five-fided, scaly; style simple, thread-shaped, the length of the filaments, a little twisted upwards; stigma capitate, with five furrows. *Peric.* Apple very large, globose, inclining to oval, pointed, entirely clothed with crowded, prominent, pyramidal, acute tubercles, of five cells which open outwardly. *Seeds* from two to five in each cell, ovate-oblong, shining, enclosed in one, common, aggregate, soft, pulpy tunic, which fills each cell, and is firmly attached to the central column. Cotyledons two, without any separate albumen. Embryo straight, in the base of the seed.

Eff. Ch. Calyx double, the outer one two-lobed. Petals five. Style one. Apple with five cells. Seeds in a pulpy tunic.

D. *zibethinus*, the only species. Kön. Tr. of L. Soc. v. 7. 266—273. t. 14, 15, 16. Mart. Mill. Dict. v. 2. Lamarck Dict. v. 2. 333. t. 641. (Durio. Rumph. Amb. v. 1. 69. t. 29.) Native of Malacca, Sumatra, Java, Borneo, and the Molucca islands. It forms a very lofty tree. *Leaves* alternate, on swelling stalks, elliptic-oblong, pointed, entire, with one rib and numerous veins; smooth and dark green above; clothed with minute rusty scales beneath. Stipulas none? *Flowers* in lateral bracteated branches from the larger branches, unpleasantly scented. *Partial stalks* two or three inches long, round, scaly, jointed at the base. *Petals* of a dirty white. *Stamens* and style red. *Fruit* yellowish-green externally. *Seeds* of a yellowish brown; their tunics white, of a soft, mucous, and very tender substance. These tunics constitute the eatable part of the Durion fruit, which is esteemed one of the most delicious vegetable productions of India, and compared by Rumphius to cream or *blanc manger*. This author tells us, however, that persons not accustomed to eat this fruit, are at first deterred from tasting it by the intolerable smell which it diffuses, resembling rotten onions; but those who overcome their first repugnance grow extremely fond of it. He further mentions, that it is not always to be eaten with impunity. The pulp of one or two Durions is sufficient for one person at a time, though some stomachs will bear a much greater quantity. Their immoderate use causes violent and dangerous inflammatory disorders, and the seasons when they abound are generally

very unhealthy. It is forbidden by law to throw the rinds of this fruit into much-requested places, on account of their dangerous factor. The Chinese use their ashes in painting and dyeing. Mr. König is the first who has given an accurate botanical description of this plant.

DURIUS, in *Ancient Geography*, a river of Hispania Interior, now *Douero* or *Douro*.

DURKO, in *Geography*, a town of Asiatic Turkey, in the province of Natolia; 42 miles S.W. of Amasch.

DURLACH, or DOURLACH, a small but handsome town of Germany, in the grand duchy of Baden, on the river Pfinz, with a castle called Karlsburg. It was formerly the residence of one branch of the house of Baden, the sons of margrave Christophor of Baden, who had reunited two former lines in 1503, having commenced two new lines of Baden Baden, and Baden Durlach. See BADEN.

DURLAH, a river of Bengal, which divides the district of Cooch Bahar from that of Rungpore.

DURNES, a town of Scotland, in the county of Sutherland, near the N. coast, at the bottom of a bay, formed by a river of the same name, called the "Kyle of Durnes;" 46 miles N.N.W. of Dornoch. N. lat. 58° 33'. Long. 1° 21' W. of Edinburgh.

DURNISH, a town of Scotland, on the western coast of the island of Skye.

DURNOVARIA, in *Ancient Geography*, a town of Albion, which all our antiquaries agree to fix at Dorchester, where many Roman antiquities have been found, and where the vestiges of the Roman walls of the city and of an amphitheatre without them are still visible. See DORCHESTER. It was also called DURNIUM, which see.

DUROBRIVIS, the ancient name of Rochester in Antonine's Itinerary, which our antiquaries derive from *Dur*, a river, or water, and *Brio*, a town.

DUROBRIVIS, is also a name given in the 5th Iter of Antonine to a place situated between Cambridge and Ancaster. Dr. Gale fixes it at Bridge Causton, two miles N. from Stamford; but Camden, Baxter, and Horsley, place it at Caistor upon the river Nen, or rather at the village of Dornford, near Caistor, where many Roman coins and other antiquities have been found.

DUROCHSKOI, in *Geography*, a town of Russia, in the government of Irkutsch, on the borders of China, near the river Argovia; 166 miles S.S.E. of Nertchinsk.

DUROCIBRIVIS, in *Ancient Geography*, a place marked in Antonine's Itinerary between Fenny Stratford and St. Alban, which is generally fixed at Dunstable; though Mr. Horsley conjectures, that the two stations Magiovinum and Durocobriva have been transposed by the carelessness of some transcriber; and that the latter was at Fenny Stratford, and the former at Dunstable; because, in that case, the meaning of the original British names of these places will be more agreeable to their situations.

DUROCORNIVUM, a station between Gloucester and Speen, supposed to be Cirencester.

DUROIA, in *Botany*, (in commemoration of Dr. John Philip Duroi, a physician of Brunwick, author of an inaugural dissertation, consisting of botanical remarks, published in 1771, and of a German work on trees and economical plants, with figures. He was a frequent correspondent of Linnæus, whose herbarium, as we are informed by Dr. Smith, he much enriched.) Linn. Suppl. 30. Schreb. 230. Willd. Sp. Pl. v. 2. 222. Juss. 203. Mart. Mill. Dict. v. 2. (Pubet; Linn. Amœn. Acad. v. 8. 264.) Clais and order, *Hexandria Monogynia*. Nat. Ord. *Rubiaceæ*, Juss.

Gen. Ch. *Cal.* Perianth of one leaf, superior, cylindrical, abrupt, short, contracted. *Cor.* of one petal. Tube cylindrical; limb

the length of the tube, in six deep, oval, spreading segments. *Stam.* Filaments none; anthers six, oblong, sessile in the tube of the corolla. *Pist.* Germen inferior; style thread shaped, the length of the tube; stigmas two. *Peric.* Berry globose, umbilicated, densely clothed with prominent hairs. *Seeds* numerous, imbedded in pulp, oval, flat, very smooth, lying in two rows over each other. The flowers are often abortive, and there are many of them also male, wanting the germen altogether. Linn.

Jussieu, from the evident characters of his natural order of *Rubiacæ* in this plant, presumes its fruit to be of two cells. Its characters very nearly approach *Gardenia*.

Eff. Ch. Calyx superior, cylindrical, abrupt. Corolla with a cylindrical tube, and six-cleft regular border. Anthers sessile in the tube. Berry hispid, umbilicated.

D. Eriopila, is the only species. Linn. Suppl. 209. (Marmelade-Doosjes-Boom; Merian Surin. 43. t. 43.) Native of Surinam, whence it was sent by Dalberg to Linnaeus, from whose account and the figure in Merian, concerning whose synonym there surely can be no reasonable doubt, all our knowledge is derived, for we have never seen a specimen. It is described as a lofty tree, with thick, unequal branches, hairy in their upper part. *Leaves* about the summits of the branches, opposite, crowded, a span long, obovate, bluntish, entire, hard, rigid, downy above, reticulated beneath, with one rib, and many transverse veins. *Foot stalks* short, hairy. Merian describes a kind of rough excrescences, growing either on the stalks or branches, throwing out numerous cylindrical or awl-shaped horns, which are prescribed in pulmonary disorders. The *flowers* are terminal, sessile, clustered, numerous, but most of them abortive; their *corolla* white, resembling the Arabian Jasmine. *Fruit* rather larger than a turkey's egg, globose, with a furrow on each side, yellow, covered with short, dense, brown, prominent hairs, crowned with the cup-like permanent base of the calyx, and filled with numerous seeds lodged in pulp which is eatable, and compared by Madam Merian to that of the European medlar. Her figure evidently indicates a separation of the berry into two cells, as suspected by Jussieu. The bark resembles a box, and hence the above Dutch name, equivalent to Marmelade-box tree.

The caterpillar of a beautiful butterfly feeds on this tree, which is near *Papilio Protosflaus* of Linnaeus, but, we believe, very distinct, though cited for it by him as well as by Fabricius.

DUROLEVUM, the name of a station between Rochester and Canterbury; the situation of which is uncertain; and Mr. Hervey seems to be singular in placing it at Milton.

DUROLIPONS, a station fixed by some at Cambridge; but those antiquarians who place Camboricum at Cambridge, fix Durolipons at Godmanchester.

DUROLITUM, in *Ancient Geography*, a station between Chelmsford and London, supposed to be LeCton.

DURONIA, a town of Italy, placed by Livy in the country of the Samnites.

DUROT, in *Geography*, a bay on the N. side of the S. peninsula of the island of St. Domingo.

DUROTRIGES, in *Ancient Geography*, the name of an ancient British nation, seated next to the Danmonii on the east side, and possessing that country, which is now called Dorsetshire. The name is evidently derived from the two British words *dur* or *dour*, water, and *trigo*, to dwell; and it is equally evident that they owed this name to the situation of their country, which lies along the sea-coast. It is not very certain whether the Durotriges formed an independent state under a prince of their own, or were united with their neighbours, the Danmonii; as they were reduced by Vespasian

under the dominion of the Romans, at the same time, and with the same ease, and never revolted. (Eutrop. l. 5. c. 8.) The pre-accable disposition of the inhabitants is the reason why the Romans had few towns, forts, and garrisons in this pleasant country. Dorchester, its present capital, was a Roman city of some consideration, and is supposed to have been called Durnovaria. The country of the Durotriges was included in the Roman province called Flavia Caesariensis, and governed by the president of that province, as long as the Romans kept any footing in these parts.

DUROVERNUM, a station about the situation of which at Canterbury there is no doubt; and Mr. Baxter derives its name from *dur* a river, and *vern*, a ferry.

DUROUR'S ISLAND, in *Geography*, an island in the Pacific ocean, discovered by Capt. Carteret, in September, 1767. S. lat. 1° 14' or 16'. E. long. 143° 21'.

DURRENBERG, a small town of the kingdom of Saxony, in the district of Merseburg, remarkable for some very abundant salt-springs, which furnish as much salt as the whole consumption of the kingdom requires.

DURROW, a market and post town of the county of Kilkenny, Ireland, on one of the roads from Dublin to Cork. It is very neat, and has an excellent inn. The roads near it are peculiarly pleasant, passing through the demesne and plantations of Lord Ashbrook, whose residence is at Castle Durrow adjoining the town. It has been observed that this tract contains more extensive woods, and presents a greater variety of beautiful prospects from the diversity of well planted hills, and rich vallies, than any other part of Ireland. Durrow, though surrounded by the Queen's county, is in Kilkenny, which is thus accounted for. On its coming into the possession of the Butler family, who were perpetually harassed by the powerful sept of the Fitzpatricks, the earl of Ormond procured an act of parliament to make this estate part and parcel of the county of Kilkenny, and the ensuing Fitzpatricks being taken were transferred immediately to Kilkenny, and there, removed from their connections, they suffered the penalties of the law. Durrow is 52 miles S.W. from Dublin, and 12 from Maryborough. Wilson's Directory, &c.

DURSEY, an island in the Atlantic, about two miles long, and half a mile broad, situated near the south-west coast of Ireland, belonging to the county of Cork. It is near the northern point of Bantry bay. It is in long. 10° 4' W. Lat. 51° 33' N. Beaufort.

DURSIANS, or DURURIANS, in *Ecclesiastical History*, See DRUSES.

DURSLEY, in *Geography*, a town in the hundred of Berkeley, Gloucestershire, England, was formerly a borough, but has long since lost the privilege of sending members to parliament. It consists of two narrow streets. The government is vested in a bailiff and four constables. The church is a spacious structure, having two aisles and a tower. On the south side of the church-yard a copious spring of water rises, which gives motion to a fulling mill. In the vicinity is a peculiar rock, called by Leland *Towse flons*, and by the natives Puff-stone, which, though soft in hewing, becomes very durable when exposed to the air: of this stone the church is built. Dursley is 108 miles N.W. from London: has two annual fairs; and a market on Thursdays: the market house, which is a handsome edifice, was erected in 1738. By the late return, the town contained 460 houses, inhabited by 2379 persons, of whom 1040 were described as being employed in trade and manufacture; there being a considerable traffic in broad cloth, and card making for the clothiers; and an extensive paper manufactory. Here was anciently a castle, the site of which is still

called *Coffinfield*, where some earth-works are still to be seen. *Rudge's History of Gloucestershire*, vol. ii. p. 219.

DURSTUS, or DRUST, in *Biography*, was the son of Erp, or Erpio, a distinguished character in the line of Pétidish kings; who began to reign A. D. 406; and after fighting more than a hundred battles, and living to the protracted age of one hundred years, died A. D. 451. In that monarch's reign the Pétids were converted to Christianity by St. Ninian. See Dr. Anderfon's Royal Genealogies.

DURTAL or DURETAL, in *Geography*, a small town of France, in the department of Mayenne and Loire, chief place of a canton in the district of Segré, 9 miles S. W. of la Flèche, with a population of 3107 individuals, and remarkable for the fertility of its territory, which produces excellent wine, and abundance of corn. The canton contains six communes and 9498 inhabitants, upon a territorial extent of 205 kilometres.

DURVES, a town of Asia, in the country of Candahar; 130 miles S. E. of Candahar.

DURUM, *Latin*, in *Music*, hard, harsh, sharp, one of the distinctive terms applied to the three original major keys, in forming the hexachords. G is the *ut* of the diatonic hexachord. C of the natural hexachord, and F of the *molle*. These furnish a series of six sounds ascending in each, by the same intervals.

G A B C E

C D E F G A

F G A B C D

By these hexachords the three keys are connected: there being three notes of each, in common with the next hexachord above or below.

DURUNGI, or DURUNIGI, in *Botany*, the Arabic appellation of the *Doronicum Pardalitanche*, from which its present generic name is supposed to have been corrupted by modern writers, as some still more recently have made *Ailanthus* from *Aylanto*, and *Pandanus* from *Pandang*, words which, to use the expression of Linnaeus, "may be tolerated, but are not to be imitated." See *DORONICUM*.

DURVUS MONS, in *Ancient Geography*, a mountain of Gaul, in the province called "Maxima Sequanorum." By this mountain there was a passage from the country of the Rauraci on the north to that of the Helvetii in the south.

DURY, JOHN, in *Biography*, a learned divine, who flourished in the seventeenth century, was born in Scotland, and educated for the ministry. The great object of his early life was an endeavour to unite the Lutherans and Calvinists; for this purpose he obtained the approbation of the archbishop of Canterbury, and some other of the bishops. He circulated his plans over the whole of protestant Europe, which he seconded by his own personal labours, and by almost innumerable journeys taken expressly with this view. After many years of labour and toil, he gave up the hope of uniting the Protestants; and began a still more arduous work, *viz.* of uniting in the bonds of friendship Christians of all sects, which he expected to effect by a new explanation of the Apocalypse. Besides this work he published a book, entitled "Johannis Duræi Irenicorum Tractatum Prodromus, in quo præliminares continenter tractatus de I. pacis ecclesiasticæ remoris & medio tententur. II. Concordiæ Evangelicæ fundamentis sufficienter jactis. III. Reconciliationis Religiosæ procurandæ argumentis et mediis. IV. Methodo investigatoria ad controversias omnes, sine contradicendi studio et præjudicio pacificè decidendas, &c." In this book the author gives an account of the works which he had promised to the public, and of the expedients which he thought most favourable to his design. Dury wrote a

letter to Peter du Monin, concerning the state of the English, Scotch, and Irish churches under Cromwell, which, with other pieces, was printed at London, in the year 1658, by the care of Louis du Moulin. It is uncertain in what year he died. Bayle.

DUSART, CORNELIUS, painter of conversations, dancing, and taverns, born at Harlem 1665, disciple of Adrian Ostade. He studied with great assiduity, and expressed with equal humour and spirit the manners and passions of the bores in their seats, sports, &c. and he nearly approached, although he never equalled, the merit of his master. He was naturally of a weak constitution, which he had still more impaired by study; but his memory continued so surprisingly retentive, that he could, at any distance of time, retrace any striking object which he had once seen, with the utmost accuracy and precision in every point. He died in 1704. Pilkington.

DUSENSUS, or DUSITANUS, in *Ancient Geography*, an episcopal see of Africa.

DUSKY BAY, in *Geography*, a bay on the S. W. coast of the most southerly island of New Zealand, discovered and so named by Cook in March 1770. It is between three and four miles broad at the entrance, and seemed to be as deep as broad: it contains several islands, behind which a shelter is afforded from all winds. The north point of this bay, when it bears S. E. by S. is rendered very remarkable by five high peaked rocks which lie off it, and have the appearance of the four fingers and thumb of a man's hand, on which account it was called "Point Five Fingers;" and the land of this point is further remarkable, for being the only level land within a considerable distance.

It extends nearly two leagues to the northward; it is lofty and covered with wood. The land behind it is very different, consisting wholly of mountains, totally barren and rocky; and this difference gives the cape the appearance of an island. The westernmost point of land upon the whole coast, called "West Cape," lies about three leagues to the southward of Dusky bay, in the latitude of 45° 54' S. and in the longitude of 193° 17' W. The land of this cape is of a moderate height next the sea, and is distinguished by a very white cliff, two or three leagues to the southward of it. Captain Cook again visited Dusky bay in March 1773; and found, at the entrance of it, 44 fathoms water, a sandy bottom, the West Cape bearing S. S. E. and Five Fingers point, or the north-point of the bay, north. A great swell rolled in from the S. W. The depth of water decreased to 40 fathoms; and afterwards they had no ground with 60. Disliking the place in which they had anchored, they removed to another on the S. E. side of the bay, where they had a good harbour, with every convenience. Captain Cook determined to make some stay in this bay, and thoroughly to examine it; as no one had ever landed before, on any of the southern parts of this country. He also availed himself of the opportunity that was now afforded for necessary repairs, and for other occupations that were conducive to the health and convenience of his fellow-navigators. Here he found a tree, resembling the American black spruce, from the branches and leaves of which he made a kind of beer, that with the addition of inspissated juice of wort and molasses furnished a very wholesome beverage, and supplied the want of vegetables, which the place did not afford.

The south entrance of Dusky bay is situated on the N. side of Cape West, in S. lat. 45° 48'; and is formed by the land of the cape to the south, and Five Fingers point to the north. This land, when viewed from certain situations, bears some resemblance to the five fingers of a man's hand, whence

whence it takes its name; and different from the other adjacent lands, it is a narrow peninsula, lying north and south, of a moderate and equal height; altogether covered with wood. The depth of water is the only inconvenience that attends the entrance into this bay, as it affords no anchorage, except in the coves and harbours, and very near the shores, which is sometimes impracticable. The anchoring places, however, are sufficiently numerous, and equally safe and commodious. "Pickergill harbour," where captain Cook lay, is not inferior to any other bay for two or three ships; it is situated on the fourth shore abreast of the west end of "Indian island," which island may be known from the others by its greater proximity to that shore. There is a passage into the harbour on both sides of the isle, which lies before it. The next place on the upper or east side is "Cascade Cove," so called from a large cascade at the east point of the cove, that falls from a high mountain on the S. side of the bay. In this cove there is room for a fleet of ships, and a passage in, on either side of the island which lies in the entrance. The several anchoring places in this capacious bay are marked in Cook's chart, which will be a sufficient guide to all who need information. The north entrance into this bay lies in S. lat. $45^{\circ} 38'$, and five leagues to the north of Five Fingers Point.

The adjacent country is very mountainous; not only about Dusky bay, but through all the northern part of the western coast of "Tavai Poenamoo." Within land nothing appears but the summits of mountains of a stupendous height, and consisting of rocks that are totally barren and naked, except where they are covered with snow. But the land bordering on the sea-coast, and all the islands, are thickly covered with wood, almost down to the water's edge. The trees are of various kinds, and are fit for the shipwright, house-carpenter, cabinet-maker, and many other uses. The most considerable for size is the spruce tree, many of which trees are from six to eight or ten feet in girth, and from 60 to 80 or 100 feet in length; large enough to make a main mast for a 50 gun ship. The woods in many parts are so overrun with supple-jacks, 50 or 60 fathoms in length, that it is scarcely possible to force one's way amongst them. The soil is a deep black mould, composed of decayed vegetables; and the ground amongst the trees is covered with moss and fern, of both which there is great variety; but except the flax or hemp plant, and a few other plants, there is very little herbage, and none that is eatable, except some few creffes and a small quantity of celery. Dusky bay abounds most with fish; so that a boat with six or eight men, with hooks and lines, caught every day enough to serve the whole ship's company. Of ducks there is also great plenty, and no less than five different kinds. One cove, which abounds with them, was called "Duck-cove." The most mischievous animals are the small black sand flies, which are very numerous and very troublesome. Wherever they bite they cause a swelling, and such an intolerable itching, which induces a scratching that brings on ulcers like the small-pox. The almost continual rains may be reckoned another evil attending this bay. But though our navigators were perpetually exposed to them, they experienced no pernicious effects. Those who were sick and complaining, when they entered the bay, recovered daily, and the whole crew soon became strong and vigorous. This happy circumstance could only be attributed to the healthiness of the place, and the fresh provisions it afforded; and more particularly to the liberal supply of beer.

The inhabitants of this bay belong to the same race of people with those in the other parts of this country; they speak the same language and observe nearly the same cus-

oms. They live a kind of wandering life, and one family seems to maintain no perfect amity with another.

From a great variety of observations made by Mr. Wales, he found that the latitude of his observatory at Pickergill harbour was $45^{\circ} 47' 26\frac{1}{2}''$ S.; and by the mean of several distances of the moon from the sun, that its longitude was $166^{\circ} 18'$ E. The variation of the needle or compass was found to be $13^{\circ} 49'$ E., and the dip of the south end $70^{\circ} 53'$. The times of high water, on the full and change days, he found to be at $10^{\circ} 57'$, and the tide to rise and fall at the former eight feet, at the latter five feet eight inches. Hawksworth's Voyage, vol. iii. Cook's Voyage, vol. i.

DUSRACH, a town of Persia, in the province of Kerman; 156 miles S. of Sirgjan.

DUSSAC, a town of France, in the department of the Dordogne and district of Exideuil; 4 miles N. of Exideuil.

DUSSEL, a river of Germany, in the kingdom of Westphalia, which runs into the Rhine at Duffeldorp.

DUSSELDORF, or DUSSELDORP, a very handsome town of Germany, chief city of the grand duchy of Berg, which, since the appointment of its grand duke, Joachim Murat, to the throne of Naples in 1808, has been taken possession of by the French. Dusseldorf is situated on the river Duffel, at the place where this river falls into the Rhine. Till the peace of Lunéville it belonged to the elector palatine of Bavaria, now king of Bavaria, to whom it is principally indebted for its embellishments. It is 27 miles N.W. of Cologne, 27 miles N. E. of Juliers, and 75 S.W. of Munster. The streets are wide, regular, and clean; the houses lofty, and the inhabitants extremely industrious. Their number amounts to about 15,000.

Dusseldorf is chiefly remarkable for its celebrated gallery of pictures, which consists of three large and two smaller rooms, bearing each the name of the school to which the pictures belong, viz. the Flemish school, Gerard Dow, the Italian school, Vander Werff, and Rubens.

DUSSENT, JOSEF, in *Biography*, a Spanish painter, disciple of Vanloo, and one of the competitors in public, at the opening of the Royal Academy of San Fernando, at Madrid, in 1752. *Diccionario Historico, &c. de las Bellas Artes.*

DUST, minute and almost insensible particles broken off from any hard body.

Those broken from stones, or formed of extremely small stones, are more properly called *sand*. See SAND.

The subtle matter of DÉS CARTES is a sort of dust produced by the collision of the matter of the second element.

DUST, *Gold and Lead*. See the respective articles.

DUST, *Moss*. See BYSSUS.

DUSZMIANY, in *Geography*, a town of Lithuania, in the palatinate of Troki; 20 miles S.S.W. of Troki.

DUTCH COINS, *Fortification, Monies, Pens, Pink, Telescope, Tyles, Trading Companies, Measurers*. See the substantives.

DUTCHESS COUNTY, in *Geography*, a county of New York, in America, lying on the east side of Hudson river. It has the state of Connecticut on the E., West Chester on the S., and Columbia county on the N. It is about 43 miles long, and 23 broad, and contains 17 townships, of which Poughkeepsie and Fish-kill are the chief. The number of its inhabitants is 47,775, of whom 1609 are slaves. This county sends seven representatives to the assembly of the state.

DUTCHMAN'S BAY, a bay on the N. coast of the island of Antigua.

DUTCHMAN'S Island, an island of America, in the Potomack river; 14 miles above Washington.

DUTCHMAN'S Point, a point of land on the Vermont side of the lake Champlain, about 16 miles S. of the Canada line. It was retained by Britain for some time after the peace of 1783; but it has been since surrendered to the United States.

DUTCHY, an appellation given to the dominions of a Duke. See **DUKE**.

DUTCHY-Court. See **COURT**.

DUTHILL, in *Geography*, a town of Scotland, in the county of Inverness; 20 miles S.E. of Inverness.

DUTKINA, a town of Russian Siberia, in the government of Irkutsk, on the Lena; 16 miles S. of Orlenga.

DUTLINGEN, a small town of the kingdom of Wirtemberg, with a castle and a bridge over the Danube; 36 miles N.E. of Schaffhouse, and 40 miles N.W. of Constance, remarkable for some rich iron mines situated in its neighbourhood. N. lat. 47° 55'. E. long. 8° 40'.

DUTY, in a moral sense. See **OFFICE**.

DUTY of Marriage. See **MARRIAGE**.

DUTIES, taxes, or imposts, levied for the purpose of raising a public revenue. It has been said, that there is no branch of the art of government which is attended with more difficulty, than how to take from the pockets of individuals the sums necessary for the exigencies of the state, without disabling the persons who contribute from enjoying most of the necessaries and conveniences of life to which they have been accustomed. It is proper that individuals should contribute in proportion to the benefit they derive from government; and this is, in some degree, determined by the quantity of property, in the possession of which they are protected. But, unfortunately, the vast increase of the public expenditure, and the necessity of large and immediate supplies, have furnished modern financiers with a pretext for overlooking these principles; and in the duty imposed expressly on property, different classes of the community are so very differently affected by it, that formerly while duties were prefixed to be imposed on equitable principles, it would have been deemed very unequal and unjust.

Duties have been levied on property of various descriptions, but particularly on goods imported from other countries, on which the impost appears as a toll for receiving them into protection. It has been the policy of some countries to keep the duties on the importation and exportation of merchandise very low; this was the case in Holland, previous to the revolution, which gave great advantages to the trade of that country, as from the easiness of paying the duties, both strangers and natives were invited to bring great quantities of merchandise there, not only as to a market, but as to a great magazine, where it might be lodged, with little expence, till demanded for other markets; so that Amsterdam and Rotterdam were filled with the produce and manufactures of every part of the world. At Hamburgli, Bremen, and Lubbeck, the duties on exportation and importation were very moderate, which contributed materially to the commercial prosperity of those cities. In most countries, a distinction was formerly made between the duties paid by natives and by foreigners, the latter being subject to a much higher rate.

High duties give rise to smuggling, and diminish the consumption of the article on which they are laid. This important financial principle has, however, been frequently disregarded, and the actual produce of an existing duty being thought to furnish the means of computing, with tolerable certainty, the sum to be procured by an augmenta-

tion of it, new duties have been added to the old ones, either by separate rates, or a proportion of the former rates, which have not only created much perplexity in the revenue, and trouble to traders, but often diminished the old duty, on the produce of which the computation of the additional revenue had been founded. Before the passing of the Consolidation Act, there were seven duties on ale, six duties on malt, nine duties on foreign spirits, as great a number on the distillery; and on many articles of the customs there were ten, twelve, and even fifteen duties: the abolition of these complex rates, and the substitution of a single duty on each article, contributed materially to the improvement of the revenue; and this simplification of duties has been repeated at several subsequent periods.

The evidence so frequently produced of the encouragement given to smuggling by high duties, has occasionally induced the legislature to lower the duties, with the view of augmenting the revenue. Thus, in the year 1745, when the gross produce of the inland duty on tea was 154,168*l.* 7*s.* 1*d.* the duty was reduced from 4*s.* in the pound to 1*s.* in the pound, and 2*s.* per cent. on the price. The consequence of this reduction was, that in the year following, the produce of the duty rose to 249,018*l.* 19*s.* 11*d.*, and in 1747, it was 263,514*l.* 4*s.* 3*d.* But the advantage which evidently flowed from this measure was not long kept in view, the duties being raised again, at different times, till they exceeded their former amount. The revenue committee, in their first report, state, that in the year 1783, the total duties of customs and excise, paid on tea, before it could legally come into the hands of the consumer, amounted, on the lowest kinds of tea, to more than cent. per cent. on the prime cost, and on other kinds of tea, on an average, to about 75 per cent. It was, therefore, thought proper to recur again to the former principle of lowering the rate of the duties, with the view of augmenting the revenue; in consequence of which, the act, known by the name of the Commutation Act, was passed, by which the duties on tea were reduced to 12½ per cent. on the prime cost. Before this period, on an average of ten years, there were very little more than six million pounds weight per annum, legally consumed in Great Britain; but within the first twelve months after the act took place, the quantity legally sold exceeded 16 millions of pounds, which has since increased to upwards of 20 million pounds.

For an account of the various duties constituting the permanent public revenue, see **CUSTOMS, EXCISE, STAMPS, &c.**

DUTY, in the *Military Art*, is the exercise of those functions that belong to a soldier; with this distinction, that mounting guard, and the like, where there is no enemy directly to be engaged, is called duty; but marching to meet and fight an enemy, is called going on service.

DUVAL, VALENTINE JAMERAY, in *Biography*, was born at Artonay, a village of Champagne, in the year 1695, of very poor parents, who died while Valentine was very young, leaving behind them a very numerous progeny, in a state of the greatest indigence. The subject of this article was in a short time taken into the service of a farmer, and employed by him in the care of his poultry. For this kind of business he was ill qualified; and, for want of steadiness of conduct, he was dismissed from his humble station, at the beginning of the severe winter of 1709. Destitute of every resource, and probably without a single friend, he set out, not knowing whither he was to proceed. In walking towards Lorraine, he was seized with the small pox, of which he must have perished, but for the humanity of a shepherd. From this time, till the age of 19, he became an attendant

on the flocks of the plains, when, being of a contemplative turn of mind, and having, by his own exertions, acquired a taste for reading, he sought protection at the hermitage of St. Anne, not far from Luneville, of which the inhabitants made him an overseer of their rural concerns. Here, besides a most diligent attention to the business in which he was engaged, he learned writing and arithmetic; and, like our own countryman Ferguson, spent his nights in examining the heavens. His observatory he made in the top of one of the highest oaks, which he constructed of ozers, in the form of a stork's nest. His finances, though very trifling, enabled him to purchase a few maps; with these he contrived to gain some knowledge in astronomy and geography, which was introductory to more sublime pursuits. He now found himself in want of money to purchase books and other things necessary to the attainment of knowledge; and to supply his need, he hunted and killed a vast number of wild animals, for the sake of their skins, the produce of which he converted into a fund to supply his literary exigencies. Accident procured him the protection and assistance of an Englishman, Mr. Forster, by whose liberality he obtained a library of some hundred volumes; he began now to be uneasy at his situation in life, which he thought was not that in which he ought to move. Pursuing his studies one day under the shade of a widely spreading tree, with his maps and books about him, he was accosted by a hunting party, who proved to be branches of the royal family, with their tutors. Struck with the novelty of the scene, and having learnt Dural's history, they persuaded him to follow the beat of his inclination at the Jesuits' college at Pont-à-Mousson, under the patronage of the duke of Lorraine, who was so much pleased with his progress in science and general literature, that he afforded him the opportunity of accompanying him to Paris, at the end of the year 1718. Soon after he became a professor of history in the high school of Luneville. His lectures were attended by many foreigners, particularly Englishmen, who happened to be at Luneville at that time, and by whose report the reputation of Duval was greatly increased. In the year 1738, Duval removed to Florence, and became keeper of the ducal library: the study of coins was a favourite object, and he now began to collect all that he could meet with which were valuable on account of their antiquity. Scarcely had he formed his plan, when the emperor Francis I. formed the resolution of establishing at Vienna a cabinet of ancient and modern coins, and invited Duval to that capital to undertake the inspection and arrangement of it. A house was assigned him in the imperial quarter near the palace, and he usually dined with the emperor one day in every week. He was appointed sub-preceptor to Joseph II., in 1751, and was ever held in the highest esteem and veneration by the court. He remained free from the usual infirmities of age till his 79th year, and died in 1775, in the 81st year of his age. After his death, M. de Kock, secretary of legation at Peterburgh, collected and published his works, which, with his life, written by himself, are considered as very interesting, and highly to the credit of the author. He was plain in his dress; simple in his manners; mild and kind in his disposition; and grateful to his benefactors. To the hermits of St. Anne he presented an elegant mansion, with land; and on the spot where he was born, he erected a house, and assigned it as a dwelling for a school-master. Gen. Biog.

DUVAL, PETER, born at Abbeville, about the year 1618, was nephew of the famous geographer Sanfon, and became a teacher of the science in which his uncle had so much excelled. He died at Paris in 1683, leaving behind him

various geographical treatises, maps, &c. which have been superseded by better works of the same kind: "La Geographie Françoise, contenant les descriptions, les cartes, et les blasons de France, &c." still bears some degree of reputation. He was the author of chronological tables, and several articles in genealogy and heraldry. Morei.

DUVAL, NICHOLAS, a painter of history; born at the Hague, 1644, where he learned the art of painting; travelled to Italy; became the disciple of Pietro da Cortona, whose manner he imitated. He was recommended to the prince of Orange, (William III.) who employed him in several works at Loo, and afterwards, in England, entrusted him to clean and repair the cartoons of Raffaele at Hampton-court.

He was appointed director of the academy at the Hague, where he painted the ciding of the faloon. He died 1732. Pilkington Dict.

DUVENEDE, MARC VAN, painter of history, born at Bruges in 1674; went to Italy; and at Rome became a disciple of Carlo Maratti. On his return to Flanders, he painted many great works in the manner of his master, among others, the Martyrdom of St. Lawrence, in the chapel of St. Christopher at Bruges. Pilkington.

DUUMVIR, a general appellation among the ancient Romans, given to magistrates, commissioners, and officers, where two were joined together in the same function. So that they had almost as many duumviri as they had officers joined two by two in commission. There were *duumviri* to direct the building, repairing, and consecrating of temples and altars; *capital duumviri*, who took cognizance of crimes, and condemned to death; *duumviri* of the marine, or navy, &c. But the most considerable of the duumviri, and those usually thus called by way of eminence, were the

DUUMVIRI Sacrorum, created by Tarquin the Proud, for the performance of sacrifices, and keeping of the Sibyls' books. These were chosen from among the nobility, or patricians, and held their office for life: they were exempted from serving in war, and from the offices imposed on the other citizens; and without them the oracles of the Sibyls could not be consulted.

The commission lasted till the year of Rome 387, when, at the request of C. Licinius, and L. Sextius, tribunes of the people, they were changed into *decemviri*; that is, in lieu of two persons, the trust was committed to ten, who were half patricians, half plebeians.

Sylla A. U. C. 671, added five more to their number, upon which they became denominated *quindecimviri*; their body was afterwards much increased, and at length amounted to sixty; yet still it retained the denomination of *quindecimviri*.

They were entirely abolished under the emperor Theodosius, towards the close of the 4th century, along with the rest of the heathen superstitions. See PAGANISM.

DUUMVIRI, *The capital, Duumviri Perduellionis*, were not ordinary magistrates; but created only on certain occurrences.

The first commissioners of this kind were those appointed to judge the surviving Horstius, for killing his sister, after vanquishing the Curiatii, in the reign of Tullus Hostilius. See CURIATII.

There were also duumviri in the Roman colonies, who held the same rank and authority in their respective colonies, that the consuls held at Rome. They were chosen out of the body of decuriones, and wore the *prætecta*, or robe, bordered with purple.

We also read of municipal duumviri, whom Vigenere com-

gares to our sheriffs, or rather mayors of towns, whose authority lasted only five years.

DUUMVIRATE, DUUMVIRATUS, the magistrature, office, or dignity, of the duumviri. See **DUUMVIR**.

DUX, in *Geography*, a town of Bohemia, in the circle of Leitmeritz; 15 miles W.N.W. of Leitmeritz.

DUXBOROUGH, a maritime and post town of America, in the state of Massachusetts, and county of Plymouth, incorporated in 1637. This is a healthy town; employs 20 vessels, most of them being from 60 to 90 tons, and contains 1664 inhabitants. It lies N. by W. of Plymouth, 3 miles from it by water, and 8 by land, and 58 S.E. by S. from Boston. Within the harbour are Clarke's island, containing about 100 acres of excellent land, and Squish island formerly joined to the Gurnet, which is an eminence at the southern extremity of the beach, having on it a light-house, but now insulated by the water. The Indian name of this town was Mattakeefet, or Namakeefet. It was first settled by Standish and his associates, who came to Plymouth with the first settlers in 1620.

DUXBURY, a township of America, in Chittenden county, Vermont, about 20 miles S.E. of Burlington; containing 153 inhabitants.

DUYT, in *Commerce*, a Dutch copper coin.

DUYVELAND, in *Geography*, an island of Zealand, separated from the south-east part of Schouwen by a narrow passage; its dimensions being about three leagues by two.

DUZDEB, a town of Asiatic Turkey, in the province of Natolia; 28 miles W. of Eregr.

DUZEY, a town of France, in the department of the Meuse and district of Etain; three leagues N.E. of Etain.

DWALE, or **DWAL**, in *Heraldry*, the herb nightshade; used by such as blazon with flowers and herbs, instead of colours and metals, for fable or black.

DWARF. See **PYGMY** and **STATURE**.

Dwarfs were called nani and namu among the Romans; and were held in such request, that artificial methods were used in order to prevent the growth of boys designed for dwarfs, by inclosing them in a box, or binding them with bandages. Augustus's niece, Julia, was very fond of one of these dwarfs, called Sonopas, who was only two feet and a hand-breadth high.

In the Philosophical Transactions we have well authenticated accounts of two dwarfs; one born in Norfolk, who, at the age of 22, weighed no more than 34 pounds with all his cloaths on, and whose height, including hat, wig, and shoes, was only 38 inches; and another, in Wales, who, at the age of 15, measured no more than two feet seven inches, and weighed only 13 pounds; and who, at that early period of life, laboured under all the infirmities and calamities of very old age. Phil. Trans. vol. xlvii., p. 67., and vol. xlvii., p. 279.

DWARF-trees, a sort of diminutive fruit trees, frequently planted in the borders of gardens; thus called from the lowness of their stature.

Dwarf-trees were formerly very much in request in gardens; but, since the introducing of espaliers, they are much neglected. The manner however of propagating dwarf pears, which have been found to succeed the best of any dwarfs, is this: they are to be grafted on a quince stock, and that at about six inches above the ground; and when the bud has shot so far as to have four eyes, it is to be stopped, to give rise to lateral branches. Two years after the budding the trees will be fit to transplant to the spot where they must remain. They should be set at 25 or 30 feet square distance, and the ground between may be sown or planted for kitchen use while the trees are young, only ob-

erving not to plant too near their roots. There should be stakes driven down all round the tree, to which the branches must be nailed with liff while they are young, training them into an horizontal direction, and no branches are to be suffered afterwards to cross one another, and in shortening the shoots the uppermost eye must always be left outwards. The summer and autumn pears are those which do best in dwarfs, for the winter ones never succeed well on them.

Apples are also sometimes planted as dwarfs, and are for this purpose most commonly grafted on paradise stocks; these spread much less than the pears, and therefore need only be set at about eight feet distance. Some also plant apricots and plums for dwarfs, but these being of a more tender constitution seldom succeed well. Miller. See **ES-PALIER**.

DYE, in *Architecture*, the part of a pedestal contained between the base and the cornice, in the form of a square prism, approaching frequently to a cube or dye, whence the name originates.

DYE is also used for a cube of stone, placed under the feet of a statue and over its pedestal, to raise it and shew it the more.

DYEING, *History of*. The origin of the art of dyeing is involved in that obscurity which pervades the history of all those arts connected with the common wants and necessities of life. They have originated in times beyond the reach of history or tradition, and are the offspring of the natural faculties of man directed by the great primeval wants of food, shelter, and raiment: The art of dyeing is, of course, posterior to many of these, and is founded less on the necessities than passions of mankind. A love of distinction is common to man in every stage of civilization, but that passion for admiration which is displayed in a love of finery and ornament is peculiar to him in his most barbarous and uncultivated state. Hence savage nations delight in brilliant and gaudy colours, and many paint their skins, and adorn themselves with feathers, stones, and shells of various hues. History has not furnished us even with her fables on the origin of dyeing; but from analogy, as well as observation of the practice of barbarous nations at the present day, we may trace the rude beginnings from whence the art has sprung. The rich and gaudy plumage of birds, the finely spotted skins of animals, coloured stones, and such other substances as nature herself supplies, would afford the first materials for savage finery and dress. The caps and mantles of the chiefs of the South Sea islands, such as were brought home by captain Cook, are composed almost wholly of feathers richly coloured.

It is easy to conceive that accident must furnish innumerable instances of observation even to the eye of a savage, that many of these colours were capable of imitation, and that some substances readily imparted their colour to others. The bruising of a fruit, a flower, or leaf, is one of the most natural and obvious occurrences to which we should look for the first notion of applying vegetable juices to dyeing, and doubtless the knowledge of the tingent properties of various herbs was thus early acquired. The art, however,

must have waited the progress of industry and luxury, before it became extended and improved. Long antecedent, however, to the period when authentic history begins, it must have made considerable progress. Moses speaks of stuffs dyed blue, and purple, and scarlet, and of sheep-skins dyed red. These colours require great skill in the preparation, and the knowledge of them implies a very advanced state of the art at that period.

The colour which appears to have been earliest brought to perfection, and which was held in such high estimation among the ancients, is purple. It was to chance alone, according to the tradition of antiquity, that they owed this discovery. A shepherd's dog, incited by hunger, having broken a shell on the sea shore, his mouth became stained with such a colour as excited the admiration of all who saw it. They endeavoured to apply it to stuffs, and succeeded. There is some discordance in the details of the ancient writers of the circumstances of this event. Some place this discovery in the reign of Phoenix, second king of Tyre, that is to say, a little more than 500 years before Christ; others, at the time that Minos the first reigned in Crete, about 1439 years before the Christian era. But the greatest number agree in giving the honour of the invention of dyeing purple stuffs to the Tyrian Hercules. He gave his first trials to the king of Phœnicia, who was so jealous of the beauty of this new colour, that he forbade the use of it to all his subjects, reserving it for the garments of royalty alone.

Some authors relate the story differently. Hercules's dog having stained his mouth with a shell, which he had broken on the sea shore, Tyras, a nymph of whom Hercules was enamoured, was so charmed with the beauty of the colour, that she declared to her lover she would see him no more till he brought her a suit dyed the same. Hercules thought of a way to satisfy his mistress; he collected a great number of the shells, and succeeded in staining a robe of the colour the nymph had demanded. Such are the different traditions handed down by the ancients of the origin of the purple dye. They are evidently blended with fiction, yet they may serve to fix the epoch of this discovery, which appears to have been made about fifteen centuries before the Christian era. Whether the purple of Tyre was similar to that mentioned in holy writ, as used by Moses for the vestments of the high priest, and the ornaments of the tabernacle, may admit of some dispute, since it is not certain, according to M. Huet, that the word *argaman*, of the Hebrew text, which all the interpreters translate by *purpura*, means in reality that colour.

The testimony of Homer confirms the antiquity of this discovery. This great poet and accurate observer, ascribes to the heroes of that age, in which we have supposed it became known, ornaments and cloths of purple.

The ancients had such an esteem for this colour, that it was especially consecrated to the service of the deity. Moses, as we have just observed, used stuffs of purple for the works of the tabernacle, and the habits of the high priest. The Babylonians gave purple habits to their idols; it was the same with most of the other people of antiquity. The Pagans were even persuaded that the purple dye had a particular virtue, and was capable of appeasing the wrath of the gods.

Purple was also the distinguishing mark of the greatest dignities from the earliest times. We have seen that the king of Phœnicia, to whom tradition says the first essays of this colour were presented, had it reserved for the sovereign. Among the presents which the Israelites made to Gideon, the scripture makes mention of purple habits found among the spoils of the kings of Midian. Homer gives us plainly

to understand, that it only belonged to princes to wear this colour; and we may remark, that this custom was observed by all the nations of antiquity.

It is not easy to give a clear and precise idea of the process followed by the ancients in the production of this highly valued colour. We find some details in the works of Aristotle and of Pliny, in whose days the practice was very common, but they are not sufficiently circumstantial. The purple dye, according to Pliny, was drawn from many species of shell fish. The best were found near the Isle where New Tyre was built. They fished for them in other parts of the Mediterranean. The coasts of Africa were famous for the purple of Getulia. The coasts of Europe supplied the purple of Laconia, which was held in great esteem.

In the 36th chapter of his seventh book, Pliny ranges in two classes the different kinds of shell fish which produced the purple. The first comprehended the smaller species under the denomination of *buccinum*, from their resemblance to a hunting horn; the second included those denominated *purpura*. These Fabius Columna conceives to have been also distinguished by the generic name of *murex*, though others suppose this to have signified all the different species generally. All these several species, the chief of which are enumerated by Pliny, appear to have given colours of different shades, from which, by mixture of the liquors in various proportions, other varieties of colour were produced. A few drops only of this precious dye were obtained from each fish, by extracting a white vein placed in the throat; but to avoid this trouble with the smaller species, according to Aristotle and Pliny, the whole fish was bruised in a mortar, a practice which, according to Vitruvius, was often followed with the larger. The liquor, when extracted, was mixed with a considerable portion of salt, and suffered to remain three days; after which it was diluted with five or six times its quantity of water, and digested, moderately hot, during ten days, in a lead or tin vessel, skimming it frequently, to separate all impurities. The wool was afterwards put in, being well washed, cleaned, and properly prepared. After soaking five hours, it was taken out, carded, and again immersed in the boiling dye, till all the colour was taken up or exhausted. To produce particular shades of colour, nitre, urine, and a marine plant called fucus, of which the best kind is found on the rocks of the Isle of Crete, were occasionally added.

The Tyrians, by the confession of all antiquity, succeeded best in dyeing stuffs purple. Their process differed a little from what we have related above. They used nothing to make their colour but purple shells taken out at sea. They made a bath of the liquor they drew from these fishes. They steeped their wool in this a certain time, and afterwards took it out and steeped it in another boiler, in which was nothing but *buccina* or trumpet fish. This is all the ancients tell us of the practice of the Tyrians. Wool, which had received this double Tyrian dye, (*diabapha*) was so very costly, that in the reign of Augustus, each pound sold for 1000 Roman denarii, about 36*l.* sterling. Nor need we wonder at this excessive price, when we consider the tedious nature of the process, and the small quantity of dye afforded by the shell fish, from each of which not more than a single drop was obtained. For 50*lb.* of wool they used no less than 200*lb.* of the liquor of the *buccinum*, and 100*lb.* of that of the *purpura*, or 6*lbs.* of liquor to 1*lb.* of wool. We ought not to be much surprized, therefore, that this colour varied in value even with gold itself. The ancient writers distinguish many different shades of purple. One of them, which was very dark, appears to have been a kind of violet, inclining towards a reddish hue. "Nigrantis rosæ colore subluccens."

fulcrae," Pliny, lib. 9. sec. 50. Another, less esteemed, was a kind of crimson. "Rubens color, nigrante deterior," lib. 9. sec. 62. The most valued of all, and in which the Tyrians particularly excelled, was a deep red purple, of the colour of congealed blood. "Laus ei summa in colore sanguinis concreti," Pliny, *ibid.* It is in allusion to this that Homer and Virgil give to blood the epithet *purple*. There was a fourth kind known in later times, very different from those we have spoken of. The colour was whitish; an account of which may be seen in Perrault's translation of Vitruvius.

The purple has been almost every where a mark of distinction attached to high birth and dignity. It was an ornament of the first offices of Rome; but luxury, which was carried to great excess in that capital of the world, rendered the use of it common among the opulent, till the emperors referred to themselves the right of wearing it. Soon afterwards it became the symbol of their inauguration. They appointed officers to superintend the manufactories, principally established in Phœnicia, where it was prepared solely for their use. The punishment of death was decreed against all who should have the audacity to wear it, though covered with another colour. The penalty, so tyrannically denounced against this whimsical species of treason, doubtless occasioned the loss of the art of dyeing purple; first in the West, but much later in the East, where it flourished considerably till the eleventh century.

It appears that some kinds of purple preserved their colour for a very long time. Plutarch, in his life of Alexander, relates that the Greeks found in the treasury of the king of Persia a great quantity of purple which had not lost its beauty, though it was 190 years old.

It is commonly asserted, on the authority of most of the ancient writers, that the purple had a very strong and disagreeable odour. It would appear, however, from Pliny, lib. 9. sec. 36. that this was the case only with some particular kinds. After extolling the beauty of the true purple, and allowing that it was justly an object of ambition, he asks, how it happens that the other kinds of purple, obtained from the shell-fish called *conchyliæ*, should be so high priced, considering the stinking disagreeable odour which the shells have that are dyed with them.

After all, the boasted purple of antiquity was a miserable dye compared with many which we now possess, and affords a strong proof of the imperfect state of the art at the period when it was held in such esteem. It was, no doubt, the most rich and brilliant colour then known.

It is a curious fact, that Mr. Bruce, whose acquaintance with ancient authors ought to have convinced him of the contrary, maintains that the Tyrian purple was produced with cochineal, and that the story of its being the blood of a shell-fish was invented and propagated by the Tyrians with a view of deceiving other nations, and keeping the art of dyeing this colour exclusively to themselves. He even adduces this as a proof of the early intercourse carried on with the new world, in times long antecedent to those in which we suppose the discovery of the continent of America was first made.

The ancients obtained from the *coccus*, now known by the name of kermes, a colour which was almost as highly esteemed as purple, and which was sometimes mixed with it. Pliny informs us it was employed in the preparation of the imperial robes. It was generally called scarlet, and was sometimes confounded with the purple. The use of the *coccus* in dyeing is very ancient, since it appears from the commentators, to be alluded to in Exodus, chap. xxxix. ver. 1. and 28.

Our materials for a history of the art of dyeing, during the ages of classical antiquity, are very scanty. Amongst the Greeks the useful arts were degraded even in the eyes of philosophers, and this contempt descended to the Romans; for Pliny, speaking of dyeing, avowedly neglects the description of operations which are unconnected with the liberal arts. "Nec tingendi rationem omnifidius, si unquam ea liberalium artium fuisse."

The art of dyeing among the Greeks appears to have made no great progress; the dresses of the people was of cloth which had received no dye, and which might be washed. The rich preferred coloured clothes; they esteemed such as were dyed scarlet with the kermes, but they valued still more highly those of purple.

The few details relative to dyeing into which Pliny has entered in his great work, are almost wholly confined to the purple, of which we have given an account. The few scattered facts to be met with, that serve at all to illustrate the history of the art, we shall briefly notice. Some varieties of colour, derived from the purple, and produced by different mixtures of the various kinds of shell-fish, and also by admixture with the dye of the *coccus*, or kermes, appear to have been fashionable in Pliny's time. These originated, according to our author, in the errors and failure of the dyers, who having, in the first instance, spoiled their cloth, endeavoured to hide the defects by giving it another shade: hence arose those compound twice-dyed colours which were soon held in high repute.

Besides the Tyrian purple, scarlet, and the varieties and compounds of those colours, Pliny mentions yellow as a very ancient dye, and highly esteemed in former times. The veil which the bride wore on her wedding day was of yellow, and none but women were permitted to use it. They had also a colour resembling the cyanos, or blue-bottle, and another like the golden yellow flower *elichryon*. None of these colours, says Pliny, were known, or at least in request in the days of Alexander the Great; for the Greek writers, who wrote soon after his decease, make no mention of them. They are evidently, however, of Greek origin, as appears from their names, which, though Greek, were current in Italy in Pliny's time.

The use of vegetable dyes appears to have been in a great measure unknown to the Romans: though the inhabitants of Gaul, according to Pliny, imitated all colours, even the Tyrian purple and the scarlet, with the juice of certain herbs. In the eleventh chapter of the thirty-fifth book of Pliny's history, is preserved a valuable notice of the process followed by the Egyptians in dyeing linen. They stained, says he, white cloth, not with colours, but with certain drugs, which have the property of absorbing them, but which exhibit no appearance of any dye till they have been boiled some time in a cauldron, from which they are withdrawn painted or stained of various colours. What is most extraordinary, says Pliny, is, that the cauldron containing only colour of one kind should impart to the cloth shades of various hues according to the nature of the drugs which were laid on, and the colours are so fixed that they can never be washed out, but are more durable and fixed than if they had never been immersed in the boiling dye.

We have here a tolerably accurate description of the process of calico printing; and the only mention in any ancient author of an art which has existed for ages past in the East, and is practised there at this day, probably with little variation from the mode described by Pliny.

The art of dyeing linen appears not to have been known in Greece before Alexander's invasion of India, where they

died the sails of his vessels of different colours. The Greeks seem to have borrowed this art from the Indians.

We may form some idea of the state of the art of dyeing amongst the Romans, from the enumeration of the different colours which were in use, and the substances employed in producing them. In addition to those enumerated by Pliny, we find, that in the equestrian games of the circus, the different divisions were distinguished by the colours *green*, color *prasinus*; *orange*, *rufatus*; *gray*, *venetus*; and white. We shall enumerate, after Mr. Biehoff, who has minutely examined the subject, the ingredients employed at that time in the art of dyeing, in addition to the two important ones already mentioned, the purple fish and coccus.

1. Alum. It is probable, from what we shall state hereafter, that the ancients were unacquainted with our alum in its state of purity.

2. Alkanet. Suidas says, that this substance was also used by women as a paint.

3. The blood of birds, which was used amongst the Jews.

4. The fucus; that of Crete was preferred, and it was generally employed as a ground or preparative for valuable colours.

5. Broom.

6. The violet, from which the Gauls prepared a kind of purple.

7. *Lotos medicago arborea*; snail trefoil; the bark was used in dyeing skins, and the root in dyeing wool.

8. The bark of the walnut-tree and the peel of the shell.

9. Madder. We are not certain whether the madder of the ancients was the same as ours, or another root of the same tribe.

10. Woad (*glastum*). This plant was undoubtedly in use among the ancients, but we do not know whether their preparation of it was the same as ours.

We are not to infer, however, that these were the only substances employed by the ancients in the art of dyeing; many more being, in all probability, in use, of which we have no account. Indigo (*indicum nigrum*) is mentioned by Pliny, and though some doubts have been entertained by his commentators respecting the true nature of this substance, some supposing it to have been Indian ink, yet it is very evident he meant the indigo of the moderns, from the purple smoke which he says it emitted when set on fire, and which we believe is peculiar to indigo. It was never, however, we believe, employed in dyeing, but simply as a pigment.

India was the nursery of the arts and sciences, which were afterwards spread and perfected among other nations. Accidents, which had a tendency to improve the art, could not fail to be multiplied rapidly in a country rich in natural productions, which requires little labour for the support of its inhabitants, and the population of which was favoured by the bounty of nature and the simplicity of manners, till it was opposed by the tyranny of succeeding conquerors. But religious prejudices, and the unalterable division into castes, soon put shackles upon industry; the arts became stationary, and it would seem that the knowledge of dyeing cotton in that country was as far advanced in the time of Alexander as it is at present.

The beautiful colours which we observe in their printed calicoes, would lead us to suppose that the art of dyeing had then attained a high degree of perfection, yet we find, from the details of those who have witnessed their operations, that the Indian processes are so complicated, tedious, and imperfect, that they would be impracticable in any other

country, on account of the difference in the price of labour. The art of printing calicoes has been practised in India at least twenty-two centuries; for the historians of Alexander's invasion of that ill-fated country speak of their flowered cloths or chintz. If they excelled therefore in the richness and brilliancy of two or three colours; it is to be attributed to the superior quality of some of their dyes, peculiar to their own country, the effect of which was perhaps heightened by the length and multiplicity of their operations. The knowledge of this art appears to have spread over a considerable part of Asia. It was practised, and is to this day, by the Persians; and we have seen that in Pliny's time, it was established in Egypt.

From the fifth volume of the "Memoires concernant l'Histoire, les Sciences, les Arts, les Mœurs, &c. des Chinois," it appears, that wool was never worn in China but as a substitute for fur, and that cotton and silk, being the only substances ever dyed by the inhabitants, received all their colours from vegetable tincture matters; that their colours were principally red, blue, violet, and what is called a woad colour; and that under the three first dynasties the business of dyeing was chiefly practised by the female part of each family, for its own particular use; and it probably continued to be practised without any thing like principle or science until near the end of the seventh century, when the Chinese discarding their own, borrowed the art and means of dyeing which were then in use among the Indians and Persians; and it is said, that alum and coppers, which the Chinese did not use before, were among the means so borrowed; a fact which renders it probable, that there was little, if any thing, in the Chinese art of dyeing, of which the loss need now be regretted.

It appears, however, that long before this time a knowledge of the uses of alum and of iron in dyeing had spread from Hindoustan and Persia westward to Egypt, and thence to Greece and Rome. Bergmann, indeed, and after him, Beckmann, have represented the alum of the ancients as different from the crystallized salt of the moderns; and have supposed that the varieties of alum mentioned by Dioscorides, were italcities, containing but little alum, and consisting chiefly of calcareous earth. Nature, however, does produce some, though but little, crystallized alum, particularly in Egypt and some parts of Asia; and it probably was in this state that its good effect in dyeing had been first observed, before mankind were led to the means and operations since employed for separating and collecting it from the various aluminous ores. Bergmann informs us, that the factitious salt which is now called alum, was first discovered in the eastern countries, and that among the most early works established for the preparation of alum, we may justly number that of *Roccho*, a city in Syria, now called Edessa, hence the appellation of *roch alum*. He adds, that Bartholomew Perdig, or Pernix, a merchant of Geroa, who had been at Roccho, discovered the matrix of alum in the island of Ichia, about the year 1459, and established a manufactory there; at the same time, John de Castro, who had visited the manufactories at Constantinople, discovered a matrix at Tolia, by means of the *ilex aquifolium*, which he had also observed to grow in the adjacent mountains of Turkey; and his opinion was confirmed by the taste of the stones. The attempts made by the Genoese at Viterbium and at Volaterra succeeded extremely well; and the preparation of it in Italy soon increased wonderfully fast. The first manufactory of alum in England was established in the reign of Elizabeth, at Gisborough, by one Thomas Chaloner.

In the fifth century all the arts were lost throughout the West, except a few, which in a state of decay were preserved

in Italy; and no traces were left of knowledge, industry, or humanity.

Muratori quotes a manuscript of the eighth century, in which we find a description of some dyes, principally for blues, and some processes connected with the arts; but the Latin, which is almost unintelligible, and the chafms we find here and there, prevent us from being able to form a just idea of these processes.

The arts were better preserved in the East, where articles of luxury were procured by some of the great, even so late as the twelfth century. During the crusades, the Venetians derived their power from the barbarous mania of the age: their commerce increased; the arts were established among them, and improved by the industry of the Greeks, and spread from thence through the other parts of Italy. In the year 1338, Florence contained two hundred manufacturers, who are said to have made from seventy to eighty thousand pieces of cloth, which, as an object of commerce, were worth twelve hundred thousand crowns of gold.

It is said that archil was accidentally discovered by a Florentine merchant, about the year 1300. Having observed that urine imparted a very fine colour to a certain species of moss, he made experiments, and learned to prepare archil. He kept his discovery secret a long time; his posterity, a branch of which still exists, according to Dominique Manni, have retained the appellation of Ruccellai, from oreiglia, the Spanish term for that kind of moss.

The arts continued for a long time to be cultivated in Italy with increasing success. In the year 1429, the first collection of the processes employed in dyeing appeared at Venice under the name of "Mariegola dell'arte dei tentori;" a second edition, much improved, came out in 1510. A certain person, named Gioran Ventura Rosetti, formed the design of rendering this description more useful and extensive. He travelled through the different parts of Italy, and the adjacent countries, where the arts had begun again to flourish, in order to make himself acquainted with the various processes employed, and he published, under the title of "Plütho de l'arte dei tentori," &c. a collection which, according to Mr. Bischoff, is the first that united the different processes, and which ought to be regarded as the leading step toward the perfection which the art of dyeing has attained. This work was printed at Venice, in 1548; a French translation of it appeared at Paris in 1716. It is remarkable that in the work entitled "Plütho," not a word is said either of cochineal or indigo; from which we may conclude that these two dyes were either unknown or not employed at that time in Italy.

The first indigo used in Europe appears to have been brought from the East Indies by the Dutch. India was doubtless the country where that valuable substance was first produced. The uncivilized inhabitants of other countries have, indeed, discovered modes of obtaining colouring matter, very nearly resembling that of indigo, from other plants, as the *ilatis tinctoria*, or woad, and the *genipa americana*, but they obtained these matters in a liquid form only, and employed them in their recent state.

The natives of India, however, went farther, they precipitated and collected, in a dry solid form, the colouring matter of indigo, and discovered the means of afterwards dissolving and applying it to stuffs. In Africa, the Mandingo negroes, according to Mr. Park, dye their cloth of a lasting blue colour, by the following simple process. The leaves of the indigo, when fresh gathered, are pounded in a wooden mortar, and mixed in a large earthen jar, with a strong ley of wood ashes; chamber-ley is sometimes added.

The cloth is steeped in this mixture, and allowed to remain until it has acquired the proper shade. In Kaarta and Lundamar, where indigo is not plentiful, they collect the leaves and dry them in the sun, and when they wish to use them, they reduce a sufficient quantity to powder, and mix it with the ley as before. "Either way," says Mr. Park, "the colour is very beautiful, and equal to the best Indian or European blue." The use of indigo was known to the Mexicans before the arrival of the Spaniards, and Clavigero, in his history of that country, gives an account of the method of obtaining it. Hernandez had long before described the plant as being indigenous in Mexico, and employed by its ancient inhabitants; and Ferdinand Columbus, in his "Life of Christopher Columbus," mentions it as one of the native plants of Hispaniola. What the abbé Raynal therefore asserts, of its being transplanted from the East Indies to America, can be true only of one species, the *indigofera tinctoria*, Linn. The manufacture of indigo, however, was not established in America till some time after the discovery of that country; and on the plant which produces it being recognized by the Portuguese in Brazil as identical with that from which indigo was extracted in the East Indies. The use of indigo, which was a great acquisition to the art of dyeing, was not established without considerable difficulty. It was strictly prohibited in England in the reign of Elizabeth, as was also logwood, which was ordered to be burned if found in any manufactory. This prohibition was not taken off till the reign of Charles II.

In like manner the use of indigo was proscribed in Saxony, in the edict against it, which brings to one's mind the edict against the employment of antimonial emetics; it is spoken of as a highly corrosive colour. This is a striking example of the errors into which an unenlightened administration may fall, which listens to the suggestions of interested individuals. Those who dyed blue, and were accustomed to use pastel and woad, represented that indigo would destroy the sale of those two articles, which were the produce of the country. Such a reason, which would appear specious to many, even in the present day, easily produced a prohibition which would be soon eluded by paying a tribute to the industry of other nations. The prejudice against indigo was likewise communicated to France, and Colbert's instructions forbade the use of more than a certain quantity in the pastel vats.

Cochineal was another important acquisition to the art of dyeing, for which we are indebted to the first conquerors of Mexico. The Spaniards, having observed that the inhabitants of Mexico employed cochineal in painting their houses and dyeing their cotton, gave their government an account of the beauty of the colour; and Cortes, in the year 1523, was ordered to promote the increase of the valuable insect from which it is obtained. The natural colour, however, which the cochineal gives, is but a dull colour. Soon after cochineal was known in Europe, a great chemist of the name of Kuffer, Kuffler, or Kessler, found out the present process for dyeing scarlet by means of a solution of tin, and carried the secret to London in the year 1543. See COCHINEAL and SCARLET.

The ancients applied the name scarlet to the colour obtained from kermes, which was much inferior in beauty to the colour we distinguish by that appellation. We probably know how to employ the kermes to greater advantage than they did, since we possess a pure alum which disposes the stuff to receive a more beautiful and durable colour; yet our dyers have almost entirely discontinued the use of it, because they can obtain from cochineal a colour beyond all comparison more beautiful. The supposition, that the colour

colour which we obtain from kermes is preferable to that obtained by the ancients, is supported by the testimony of Pliny, who insinuates that it was not a durable colour; now the colour we give by means of kermes to wool prepared with alum, is exceedingly durable. The discovery of scarlet may be considered as the most important era in the art of dyeing, as it introduced to our knowledge the solution of tin, since for variously and happily applied. A Flemish painter, called Gluck, got possession of this secret, and communicated it to Gobelin. The knowledge of the process afterwards spread throughout all Europe. Gluck travelled into the East, where there were still some remains of Grecian industry, and afterwards settled in Flanders, where he spent a long and prosperous life. According to Mr. Francheville, this man, who had been so useful to his country, died about the year 1550.

For a long time Italy, and especially Venice, possessed the art of dyeing almost exclusively; a circumstance which contributed to the prosperity of their manufactures and commerce: by degrees it was introduced into France. Giles Gobelin, to whom the process for making the true scarlet had been communicated, established a manufactory in the place which still bears his name; and this undertaking was deemed so rash, that it was termed *Gobelin's folly*.

The attention of the Royal Society appears to have been early directed to the improvement of the art of dyeing. At a meeting of that learned body on the 30th of April, 1662, Mr. Hook was desired to translate into English, a work on dyeing, which appears to have been that already mentioned under the title of *Plütho*. On the same day also, sir William Petty, one of its earliest and most active members, in consequence of a previous request from the society, brought in "An Apparatus to the History of the common practices of Dyers," which was afterwards printed in "Dr. Spratt's History of the Royal Society," and seems to have been the first work published in the English language on the processes and operations of dyeing. Nearly two years afterwards Mr. Boyle presented to the society his "Experiments and Considerations touching Colours." And on the 10th of August, 1664, it was ordered by the society, "that the way of *fixing colours* should be recommended to Mr. Howard, Mr. Boyle, and Dr. Merritt." These, and especially the two first, were amongst the most distinguished members of the society; but it does not appear that any thing deserving of notice was done in consequence of this recommendation. However, at a meeting of the society on the 11th of November, 1669, that very ingenious and useful member, Mr. Hook, produced a piece of calico stained after the way contrived by himself, which he was desired to prosecute in other colours besides those that appeared in this piece; and accordingly on the 9th of the following month, Mr. Hook produced another specimen of staining with yellow, red, green, blue, and purple colours, which he said would endure washing with warm water and soap. But from this time it does not appear that any thing considerable was done for nearly the space of a century by men of science in this country towards the improvement of the arts of dyeing and calico printing.

In France, however, the minister Colbert, anxious to extend the commerce and manufactures of his country, which had languished during the stormy administrations of Richlieu and Mazarin, turned his attention particularly to the art of dyeing. He invited the most skilful artists, rewarded their talents, and established many manufactories; and it is curious to remark, that those of Vaurobais and Sedan were called, in the letters patent which were granted them, manufacturers of fine cloth after the Dutch and

English fashion. In 1672, he published a Table of Instructions for Dyeing, under the title of "General Instructions for dyeing Wool and woollen Manufactures of all Colours, and for the Culture of the Drugs or Ingredients employed in them." This, however, was not intended merely to diffuse information, but as a legislative act, to controul the dyers in their operations. This work merits attention; we shall first notice the reason which he gives for considering the subject as one of great importance.

"If," says Colbert, "the manufactures of silk, wool, and thread are to be reckoned amongst those which most contribute to the support of commerce, dyeing, which gives them that striking variety of colour by which they resemble what is most beautiful in nature, may be considered as the fruit of them, without which the body could scarcely exist. Wool and silk, the natural colour of which rather indicates the rudeness of former ages, than the genius and improvement of the present, would be in no great request if the art of dyeing did not furnish attractions which recommend them even to the most barbarous nations. All visible objects are distinguished and recommended by colours, but for the purposes of commerce it is not only necessary that they should be beautiful, but that they should be good, and that their duration should equal that of the materials they adorn."—But Colbert, though he instituted many useful regulations for the instruction of the farmer and the artist, imposed a system of prohibition and restraint so excessive, as almost to bar all future improvement. He divided the dyers into two classes, to one of which were confined the colours deemed durable and fixed, whilst the other class was allowed only to meddle with those which were considered fugitive. In the dyeing of black cloth he insisted that the operation should be begun by the dyers in grain, or those who gave the durable colour, and finished by those who produced the false one. Each was confined to a certain number of ingredients, and neither were suffered to have Brazil wood, and various other articles. The bad effects of this prohibition were moderated by the facility of eluding it, and by the rewards bestowed on those whose experiments promoted the progress of the art, and whose discoveries were afterwards to be published, and to modify the existing regulations.

French industry lost its pre-eminence by the criminal revocation of the edict of Nantz, which carried desolation into her manufactories, and dispersed her workmen, and the knowledge of her arts, throughout all Europe.

Since that time the department of administration, charged with the superintendance of the arts and manufactures, has constantly sought to repair those errors, and to encourage industry and exertion by the diffusion of knowledge, which, under wise laws, is the most efficacious means that can be employed.

Dufay, Hellot, Macquer, and Berthollet, have been successively charged with the care of improving the art of dyeing; and to their labours all Europe is indebted for most valuable acquisitions.

Dufay amended, or rather superseded, the "Instructions, &c." of Colbert, by the publication of a new one, under the administration of M. d'Orry, in 1739. He appears to have been the first who entertained just, though incomplete, ideas of the true nature of colouring substances, and the cause of their adhesion to stuffs when dyed. In his "Observations physiques sur le mélange de quelques couleurs dans le teinture," Mem. de l'Academ. 1737, he observes, that colouring particles are naturally disposed to adhere, more or less firmly, to the filaments which receive them; and he remarks very justly, that without this disposition

stuffs would never assume any colour but that of the bath, and would always divide the colouring particles equally with it; whereas the liquor of the bath sometimes becomes as limpid as water, giving out all the colouring matter to the stuff, "which seems to indicate," says he, "that the ingredients have less attraction for the water than for the particles of the wool." He also noticed, the difference in the degree of attraction which different substances, as wool and cotton, exert on the same colouring matters, and which he found so great, that a skin of each having been in an equal degree subjected to the operation for dyeing scarlet, the woollen yarn was found to be fully and permanently dyed, while the cotton retained all its former whiteness. Yet these facts, important as they were, to the foundation of a theory of the art of dyeing, were unproductive in his hands; for though satisfied with the explanation they offered of many phenomena, yet they left, says he, so much to be wished for, that he would relinquish it readily, if a more probable one could be found. He appears to have had no idea of the other and more important cause of the permanency of colours, that which arises from the use of mordants, or the interposition of a suitable basis, possessing a particular attraction both for the colouring matter and dyed substance, and acting as a bond of union between them. He examined, with great sagacity, certain processes, and established the surest methods that could at that time be employed for determining the goodness of a colour, and this he did in an easy and familiar manner. His labours, on the whole, entitle him to the gratitude of posterity, and he may justly lay claim to the merit of having first discovered and enunciated the facts, and of having drawn some partial conclusions from which the true theory of dyeing was some years afterwards clearly and luminously deduced.

He was succeeded by Hellot, to whom we are indebted for one of the best practical treatises on the art of dyeing wool and woollen cloths now extant. This work is valuable for the accuracy with which the numerous processes are described: without profiting however by the hints thrown out by his predecessors, he suffered himself to be misled by a vague and groundless hypothesis, on the cause of the adhesion of the colouring particles to the substance dyed, the action of mordants, and the difference between the true or durable, and false or fading dyes. Of his theoretical ideas, and the principles he laid down, some judgment may be formed from the following passage taken from his work. "I believe it may be laid down as a general principle in the art of which I am now treating, that all the invisible mechanism of dyeing consists in dilating the pores of the body to be dyed, in depositing in them particles of foreign matter, and retaining them there by a kind of covering not liable to be affected by water, rain, or the rays of the sun; in choosing colouring particles of such a degree of fineness as to be rendered sufficiently fixed in the pores of the stuff opened by the heat of boiling water, and again constricted by cold, and also coated by the kind of varnish which the salts, employed in its preparation, had left in those pores; whence it follows that the pores of the fibres of the wool which has been wrought, or is to be wrought into cloth, should be cleaned, enlarged, coated over, and then constricted, so that the colouring particles may be retained in them nearly in the same manner as the diamond is retained in the collet of a ring." He fancied that he could discern in every dyeing process some means by which sulphate of pot-ash, then called vitriolated tartar, might be formed; and this neutral salt not being readily soluble by cold water, nor air, nor light, he conceived the whole art of dyeing to consist in first dilating the pores of the substance

to be dyed, so as to procure a copious admission of colouring matter, divided by a suitable preparation into atoms, and then wedging or fastening these atoms within the pores of the dyed substance, by the small particles or crystals of this difficultly soluble salt. Upon this *mechanical* hypothesis, he supposed that alum became useful in dyeing, not by the pure clay or alumine which it contains, but by furnishing sulphuric or vitriolic acid, to assist in forming the sulphate of pot-ash, which was to perform the important function of wedging or fastening the colouring atoms. But though nothing could be more groundless than such a theory, the learned in all countries appear to have been satisfied with it for a considerable length of time, it being always less troublesome to believe than to make experiments.—Macquer followed next. He has given us an exact description of the processes employed in dyeing silk, and his practical treatise, published in 1763, is held in deserved estimation. He has made us acquainted with the combinations of the colouring principle of Prussian blue; he has endeavoured to make an application of it to the art of dyeing, and has given us a process for communicating the most brilliant colour to silk, by means of cochineal. Macquer intended to have published a general treatise on the art of dyeing, the prospectus of which he issued in the year 1781, but the indisposition which so long preceded his death, prevented his engaging in it, and he died in 1784, before he had been able to carry into effect any part of his plan. It is surprising that Macquer, who was an excellent chemist, and amongst the first who entertained correct ideas of the nature of chemical affinity should have been seduced by the hypothesis of Hellot. "I should now," says he in his treatise on dyeing silk, "explain the action of mordants, and unfold the causes of durable and fading dyes; but this subject has been treated with such sagacity by Mr. Hellot, that I shall refer the reader to him." Bergmann seems to have been the first who referred the phenomena of dyeing *entirely* to chemical principles. Having dyed some wool and silk in a dilute solution of indigo in sulphuric acid, he explains the effects he observed in the operation, by attributing them to the precipitation occasioned by the blue particles having a stronger attraction for the particles of the wool and silk than for those of the acidulated water: he remarks, that this attraction of the wool is so strong as to deprive the liquor entirely of the colouring particles, but that the weaker attraction of the silk can only diminish the proportion of those particles in the bath; and he shews that both the durability of the colour, and the degree of intensity it is capable of acquiring, depend on these different attractions. This is the true light in which the phenomena of dyeing, which are purely chemical, should be considered. Dufay had advanced thus far, but overlooked the importance of his own simple truths, in the search after more recondite and complicated causes. But the peculiar action of mordants was still unexplained, except on the wild hypothesis of Hellot, till our countryman Mr. Keir, the ingenious translator of Macquer's Chemical Dictionary, suggested, "that in dyeing, the earth of alum was precipitated, and in this form attached to the material prepared or dyed." Macquer soon after adopted the opinions of Bergmann and Keir, and in the second edition of his dictionary, under the article *Dyeing*, published in 1778, treated the subject in a more extended manner, and proved that he had formed just conceptions of the nature and uses of alum, and of different metallic solutions, as mordants in dyeing. Berthollet succeeded next to the place of truth which had been successively held by Dufay, Hellot, and Macquer, a post which he has held, and still holds, with distinguished honour to himself, and advantage

advantage to his country. In a series of memoirs, inserted in the Transactions of the academy, the *Annales de Chimie*, and *Journal de Physique*, he has examined various points of chemical theory connected with the art of dyeing, and almost all his labours have since been directed to this object. In 1791, he published his elements of the art of dyeing in 2 vols. 8vo. a work which has contributed more to the progress of true theory and the general improvement of the art, than any other treatise whatever. This work has been translated into English by Dr. Hamilton, and a second edition of the original, with considerable additions, appeared in 1803. Every thing which a liberal and enlightened government could do for the encouragement and progress of the art, has been done in France, and this solicitude has been crowned with the success it merited. Mr. Anderson attributes the superiority which certain articles of French manufacture maintain over those of other nations, who possess the most beautiful wool, to the perfection of their dyes; and Mr. Home is of opinion, that the French are indebted to the academy of sciences for their superiority in many of the arts, and especially that of dyeing. Perhaps another cause of the alleged superiority of the French over other nations in the art of dyeing, may be discovered in the peculiar nature of their manufactures. Silk, of all other substances, seems best adapted to the display of fine and brilliant dyes, and it constitutes, in all its various forms, a large portion of the manufactures of France. We may look, therefore, to the dye-houses of Lyons, as well as to the academy of sciences, for the cause of that superiority which is now gradually declining. We have already spoken of our countryman Mr. Keir, as the first who suggested the true theory of mordants, which was afterwards extended and improved by Macquer. The worthy president of the literary and philosophical society of Manchester, Mr. Henry, sometime after, read a paper to the society, since published in the 3d volume of their *Memoirs*, "On the nature of wool, silk, and cotton, as objects of the art of dyeing; on the various preparations and mordants requisite for these different substances, and on the nature and properties of colouring matter." This paper, which is replete with new and ingenious views of the nature and objects of dyeing, may be considered as amongst the first attempts in this country to reduce to system and theory the subject of which it treats: Mr. Henry, in these *Memoirs*, first pointed out the peculiar nature of the aluminous mordant of the calico printers; he shewed that by double decomposition an acetate of alumine was formed, and explained the cause of its superiority over the sulphate of alumine, which consists in the substitution of a volatile vegetable acid in lieu of the sulphuric.

In the year 1794, Dr. Bancroft published his "Experimental Researches concerning the philosophy of permanent colours, and the best means of producing them by dyeing, calico printing, &c." which may be considered as the first, and indeed only original work on the subject which this country has produced. This work, as the title indicates, is rather an experimental than practical treatise: it contains, however, much valuable information, which the practical dyer may apply in many cases with considerable advantage, and is also useful as containing a history of all the different substances of which it treats, and an account of the labours of Macquer, Dufay, Hellot, Berthollet, and others, in this field of science. It is to be regretted, that the work is still imperfect, the first volume only having yet appeared. The second, which was intended to comprehend all the remaining adjective colours and colouring matters, not treated of in the first, particularly those very interesting ones which

are derived from the tribe of madders, can hardly, after an interval of fifteen years, be looked for with confidence.

Dr. Bancroft first pointed out the true action of tartar in the process for dyeing scarlet, and clearly proved that the nitro-muriate of tin, or any solution of tin alone, produced a crimson only; and that the addition of tartar produced a scarlet, by the conversion of a portion of the crimson colouring matter of the cochineal, to a pure yellow. On this observation he founded an improvement in the scarlet dye, which consisted in communicating to the cloth, by means of quercitron bark, and any suitable mordant, such a shade of yellow as would produce, with the crimson of the cochineal, a true scarlet. By this process he expected to save all that cochineal which he conceived to be expended in the production of the yellow; the trials on the large scale, however, we are informed by Dr. Bancroft, did not justify the expectations he had formed, of the importance of the process.

A more important and lasting service, however, he has rendered to the art of dyeing, by the introduction of the quercitron bark, a drug which is now become of such general and acknowledged utility, as to supersede almost every other kind of yellow colouring matter whatever. For the history of this substance, and other particulars respecting its introduction, we must refer to the article itself, under the head *QUERCITRON BARK*.

Though we have to record no brilliant discoveries or improvements in the practice of dyeing, within these few years, yet the art has continued progressively to improve, the different processes have been simplified and amended; and what some years ago was considered a matter of chance and uncertainty, is now reduced to fixed principles.

The dyeing of Turkey red is now fully understood and practised in this country, with a success at least equal to that of any other. The process has, with some modifications, been applied lately to the dyeing of piece goods, and the red thus produced surpasses in beauty and durability, all other colours which it is possible to fix on cotton. But it is not our intention here to enter into a history of all the minor improvements that have been made in the art of dyeing; they will be treated of at large, during the progress of the work, under their respective heads.

DYEING, the Laws relating to, are as follow: Dyers shall dye both the cloth and the lilt, or forfeit it. 1 R. III. cap. 4. No dyer may dye any cloth with archil, or with brazil, to make a false colour in cloth or wool, &c. on pain of twenty shillings. Stat. 3 & 4 Edw. VI. cap. 2. Dyers are to fix a seal of lead to cloths, with the letter *M*, to shew that they are well maddered, &c. or forfeit three shillings and fourpence; and not to use logwood in dyeing on pain of forfeiting twenty pounds. Stat. 23 Eliz. cap. 9. And penalties are inflicted on dyers, who dye any cloths deceitfully, and not being dyed throughout with wood, indigo, and madder; also marks shall be put to the cloth dyed, &c. Dyers in London are subject to the inspection of the Dyers' company, who may appoint searchers; and out of their limits, justices of peace in sessions to appoint them: opposing the searchers incurs ten pounds penalty, by stat. 13 Geo. I. c. 24.

DYEING, in a more extensive sense, is applied to all kinds of colourings given to bodies of any sort.

In which sense, dyeing amounts to the same with *coloration*; and includes staining, painting, gilding, marbling, printing, &c. The Chinese are said to practice the dyeing of tea with catechu, which gives the worst sorts of green tea leaf the colour, and its infusion the tincture of bohea. Short. Dissert. on Tea, pref. p. 15. See *TEA* and *CATECHU*.

The forts of dyeing now commonly used in vulgar trades, are 1. Whitening of wax, and several forts of linen, and cotton cloths, by the sun, air, and reciprocal effusions of water. See BLEACHING. 2. Staining of wood and leather by lime, salt, and liquors, as in staves, canes, marble, leathers, marquetry, &c. 3. Marbling of paper by tempering the colours with ox-gall, and applying them upon a stiff-gummed liquor. See PAPER. 4. Colouring, or rather dicolouring silks, tiffanies, &c. by brimstone. 5. Colouring several iron and copper works into black with oil. 6. Giving leather a gold colour, or rather dyeing silver-leaves like gold, by varnishes; and in other cases by urine and sulphur. 7. Staining of marble and alabaſter, with heat, and coloured oils. 8. Tinging silver into braſs with brimstone or urine. 9. Colouring the barrels and locks of guns blue and purple with the temper of small-coal heat. 10. Colouring glaſs cryſtals, and earthen-ware with the ruſts and ſolutions of metals. See POTTERY, &c. 11. Colouring live hair, as in Poland, both horſe and man's hair; and alſo of furs. 12. Enamelling and annealing. See ENAMELLING. 13. Application of colours, as in the printing of books and pictures; and the making of playing cards, jappanning, &c. See PRINTING, CARDS, and JAPPANNING. 14. Gilding and tinning with mercury, block tin, and ſal ammoniac. See GILDING and TINNING. 15. Colouring metals, as copper with calamine into braſs, and with zinc or ſalt-petre into falſe gold, or into falſe ſilver with arsenic. See CALAMINE, BRASS, ZINC, ARSENIC, &c. 16. Making painters' colours, by preparing of earth, chalk, and ſlates, as in umber, oker, Cologn earth, &c. out of the calces of lead, as ceruſs and minium; by ſublimates of mercury and brimstone, as in vermilion; by tinging of white earths variously, as in verditer, and ſome of the lakes; by concrete juices or faeculae, as in indigo, pinks, ſap-green, and lakes: and by ruſts, as in verdigris, &c. See CERUSS, MINIUM, VERMILLION, INDIGO, &c. 17. The applying of theſe colours by the adheſion of ox-gall, as in the marbled paper aforeſaid; or by gum-water, as in limning: or clammy drying oils, as the oils of liſced, nuts, ſpike, turpentine, &c. See PAINTING, LIMNING, &c. 18. Watering of tabbies. See WATERING, CALENER, TABBIE, &c. Petty. Appar. Hiſt. of Dyeing, ap Sprat.

Glaſs dyed is the common matter of artificial jewels: the tinctures are given with zaſſer, manganese, ferretto, crocus martis, &c. The proceſſes are deſcribed at length in Antonio Neri, de Re Vitrariorum, lib. i. cap. 12, 13, 14, ſeq. See GLASS, GEN, &c.

The Peruvian women, when grown old, dye their grey hairs black by a very untoward operation, viz. holding the head ſome hours with the hair ſopped in a boiling tincture of the root of a tree called *cuchau*, by the Spaniards *maquey*.

DYEING of Hats, is done by boiling a hundred pounds of logwood, twelve pounds of gum, and ſix pounds of galls, in a proper quantity of water for ſome hours; after which about ſix pounds of verdigris, and ten pounds of green vitriol are added, and the liquor kept ſimmering, or of a heat a little below boiling. Ten or twelve dozen of hats are immediately put in, each on its block, and kept down by croſs bars for about an hour and an half; they are then taken out and aired, and the ſame number of others put in their room; the two ſets of hats are then dipped and aired alternately, eight times each; the liquor being reſreſhed each time with more of the ingredients, but in leſs quantity than at firſt. This proceſs affords a very good black on woollen and ſilk ſtuffs as well as on hats. Con. Phil. Tech. p. 428. See HAT.

DYEING, or ſtaining of wood, for inlaying, veneering, &c.

Red is done by boiling the wood in water and alum; then taking it out, adding brazil to the liquor; and giving the wood another boil in it. *Black*, by bruſhing it over with logwood boiled in vinegar, hot; then waſhing it over with a decoction of galls and copperas, till it be of the hue required. Any other colour may be given by ſqueezing out the moiſture of horſe-dung through a ſieve, mixing it with diſſolved roch alum, and gum-arabic; and to the whole adding green, blue, or any other colour deſigned. After ſtanding two or three days, pear-tree, or other wood, cut to the thickneſs of half a crown, is put into the liquor boiling hot, and ſuffered to remain till it be ſufficiently coloured. Park. Treat. of Japan. chap. xxvii. p. 82.

DYEING of bone, horn, or ivory. *Black* is performed by ſteeping braſs in aqua fortis till it be turned green: with this the bone, &c. is to be waſhed once or twice; and then put in a decoction of logwood and water, warm. *Green* is begun by boiling the bone, &c. in alum-water; then with verdigris, ſal ammoniac, and white wine vinegar; keeping it hot therein till ſufficiently green. *Red*, is begun by boiling it in alum-water, and finiſhed by decoction in a liquor compounded of quicklime ſteeped in rain-water, ſtrained, and to every pint an ounce of brazil wood added: the bone, &c. to be boiled therein till ſufficiently red. Other methods are given by Salmon. And from him by Houghton. Park. lib. cit. p. 83. Salm. Polygraph. lib. iii. cap. 35. p. 275. Hought. Collect. N^o 138. tom. i. p. 361. See BONES, HORN, IVORY, &c. The reſuſe of the Bow-dye, given to hogs to feed on, is ſaid to tinge their very bones red.

DYEING of Leather. See LEATHER.

DYEING of marble and ſtones. See STAINING.

DYEING of Thread. See THREAD.

DYER, SIR JAMES, in *Biography*, was born about the year 1511, and received his academical education at Oxford, whence he removed to the Middle Temple, with a view of ſtudying the law, where he diſtinguiſhed himſelf for his aſſiduity and talents. He acted ſome years as a barrifter, and, in 1552, he was, by the king's writ, called to the degree of a ſerjeant at law, and, in the ſame year, was elected ſpeaker of the houſe of commons. He roſe to the office of chief juſtice of the common pleas, an office which he held upwards of 20 years, with a high character for integrity and ability. He poſſeſſed a remarkably placid and even temper; and on the trial of Sir John Throckmorton, he ſcorned to take the ſame fort of liberties with the priſoner which were taken by the other counſel, Mr. ſerjeant Standford. He died in 1581, at his eſtate of Howton, in Huntingdonſhire, leaving behind him a "Book of Reports" in folio, containing caſes and deciſions occurring in the reigns of Henry VIII., Edward VI., Mary, and Elizabeth; this work is very highly eſteemed for its concifeſs and ſolidity, and has been ſeveral times reprinted. He was author of "A Reading upon Statute 32 Henry VIII., c. 11, of Wills, and upon two others for its Explanation." By the ſervices which he rendered his country, as well by his official duties as by his works, he obtained the reputation of being a moſt upright judge and excellent interpreter of the laws. Biog. Brit.

DYER, JOHN, was born in Carmarthenſhire in 1700, but was educated at Weſtmiſter ſchool. He was intended by his father, who was an eminent ſolicitor, for the ſame profeſſion as he had long followed himſelf; but the young man felt a repugnance to the law, and, on the death of his parent, determined upon painting as a profeſſion, and became a pupil to Mr. Richardson. In this he never greatly excelled, nor perhaps roſe higher than an itinerant artiſt. His mind ſeems to have been more inclined to poetry, and in 1727 he

made himself known by his "Grongar Hill," which became very popular, and has been admitted in many collections. After the publication of this piece Mr. Dyer travelled to Italy, by way of improvement as a landscape painter; but his acquirements in this journey were of more importance to him as a poet than a painter. In the year 1740, he displayed his taste, and the augmentation of his poetical images, by the publication entitled "The Ruins of Rome." "The title of this work," according to Dr. Johnson, "raises greater expectation than the performance gratifies." But a more candid critic says, "It contains many passages truly poetical, and the strain of moral and political reflection is that of a benevolent and enlightened mind." After this Mr. Dyer took orders, was married, and went to reside in Leicesterhire, where he had a small living; this he exchanged for one in Lincolnshire, to which another was soon added. The county, however, he soon found to be ill suited to his constitution, which had ever been delicate. In 1757 he published his "Fleece," a didactic poem, of which the theme is the care of sheep, the labours of the loom, and the arts of trade. The first part is pastoral, the second mechanical, and the third historical and geographical. The poem has been often published, and yet it has not been one of our popular poems; there are, notwithstanding, in it many pleasing, and some grand and truly impressive passages. Mr. Dyer did not survive this publication many months: he died in 1758, and, in the year 1761, his works were collected and published in one volume octavo. He lived highly respected, and at his death, left the reputation of a good poet, and the character of an honest, humane, and good man. Biog. Brit.

DYER'S *Black*. See BLACK.

DYER'S *Blue*. See BLUE.

DYER'S *Broom*, the name of a species of *Genista*; which see.

DYER'S *Green*. See GREEN.

DYER'S *Island*, in *Geography*, a small island of America, in Narragansett bay.

DYER'S *Weed*, in *Botany*, the luteola of Tournefort, and a species of the fescula in the Linnæan system. For the generic characters, see RESEDA.

It grows in most parts of the world. The Greeks, of old, used it in dyeing yellow, as we do at this time, and called it cymene, and sometimes thapsia, the word signifying, with them, several different things which had the property of dyeing yellow. It was called also by some rubia, or rubia; but those who gave it this name have always distinguished it by some peculiar epithet from the common rubia, or madder. Paulus Ægineta mentions it as an herb used in dyeing cloths; and Neophytus, and several others, give it a place among the things used to tinge the hair. See WELD.

DYER'S *Yellow*. See YELLOW.

DYHRENFURT, in *Geography*, a small town of the kingdom of Prussia, in the duchy of Silesia, on the river Oder, anciently called Prüg.

DYKE, in *Mineralogy*. This term seems to have originated among the colliers of the north of England and of Scotland, where it was and is still employed to denote those banks of basalt (locally named whin) by which the coal strata are frequently divided. The breadth of a dyke varies from a few feet to many yards, and its length and depth are generally of great but unknown extent: its direction is nearly vertical, forming with the plane of the strata that it passes through, an angle approaching, more or less, to 90 degrees.

By the Scottish mineralogists, the term dyke is employed as signifying a vein, composed of any compact earthy mineral; and in this sense is often made use of in the contro-

versial publications, wherein the Hutonian theory is attacked or defended. At present, however, the term seems, in a good measure, superseded by the more general one of vein.

DYKE, *Offa's*, or *Clawdh Offa*, a famous dyke, constructed by Offa the great king of Mercia, towards the close of the eighth century, about A. D. 780; and intended either to mark the boundaries between a colony of Saxons whom he planted in the level country between the Severn and the Wye, and the Welsh whom he had driven out of it, or to defend the former from the hostile incursions of the latter. This dyke extended from north to south, about 50 miles, running along the sides and bottoms of the hills, from the mouth of the river Dee to that of the Wye near Chepstow. It is thought to have been an imitation of the ramparts thrown up by Agricola, Adrian, and Severus, to guard the Roman province against the incursions of the northern barbarians; but from some remains of it, which are still to be seen, and for other reasons, lord Lyttelton (Hist. Hen. II. vol. ii.) concludes, that it was rather intended for a boundary, to separate the territories of the English from those of the Welsh, than to protect the former, as a fortification. Whatever the intent of so vast a work may have been, it was probably at this period, that the larger towns and cities, situated to the east of the Severn and Dee, were built, for the purpose of checking the irruptions of the Welsh by a strong line of frontier posts. The villages likewise, on the east side of Clawdh Offa, whose names terminate in *ton* or *ham*, were about this time inhabited by Saxons, who were usually called "Gwyr-y-Mars," or the men of Mercia; though in after-times the Welsh settled on each side of the dyke. During an interval of peace, Offa finished this dyke; but the Welsh were not insensible of the dishonour and injury done to their country. Accordingly they secretly concerted the plan of its destruction, and having settled a previous agreement with the kings of Northumberland, and of the South-Saxons, with whom they were then in alliance, they suddenly beset Clawdh Offa, in the night of St. Stephen's day, the night itself being extremely dark; and assisted also by the country people, they broke down the rampart, and in a short time, filled up and levelled the dyke to the length of a bow-shot. Early in the morning they assailed the camp of king Offa, and slew great numbers of his soldiers; who, depending on the time, were either asleep or unarmed, or had given themselves up to pleasure, or to the religious observance of the festival. The labour and charge of this dyke were much greater than the benefit; for soon after Offa's death, the Welsh again extended their dominions beyond that dyke, forcing their way, like a rapid torrent, which descends from the mountains, and overflows the plain country. We shall only add, that the limits of the Welsh from that time, were very uncertain; being often advanced, or set back, as the fortune of war happened to change, in favour of them or of the Saxons.

DYKE-REEVE, a bailiff, or officer, that has the care and oversight of the dykes and drains in deepening fens, &c. We find mention made of this officer ann. 16 & 17 Car. II. cap. 11. See. DIKE.

DYLE, in *Geography*, a river of France, which gives its name to the last of the thirteen departments of the first region of France, called the region of the countries added to France by the peace of Luneville (des pays réunis.) It has its source in a small spring near Marbaix, passes by Wavre, Louvain, and Malines. On coming from the latter, it takes up the Senne and the two Nethe near Rumpel, and flows not far from this place into the river Rupt. Formerly boats used to be towed on the Dyle from Wavre to Louvain. Merchant vessels, however, come up as far as Malines from the

the Scheldt, by means of the tides which flow regularly twice a day.

DYLE, *the department of the*, is the thirteenth department of the first region called a région des pays réunis in France. Brussels is its chief city. It is formed of part of the duchy of Brabant, and owes its name to the river Dyle, by which it is irrigated.

The limits of the department of the Dyle, are on the north, the department of the two Netes; on the east, the departments of the Lower Meuse and of the Ourthe; on the south, those of Sambre and Meuse and of Jemmapes; and on the west, that of the Escaut, (Scheldt.)

Its principal rivers are the Dyle, the Demer, and the Senne; it has also two fine canals, that of Louvain and that of Brussels. The soil is uncommonly rich and fertile. Agriculture in all its branches, grazing, the rearing of cattle, the business of the dairy, and horticulture, are extremely flourishing and well understood. The management of fœces, however, is rather neglected, but great attention is paid to bees. Mineral productions are scarce; there is a little iron. The quarries yield some very good white free-stones, and some blue, which are a kind of marble, besides grind-stones, and a sort of small granite, which makes good roads and keeps them in excellent repair.

There is hardly any manufacture but what flourishes in the department of the Dyle, and every one in the highest state of perfection. Its trade is in proportion to its abundance of raw and manufactured productions. Industry is every where exerted in the highest degree, of which it appears capable.

The most considerable towns, next to Brussels, are Louvain, Tirlemont, Nivelles, Dieff, Wavre, and Halle. The whole territorial extent of the department of the Dyle, is 3197 square kilometres and a half, or 671,746 arpens, 95,704 of which are covered with forests. The population amounts to 363,956 individuals, or about 1978 inhabitants upon a square league. Their average contribution to the expenses of the state is about 10s. *per head* annually. The department is divided into three districts, Brussels, Louvain, and Nivelles, 30 cantons, and 388 communes.

DYMA, or **DYME**, in *Ancient Geography*, a town of the Peloponnesus in Achaia, W. of Olene, and at the bottom of a small gulph, having to the north-west the promontory Araxum. This town was more anciently called Palea according to Pausanias, and Strabo says, that it was also called Stratos. Polybius, when he is stating the influence which the Lacedæmonians and the king of Macedonia had on the affairs of Greece, particularly after the death of Alexander, adds, that in the 124th olympiad, 284 B. C. Dyme and Patras, were two of the first cities which united to shake off the foreign yoke; afterwards, however, as we learn from Pausanias, it was the only city of those belonging to the Achæans, which took the part of Philip, son of Demetrius, when the Romans declared their opposition to him. This they honourably did by way of acknowledging the kindness of this prince for recovering and re-establishing in their city those of its inhabitants, whom the Romans had made prisoners. But Sulpicius, who commanded the Roman army, devoted this city to plunder after he had taken it. In the time of the piratical war, Pompey placed here a number of those pirates, of whom he had cleared the sea on the coast of Cilicia. Augustus subjected Dyme to the dominion of Patras; the vicinity of this city was famous for several engagements, and particularly for that which terminated in the entire defeat of the Achæans by the Lacedæmonians, under the conduct of Cleomenes in the year 227 B. C.

DYMA, or *Dyme*, a town of Thrace, seated on the eastern bank of the river Hebrus, at some distance from the sea; called by Ptolemy, and in the Itinerary of Antonine, *Dimi*.

DYNA, in *Commerce*, a kind of East Indian coin, worth about thirty shillings of English money.

DYNAMICS (from *δυναμις*, *power*) is the science of moving powers; or of the action of forces on solid bodies, when the result of that action is motion. *Mechanics*, in its most extensive meaning, is the science which treats of *quantity*, of *extension*, and of *motion*. Now that branch of it which considers the state of solids at rest, such as their equilibrium, their weight, their pressure, &c. is called *statics*; and that which treats of their motion, is called *dynamics*. When fluids are considered, instead of solids, then that branch of mechanics which treats of their equilibrium, weight, &c. is called *Hydrostatics*, and that which treats of their motion, is called *Hydrodynamics*.

An extensive and varied field of strict investigation, and of speculative discussion, falls under the denomination of dynamics. Various difficult questions are naturally connected with the more evident propositions respecting visible effects; and if instead of our remaining satisfied with facts, we endeavour to reason upon the nature of their primitive origin, the long and laborious investigation is seldom attended with any useful or satisfactory results. In our present statement of this science, we shall endeavour to explain the necessary definitions, so far as to render our meaning unequivocal in the following pages; and we shall arrange the general principles with as much additional illustration as the nature of the subject may seem to demand; but we shall avoid, as much as it may appear practicable, the discussion of abstruse and speculative particulars.

Matter denotes in general the substance of which bodies are formed. Thus a man, a stone, a tree, &c. are all formed of matter. But we do not mean to assert, that the matter which forms the man, the stone, the tree, or any other body, is, or is not, all originally of the same kind; for we are perfectly ignorant of its original nature.

Volume, *bulk*, or *magnitude*, denotes the size of a body with respect to the space it occupies. Thus the bulk of a full grown man is greater than that of a new-born child. The bulk of a ball of two inches in diameter, is eight times as great as that of a ball of one inch in diameter, and so forth.

Density means the proportional quantity of matter which is contained under a given extension; and we judge of this quantity of matter by its weight. Thus, a cubic inch of mercury weighs about $13\frac{1}{2}$ times as much as a cubic inch of water; therefore we say that the density of mercury is to the density of water as $13\frac{1}{2}$ to one.

Mass denotes, at the same time, the bulk and the density of a body, *viz.* the product of the bulk multiplied by the density. Thus, in the instance of the preceding paragraph, the mass of a cubic inch of mercury is to the mass of a cubic inch of water, as $13\frac{1}{2}$ to one; the mass of two cubic inches of mercury is double the mass of one cubic inch of the same fluid metal; but is equal to 27 times the mass of one cubic inch of water; for it is evident, that if one cubic inch of mercury contains $13\frac{1}{2}$ times as much weight as one cubic inch of water, two cubic inches of mercury must contain twice $13\frac{1}{2}$ times; or in general, that the mass is equal to the density multiplied by the bulk.

Motion is a continual and successive change of place. It is distinguished into *absolute* and *relative*, according as the motion is performed in absolute or in relative space. Thus, if a ship could remain immoveable in the universe, a man sitting in a part of it, would be absolutely at rest; but if the

ship

ship be in motion whilst the man continues sitting; then this man will be absolutely in motion with respect to the universe; but relatively at rest with respect to the parts of the ship. If you suppose, that the ship moves equally forward over a distance equal to its length, and that at the same time the man in his chair is drawn from the fore to the back part of the ship, with the same equable motion; then the man will be in motion relatively to the parts of the ship; yet he would remain in the same absolute place.

Equable motion is that which passes over equal portions of extension, or of space, in equal portions of time.

Accelerated, and retarded motion, is when equal portions of extension are passed over in portions of time either successively smaller or successively larger. Thus, if a body in motion passes over the first yard of extension in one hour, the second yard in 50 minutes, the third in 40 minutes, and so on; then its motion is said to be accelerated. But if a body passes over the first yard in one hour, the second in one hour and a quarter, the third in one hour and a half, &c. then its motion is said to be retarded.

Velocity is the ratio of the quantity of lineal extension that has been run over in a certain portion of time; or it is the ratio of the time that has been employed in moving along a determinate extension. For instance, if a body A has moved along an extension of ten miles in one hour, and another body B has moved along an extension of one mile in the same time, viz. in one hour; then the velocity of A is said to be to the velocity of B as ten to one. Also, if the body A has moved along the distance of one mile in four minutes, and the body B has moved along the same distance in two minutes, then the velocity of B is to the velocity of A, as two to one. When both the times and the spaces are unequal, then the velocity is equal to the quotient of the space divided by the time; it being evident, that if a body passes over two miles in one minute, or four miles in two minutes, or ten miles in five minutes, the velocity is constantly the same; and, therefore, in order to reduce these expressions to unity, we must divide the 4 miles by 2 minutes, or the 10 miles by 5 minutes, and the quotient is always the same, viz. 2; meaning two miles per minute. But if the body passes over the ten miles in two minutes, then the velocity, when reduced to unity by dividing the 10 miles by two minutes, is 5, meaning five miles per minute. Hence, universally, the velocity is represented by, or is equal to, the quotient of the space divided by the time. Thus, if a body A passes over four miles in 10 minutes, and another body B passes over 12 miles in 18 minutes; then the velocity of A is to the velocity of B, as $\frac{4}{10}$ to $\frac{12}{18}$; or as 0.4 to 0.666, &c. In this instance, we have taken a minute for the unit of time; but any other portion of time, such as an hour, or a second, &c. may be considered as the unit; but then in the same computation, the same portion of time must be constantly considered as the unit. In most mechanical computations, a second is usually taken for the unit.

A force is that which causes a change in the state of a body, be it of rest or of motion. Of the nature of forces we know nothing. Their effects alone come within our knowledge, and it is from the quantity of these effects, that we measure forces. Thus, if a body is set in motion by the action of a certain force, and is enabled by it to move with a certain velocity, and another equal body is set in motion by another force, which enables it to move with the double of the above-mentioned velocity; then we say, that the former force is to the latter as one to two; or that the latter is double the former.

Some authors are of opinion, that a quadruple force is required to produce a double velocity, and they alledge cer-

tain facts which seem to corroborate their opinion; but we shall in the sequel mention an argument which to us seems conclusive in favour of the above-mentioned statement. It is evident, that if the masses are unequal, and the velocities which have been produced by the action of certain forces, are equal, then the forces must be as the masses; consequently when both the masses and the velocities are unequal, then the forces are as the products of the masses multiplied by their respective velocities.

The *momentum, or quantity of motion*, is the force of a body in motion, and is equivalent to the impression which it would make on another body that should be placed at rest just before it. Therefore, according to the definition of forces, the momentum is equivalent to the product of the mass of the body multiplied by the velocity; hence forces are equivalent to, or are measured by, the momentum, or quantity of motion, they are capable of producing. From this statement then it follows, that if we put Q for the mass or quantity of matter, M for the momentum, and V for the velocity, the following proportions will stand good, viz. $Q \propto \frac{M}{V}$
 $M \propto Q V$, and $V \propto \frac{M}{Q}$, or in other words, the mass is as

the momentum divided by the velocity, the momentum is as the mass multiplied by the velocity, and the velocity is as the momentum divided by the mass.

Forces have been usually considered as being of two species, and these essentially different from each other. They have been called *pressures and impulses*. Whatever acts upon a body so as to put it in motion, and, by the continuance of the action, accelerates that motion, has been called a *pressure, or pressive force*; and the force of gravity, which, by constantly acting upon descending bodies continually accelerates their velocity, is of this kind.

An *impulse or impulsive force*, is that which acts instantaneously upon a body (according to our perception) and then leaves the body without any farther sollicitations; and such is the stroke of a hammer, or in general of one body striking against another body. Thus a ball in motion strikes against another ball at rest, and puts it in motion. The latter, having received the stroke, proceeds by itself, and its velocity will be uniform as long as it does not meet with obstructions.

The reasons which seem to prove that an impulsive force is infinitely greater than a pressure, or that the one is not capable of comparison with the other, are derived from the effects. For instance, a man with the moderate stroke of a hammer can drive a nail into a plank, when a weight of several hundreds gently laid upon the head of the nail will not produce the same effect. A pebble, likewise, which would support an immense weight, is easily broken by the stroke of another pebble, or of a hammer. This difference of effects has given rise to a variety of conjectures, of explanations, and of controversies, which towards the commencement of the last century filled up many volumes, and employed the thoughts of the most able philosophers and mathematicians. (See Reid's Essay on Quantity in the Phil. Transf. vol. xiv. and Dr. Irwin's inquiry into the measure of the force of bodies in motion, Phil. Transf. for 1745.) Yet upon a due examination of the facts, and of the reasonings which have been grounded upon those facts, it does not appear, that the gradual communication of motion by a pressure, and the instantaneous communication of it by an impulse, are clearly proved to be essentially different in their nature. Perhaps an impulse may be considered as a powerful pressure acting for a very short time, and a pressure may be considered as a weak impulse repeated at infinitely small portions of time. But let the real state of the case be as it may, we shall,

agreeably to our plan, omit any farther consideration respecting the nature of forces; acknowledging to notice merely their effects.

In the examination of these effects, it becomes necessary to state, to examine, and to explain the various motions that take place amongst the works both of nature and of art; the general laws to which they are reconcilable; the peculiarities by which they are discriminated from each other, and the consequence of which they are arranged under distinct denominations; and lastly, the application of the same to various useful purposes. The subject is vast and intricate; but since according to the nature of our work, every particular branch of motion must be explained under the article of its peculiar appellation; there remains very little more for us to arrange in the present article, than an enumeration of the various species of motion, a statement of their definitions, or of the peculiarities by which they are discriminated from each other, and that mutual dependence which evidently seems to regulate the whole doctrine of motion. We shall, at the same time, refer the reader to other articles for a more ample and satisfactory explanation respecting each particular kind of motion.

For the sake of perspicuity, the examination of the various movements of bodies, has been usually arranged under the following heads:

1. Uniform rectilinear motion, with what is commonly called the composition and resolution of forces.
2. Collision, both direct and oblique.
3. Motions arising from the actions of central forces.
4. Motions arising from the joint actions of a central and an impulsive force; viz. of a pressure and of an impulse.
5. Projectiles.
6. Descent of bodies along inclined planes.
7. Vibrations of pendulums.
8. Curve of swiftest descent.
9. Rotation of bodies about fixed axes.
10. Centres of oscillation, of percussion, of gyration, &c.
11. Movements of machines.

Each of these species of motion has certain peculiarities by which it is discriminated from the rest, or rather that render a separate examination of whatever belongs to it, more conducive to perspicuity. But there are certain rules, laws, or affections, which belong to them all, and which we shall now state. They are three in number, and are commonly known by the denomination of sir Isaac Newton's laws of motion.

First Law. Every body will remain either in a state of rest, or of uniform motion in a straight line; unless it be compelled to change that state by forces impressed.

Second Law. The change of motion is always proportionate to the moving force impressed, and is always made in the direction of the right line in which that force is impressed.

Third Law. Action and reaction are always equal and contrary to each other. Or the mutual actions of two bodies upon each other, are always equal and directed contrary ways.

These laws have been established by all the facts which have been hitherto observed, and by the strictest reasoning of the most enlightened philosophers. A careful examination of the particulars will easily manifest the evidence and the extent of these laws; which at first sight may perhaps not be easily comprehended. In order to assist the elucidation of the same, we shall add a short explanation of those parts at least, which are more likely to create any difficulty.

That a body at rest should continue in that situation, un-

less it be put in motion by some force or forces, no person will be inclined to deny, it being an idea naturally suggested by the result of common occurrences. But that a body once put in motion, and not afterwards driven by any other force, or opposed by any obstacle, should continue to move on in a straight line for ever after is not easily believed; considering that all the movements, however rapid, which fall under our observation on the surface of the earth, presently terminate in rest. This apparent difficulty, however, will be easily removed by considering that all the movements which fall under our observation near the surface of the earth, are performed under the influence of other force; the principal of which are the force of gravity, and the resistance of the air, in which the whole earth and all its separate bodies are involved; the former of which forces continually draws bodies towards the centre of the earth, whilst the latter obstructs all sorts of motion. So that a body set in motion by any impulsive force; for instance, a bullet thrown horizontally by the discharge of a gun, would continue to move uniformly in a straight line for ever after, were it not drawn downwards by the force of gravity, which, combined with the impulsive force, would oblige it to describe a particular curve, which is very nearly a parabola; but the resistance of the atmosphere, which continually obstructs it, forces it to describe another sort of curve, the nature of which is extremely intricate. Therefore it appears that the motion of the bullet, thus impelled by a gun, falls under the condition of the second part of the first law of motion; viz. it is compelled to change its state of uniform rectilinear motion, by the force of gravity, and by the pressure of an obstructing medium.

But notwithstanding these evident causes of deviation from the direction of the original impulse, it may still be supposed, that without them, the bullet would have continued its motion only some time longer; but that it would ultimately terminate in rest. The answer to this is, that as far as observations and calculations can reach, the deviation of the bullet from its original motion, or of any other body set in motion by an impulsive force, is always proportional to the obstructing cause, or causes; whence it necessarily follows, that when the obstructing cause vanishes, or becomes zero, the deviation of the original motion in the abovementioned cases must likewise vanish.

Several useful consequences are naturally deduced from the foregoing illustration. Thus, whenever we see a body in motion, we must conclude that it has been put in motion by an adequate force. If the direction, and the velocity of that motion be altered, we must conclude that its alteration has been occasioned by the action of other forces. If the movement continues without any visible alteration, or if its velocity be increased, we must suppose, that the body is continually urged by a pressing force; for otherwise it would not, even for a moment, remain uninterrupted in a resisting medium, and under the influence of other existing forces.

With respect to the second law of motion, it is only necessary to observe, that though it be expressed as if we were acquainted with the nature of the force which produces the change of motion; yet the real meaning is, that we only consider the changes of motion as the measures of the forces which occasion those changes; and we consider the direction of the change as the indication of the direction of the force.

The third law of motion, namely, that action and reaction are always equal and contrary to each other, will be easily assented to, if the least attention be paid to common occurrences. A weight fastened to a horse by means of a rope, and thus dragged over the ground, produces a resistance

which

which must be overcome by the superior power of the horse ; for the stone resists in a direction contrary to that of the horse. If a stone be thrown against a glass, or a glass be thrown against a stone, the stroke will be equally felt by both bodies ; yet the glass will be broken by it, and the stone will not, because the same stroke is sufficient to break the continuity of the former, and not of the latter. When a boat is moved by means of oars upon water, the action of one extremity of each oar against the water in one direction, re-acts upon the boat, and impels it in the opposite direction.

Thus much may be sufficient to illustrate the laws of motion for the present article ; but if farther explanation be required, see the article, MOTION, *Laws of*.

We shall now proceed to define, and to make some general observations on the different species of motion according to the enumeration stated above.

The simplest state of motion is that of a body actuated by a single impulsive force, and moving uniformly in a straight line. But such a case can exist only in our imagination ; for, as we have already remarked, all the movements which can come within our observation, are performed in resisting media, and within the influence of other forces ; yet it is from the consideration of such supposed simple case, that we can form useful theorems or useful deductions. We are also led to conclude, that the above-mentioned simple case would actually take place, if every obstructing medium, and every other interfering force could be removed, because we find, that, as far as calculation and experiments can assist us, the deviation of the body's uniform rectilinear motion is proportionate to those disturbing causes.

The particulars which may be remarked, with respect to the above-mentioned simple motion, are the relations of the time during which a certain linear extension is run through ; the extension itself when the time is given, which expresses the velocity ; the quantity of matter moved ; and the momentum. Those relations are easily obtained ; for, according to the definitions at the commencement of this article, the velocity is as the quantity of linear extension run through in a given time : for instance, in one second. Hence, of two bodies in motion, that which runs through a greater extension during a second of time is said to have the greater velocity. But if the extensions or spaces run through in different times be compared together ; then, in order to reduce them to one second, each of the spaces must be divided by the time in which it has been run through. For instance, if a body, A, has passed over ten feet in two seconds ; and another body, B, has passed over eighteen feet in three seconds ; and their velocities are to be compared together, I say, with respect to the body A, if, in two seconds, A has moved along ten feet, how much has it moved in one second ? thus, 2 : 10 :: 1 : where, in order to find the fourth proportional, I need only divide the 10 by 2, *viz.* the space by the time, and the quotient is 5. With respect to the second body, I say, by the very same way of reasoning, 3 : 18 :: 1 : and dividing the space by the time, *viz.* 18 by 3, the quotient is 6. Then the ratio of the velocities of A to B is that of 5 to 6. Therefore it appears that, universally, the velocity is as the space divided by the time : hence, putting V for the velocity, S for the space, and T for the time, we have $V \propto \frac{S}{T}$. Then, according to the usual statement of proportionable and variable quantities, it follows that S is as V T, and T is as $\frac{S}{V}$. Or, in words, the velocity is as the quotient of the space divided by the time ; the space is as the product of the velocity multiplied by the

time, and the time is as the quotient of the space divided by the velocity. The momentum, according to the explanation which has been annexed to the definition, is as the quantity of matter divided by the velocity. In this case of simple motion, there is an important observation to be made with respect to the origin of the motion, the use of which in mechanics is very extensive. What we allude to is, that a body, set in motion by two impulses at the same time, will likewise move uniformly in a straight line : therefore, when a body moves uniformly in a straight line, it may be supposed to have been actuated by one impulse, or by two in certain directions, which, as it will presently appear, may be varied indefinitely. This theorem is usually expressed in the following manner.

If a body be acted upon by two moving forces at the same time, so that each of those forces would by itself cause it to describe the side of a parallelogram, uniformly in a given time ; the body, in consequence of their joint actions, will describe the diagonal of that parallelogram uniformly in the same time.

Thus, suppose that the body A, Plate XXV. *Mechanics*, fig. 1, be impelled in the direction AD, by a force which would enable it to move at the rate of four feet *per second* ; also, that at the same time the same body be impelled by another force, in the direction AB, which would enable it to move at the rate of three feet *per second*. Make AD equal to four, and AB equal to three (inches or feet, or any other measure to represent feet). Through D draw DC parallel to AB, and through B draw BC parallel to AD, which will complete the parallelogram. Draw the diagonal AC ; and this diagonal will represent the direction and the velocity of the body, arising from the two impulses which have put it in motion ; so that at the end of one second, the body will be found at C.

That the body thus impelled by two forces must move along the diagonal AC, is easily deduced from the second law of motion : for, since the change of motion is proportionate to the moving force impressed, if from any point *c*, in the diagonal AC, you draw two right lines ; *viz.* *dc* parallel to AB, and *bc* parallel to AD, those two lines will represent the deviations of the body's motion from the directions AD and AB ; since, by the second law, the change of motion is made in the direction of the moving force impressed, and those two lines are proportional to the impelling forces, or to the lines AB and AD, which represent those forces. If it be said, that the body thus impelled will at any time be found at some other place *o*, out of the diagonal AC, draw *om* parallel to AD, and *od* parallel to AB ; then *om* and *od*, which represent the deviations, ought to be proportional to the forces which occasion those deviations, *viz.* to AD and AB. But this is not the case, because the parallelogram *Admo* is not similar to the parallelogram *ADBC*. Therefore it appears, that the body must move along the diagonal AC, and in no other direction.

This theorem is assented to, or is acknowledged by all the writers on mechanical philosophy ; and it is from this that we derive the argument mentioned above in our definition of a *force*. Thus, suppose that the two impulsive forces which put a body A, fig. 2, in motion are equal, and that their directions form a very small angle ; AD being the direction of the one, and AB the direction of the other. Complete the parallelogram, which, on account of the equality of the impulsive forces, is equilateral, and draw the diagonal AC. In consequence of the form of the parallelogram, it is evident that the diagonal AC is nearly equal to the sum of AD and DC, or of AD and AB ; *viz.* the velocity represented by AC is nearly double the velocity represented

represented by A D, or A B; that is, the velocity derived from the two impulses is nearly double the velocity derived by one of those impulses. Now if we suppose that the directions of the two forces come so near as to coincide, then the sides of the parallelogram will coincide with the diagonal A C; *viz.* the velocity represented by the diagonal will become exactly double the velocity represented by A D, or A B; and it evidently shews, that a double force produces a double velocity: for the two equal impulses joined together form a double impulsive force; and the velocity A C is double the velocity, which each of those impulses by itself would have generated.

In the above-mentioned case, the forces which would produce the movements along the sides of the parallelogram are called the *simple forces*, or the *confluent forces*; and their compound effect, which actually produces the movement along the diagonal of the parallelogram, is called the *compound force*, or the *resulting force*, or the *equivalent force*.

Now, as this compound effect is determined by finding the diagonal of a parallelogram, whose sides are the movements arising from the simple forces; so, when we have any uniform rectilinear movement of a body, we may consider it as the diagonal of any parallelogram, and may suppose it to be the compound course arising from two simple forces acting in the directions of the sides of that parallelogram. Thus, for instance, let a body A, *fig. 3*, move from A to B in a given time. We may suppose that the body has been impelled by a single force in the direction A B; or by two forces, one of which impelled it in the direction A E, and the other in the direction A F; or by two other forces, one of which impelled it in the direction A C, and the other in the direction A D; and so forth: for A B is the diagonal of the parallelogram A C B D, and of the parallelogram A E B F, and of an infinity of other parallelograms.

This mode of finding a compound course arising from more impulses than one, or of supposing that a given course is the result of more than one impulse, is called the *composition and resolution of forces*; and the application of it in mechanics is highly useful and extensive.

Besides the case of two forces, a compound course may arise from the joint actions of three, or four, or more simple forces; or it may be supposed to be the result of several simple forces. But the farther consideration of these more complicated cases, and their applications, &c. will be found under the article *Composition and Resolution of Forces*.

The next step which demands consideration in the movements of bodies, is the collision of those which happen to go against and strike each other. This is generally reduced to three cases; *viz.* the bodies may run in the same straight line, but in contrary directions; they may run in the same straight line, and in the same direction, but the preceding going at a slower rate, so that the subsequent may overtake it, and strike against it; or, lastly, the two bodies may strike against each other in oblique directions. The effects of those cases differ according as the bodies are elastic or non-elastic. See COLLISION.

The above-mentioned movements arise from the action of simple impulses, and the particulars which belong to them are easily determined; but those which arise from the actions of pressures, or of actions constantly acting are much more intricate. These are called *variable motions*. A body actuated by a single impulse will, according to the first law of motion, continue uniformly in the direction of that impulse; but if, whilst it is moving, another impulse acts upon it, then its motion will be altered; and if the direction of the second impulse coincide with that of the first, the velocity of the body will thereby be increased. If the direction of the se-

cond impulse be directly contrary to that of the former, then the first velocity will be checked; and, according to the ratio of the two velocities in opposite directions, the body may either proceed in its former direction, but at a slower rate; or, it may be entirely stopped; or, lastly, it may be obliged to go back with the excess of the second velocity above the first. If, instead of the two impulses acting in the same straight line, the direction of one of them be oblique to the other, then a compound motion arises, which must be determined according to the particular circumstances of the case. The body may also receive a third, a fourth, and many other subsequent impulses: these may succeed each other at equal or unequal intervals of time; and they may act either in the same, or in different directions; whence an indefinite variety of cases arises, which can by no means be comprehended under a few general propositions.

When a force acts continually and uniformly upon a body, it is the same thing as if equal impulses were repeated at equal and infinitely small intervals of time. In this case, the velocity of the body undergoes equal changes; and the force thus acting is called a *constant* or *uniform accelerating force*, or a *constant retarding force*, according as it tends to increase or to diminish the velocity of a body actually in motion.

The particulars which demand peculiar consideration, with respect to these forces, are the space described by the body thus set in motion, the time of description, the velocity acquired, the force which produces it, and the variations of those quantities, which arise from the difference of the forces, as well as of the masses upon which they act. The determination of these particulars (which will be necessary for the illustration of the following part of this article) has been carefully demonstrated by Mr. O. Gregory, in the following manner.

“Proposition. *The velocities generated in equal bodies by the action of constant forces, are in the compound ratio of the forces and times of acting.*”

“For, when the times are the same, the velocities generated each instant are as the forces of acceleration, and consequently the velocities generated at the end of equal times are as those forces; and if the forces are the same, the velocities generated are as the times wherein the forces act: because, when the force is given, equal velocities are generated in equal times, and consequently the whole velocities required are as the times wherein the given force acts; wherefore, both times and accelerating forces being different, the velocities generated will be as the forces and times of acting, jointly.”

“Cor. 1. *The momenta generated in unequal bodies are likewise conjointly as the forces and their times of action*—This is evident, because momenta in unequal bodies may be substituted for proportional velocities in equal bodies, throughout the whole reasoning.

“Cor. 2. *The momenta lost or destroyed in any times are likewise conjointly as the retarding forces and their times of action*.—For, whatever momenta any force generates in a given time would an equal force destroy in an equal time, by acting in a contrary direction.

“And the same is true of the increase or decrease of motion, by forces that either conspire with or oppose the motions of bodies.

“Cor. 3. *The velocities generated or destroyed in any times are directly as the forces and times, and reciprocally as the bodies or masses*.—For, since the compound ratios of the bodies and their velocities are as those of the forces and times, the velocities are as the forces and times divided by the bodies.

“Proposition. *In motions uniformly accelerated, when the force*

force and body are given, the space described during a certain time is the half of that which the body, moving uniformly, would describe in an equal time.

"Since the velocities are as the times of description, when the body and force are given, the velocities which a given body is found to have successively for the duration of each consecutive interval form an arithmetical progression, $g, 2g, 3g$, &c. of which the last term is gt , or v , the number of terms being t , that is to say, being marked by the number of solicitations of the accelerating force. And since each of the velocities is nothing else than the space which the body would describe uniformly during the corresponding interval, the total space described during the time t , will therefore be the sum of the terms of this arithmetical progression; which, because g and v are the extremes, and t the number of terms, will be expressed by $\frac{1}{2}t(g+v)$. Or, if s be the total space described by the body, then will $s = \frac{1}{2}t(g+v)$. Conceive now that the accelerating force acts (as by hyp.) without intermission, or, which comes to the same, imagine that the time t is divided into an indefinite number of infinitely small parts, or instants, and that at the beginning of each instant the accelerating force gives an impulsion to the body. Then g being infinitely minute in relation to v , which is the velocity acquired during the indefinite number of instants denoted by t , must be omitted in the equation $s = \frac{1}{2}t(g+v)$, which will become simply $s = \frac{1}{2}tv$, the space actually described.

"This granted, imagine that at the end of the time t the accelerating force ceases to act; then, by the first law, the body will reverse in its motion with the velocity v it has acquired; but in uniform motions, the spaces described are as the times and velocities jointly; therefore the body moving with the velocity v , during the time t , will describe a space $s' = tv$; which is evidently double the space $\frac{1}{2}tv$, described by the body in an equal time, by the constant action of the accelerating force.

"Proposition. The spaces described by a body uniformly accelerated are as the squares of the times.

"Since the velocities acquired increase as the time expired, if v be the velocity at the end of one second, then the velocity acquired after a number t of seconds will be ϕt : thus we have $v = \phi t$. The equation $s = \frac{1}{2}vt$, found in the preceding proposition, becomes therefore $s = \frac{1}{2}\phi t^2$. If, in like manner, we represent another space by S , which is described by uniform acceleration during the time T , we shall have $S = \frac{1}{2}\phi T^2$; hence we see, that $s : S :: \frac{1}{2}\phi t^2 : \frac{1}{2}\phi T^2 :: t^2 : T^2$.

"Cor. 1. Because the velocities acquired are as the times, we have also the spaces described as the squares of the velocities.

"Cor. 2. Therefore either the velocities or the times are as the square roots of the spaces described from the commencement of the motion.

"Cor. 3. All that has been shewn applies equally to motions uniformly retarded; provided that by the times, we mean those which are to elapse before the extinction of the velocity; and by the spaces, those which remain to be described until the body is brought to rest." See ACCELERATION.

Of forces acting irregularly, we shall not take any notice in this place; first, because they are not materially illustrative of the general theory; and, secondly, because they are very different from each other: whence they are better examined under other articles, to which they more particularly belong. The unbending of springs, the motion of a vessel upon water, when it first spreads its sails to the wind, &c. are instances of forces acting irregularly.

The principal accelerating forces, which occur in nature, are the central forces, viz. those attractive forces which are

directed to a centre. Thus, the force of gravity, which constantly draws bodies towards the centre of the earth, is of this nature. Such also is the force which retains the planets of our solar system within their orbits, and which is directed to a common centre, situated not much distant from the centre of the sun; and a similar force retains the satellites in due distances from their primary planets.

The great difference between the forces which produce motions uniformly varied, and the central forces, is that the former do not take place in nature, and the latter become more powerful nearer the centre of attraction, and less so farther from it. In short, their power generally is inversely, as the square of the distance from the centre of attraction. Yet we have above added the demonstration of the particulars belonging to the former, because they are more easily understood, and more easily, as well as safely, applied to the phenomena of the ascent and descent of bodies, and to other phenomena upon the surface of the earth, within the limits of our observation, as will be presently shewn. As for the particulars relative to the central forces, comprising their decrease and increase of power, according to the distances, &c. they will be found under the article CENTRAL FORCES.

The observations which shew, that the phenomena of ascending and descending bodies upon the surface of the earth, may be referred to the action of uniformly accelerating forces, are clearly expressed by Mr. O. Gregory in the following manner: "Gravity being that force which solicits all bodies to descend in vertical lines, or those which are perpendicular to the surface of the earth, it would follow that, if that surface, as composed of land and sea, were perfectly spherical, the directions of gravity would all concur at its centre. The earth, however, is not perfectly spherical; yet its variation from that shape is so trifling, that, with respect to the objects which fall under our observation, it need not be regarded. We have observed that the directions of gravity may be considered as parallel: that it may be seen to what extent this remark may be applied, let it be considered that a circle whose radius is 20,915,200 feet, will have more than 6000 feet for the measure of a minute of a degree, and upwards of 100 feet for that of a second; so that the directions of gravity at two places on the earth's surface, a mile asunder, will not vary one minute from parallelism."

"As to the magnitude of the gravitating force, strictly speaking, it is different at different distances from the equator, and at different distances from the centre of the earth; but the quantities of those differences, so far as they depend upon the variety of situation on the earth's surface, are very small, and need not yet be attended to; and the differences resulting from different distances from the centre of the earth, will not be sensible in any cases respecting the fall of bodies. Thus, if two bodies were situated, the one at the surface of the earth, and the other at a mile above it, the difference in the attractions to which they would be subjected, would be nearly one part in 2000 of the whole attraction; so that as a mile is greater than any altitude, or any depth from the surface, with regard to which we shall have to trace the effects of falling or rising bodies, we may consider the force of gravity as constant. We consider, therefore, this force as acting incessantly, and acting equally at each instant upon every particle of matter. Now it is clear, that if every particle of a body receive the same velocity, the aggregate of the body will move with the same velocity as would have been impressed upon a single molecule: consequently, the velocity which gravity impresses upon any mass whatever, does not depend upon the magnitude of that mass; but it is the same with respect to the smallest mass

mass as the greatest. It is true, we do not, when bodies of different masses and densities descend through the air, observe them all to fall from the same heights in equal times; but this is occasioned by the resistance of the medium, and when that is taken away, as in the receiver of an air-pump, the most dense and the most rare bodies fall through equal spaces in equal times."

It is therefore evident, that the particulars which have been demonstrated above relative to the effects of forces acting uniformly, may be safely applied to the ascent and descent of bodies near the surface of the earth. According to those particulars, when bodies simply fall from a state of rest, the velocities acquired are as the times; and the whole spaces described will be as the squares of the times. Thus if the times be as the numbers

	1,	2,	3,	4,	5,	6,	&c.
The velocities acquired will be,	2,	4,	6,	8,	10,	12,	&c.
The whole spaces, as	1,	4,	9,	16,	25,	36,	&c.
The space for each time, as	1,	3,	5,	7,	9,	11,	&c.
Their constant differences	2,	2,	2,	2,	2,	2,	&c.

Now it has been found by means of accurate experiments, that a heavy body in the latitude of London falls nearly $16\frac{1}{2}$ feet in the first second of time from its quiescent state, and has then acquired a velocity which, if uniformly continued, would carry it over twice $16\frac{1}{2}$, or, $32\frac{1}{2}$ feet, in the next second; but the action of gravity upon the body continuing, the motion will be such that at the end of the next second of time, the body will altogether have passed over 2^2 , or four times $16\frac{1}{2}$, viz. $64\frac{1}{2}$ feet, and will have acquired a velocity of twice $32\frac{1}{2}$ feet per second, and so forth.

From these data, and the particulars demonstrated above, we have the following real spaces, velocities, &c. described by bodies falling from a state of quiescence near London.

If the times, in seconds, be	1,	2,	3,	4,	&c.
The velocities acquired in feet will be	32 $\frac{1}{2}$	64 $\frac{1}{2}$	96 $\frac{1}{2}$	128 $\frac{1}{2}$,	&c.
The spaces in the whole times	16 $\frac{1}{2}$	64 $\frac{1}{2}$	144 $\frac{3}{4}$	257 $\frac{1}{2}$,	&c.
The spaces for each second	16 $\frac{1}{2}$	48 $\frac{1}{4}$	80 $\frac{1}{2}$	112 $\frac{3}{4}$,	&c.

These particulars, however, are such as would take place in vacuo; but in the air, the results are considerably different; that difference evidently arising from the resistance of that medium. The differences which have been observed between the theoretical calculations, and the results of actual experiments, may be seen under the article DESCENT of Bodies.

It has been shewn above, that in the case of simple impulses, when a body receives two impulses at the same time, but in directions oblique to each other, the body will thereby be obliged to move with an equable motion along the diagonal of a parallelogram, whose sides are the directions of the two impulses. But when one of the forces which impell a body is a simple impulse, and the other is a continued pressure, or a force uniformly accelerating, then the body is obliged to move with a changeable velocity, in a curve line; the nature of which differs according to the nature of the acting forces. A bullet fired horizontally out of a gun is an instance of this case; for, the force of the gun-powder impels it horizontally, and the force of gravity draws it downwards with an accelerating velocity; therefore the bullet moves in a curve, which, were it not for the resistance of the air, would be nearly a parabola, as the great Galileo first demonstrated.

Any other body projected in any other direction, does likewise move in a curve of a similar nature; excepting indeed when it is projected either perpendicularly upwards, or perpendicularly downwards; for in either of those cases the body will evidently move in the perpendicular line, though not with a uniform velocity.

Let a body A, fig. 4, be impelled from A towards H, with such a force as would enable it to move along the equal spaces A B, B F, F G, &c. in equal portions of time; for instance, each of those spaces in a second of time. Let at the same time an accelerative force continually draw the same body A towards the centre C, in such a manner as by itself would enable it to descend along the unequal spaces A I, I K, K L, in equal portions of time, viz. each space in a second. Then, in consequence of the actions of both those forces, the body A will be obliged to move along the curvilinear path A N O P, &c. Through B, draw B C in the direction of the centre of attraction; and through I draw I N parallel to A B. Then it is evident that at the end of the first second of time the body will be at N. Now if at this period the attractive force ceased to act, the body would proceed in the direction N R, by the first law of motion. But since the attractive force continues to act, the body at the end of the second second of time will be at O, for the same reason as above: at the end of the third second, it will be at P, and so forth. The course then, A N O P, is not straight, but consists of the lines A N, N O, O P, &c. forming certain angles.

If instead of finding the place of the body A at the end of every second, we had determined it for each thousandth part of a second, then each of the lines A N, N O, &c. would have been resolved into a thousand small lines inclined to each other. But since the attractive force acts constant y and unremittedly, therefore the path of the body A is not a polygonal course consisting of an infinite number of sides; but a continued curve which passes through the points A, N, O, P, &c. as is indicated by the dotted line.

Upon these principles the movements of projectiles in military affairs are calculated, and are determined within a useful difference from the truth; for the variable obstruction of the air, and other interfering circumstances, prevent any very accurate determination of those particulars. See the article PROJECTILES.

In the above instance of the two forces of different kinds acting upon the same body, we supposed that the attractive force was sufficient to draw the body towards the centre of attraction. But if it be supposed that the equable motion arising from the simple impulse be so great in proportion to the attractive force, that the latter, though capable of drawing the body from its rectilinear course, is, however, not able to bring it nearer to the centre of attraction, than a certain limited distance; in that case the consequence will be, that the body will continue to move in a curvilinear path round and round the centre of attraction, without actually coming to it. Now this sort of motion is called an *orbital motion*; or that curve path is called an *orbit*; and such are the motions of the planets in orbits round the common centre of attraction in our solar system. See the article ORBITS.

The descent of bodies arising from the force of gravity is, in many cases, modified by certain circumstances, which frequently and necessarily occur, and on which account they are in need of examination. Thus the descent of bodies upon inclined planes is one of those cases; for instead of descending in a straight line perpendicular to the surface of the earth, the body is obliged to roll along the surface of the plane in an oblique direction. The vibrations of pendulums are likewise of this kind, and so on. The principal of those cases will be mentioned in the sequel.

When a body is placed upon an inclined plane, the gravitating power which draws that body downwards, acts with a force so much less than if the body descended freely and perpendicularly, as the elevation of the plane is less than its length.

If a body be placed upon an horizontal plane, the

force of gravity acting in a direction perpendicular to that plane, cannot draw the body one way more than another, therefore the body remains motionless; but if the plane be inclined, then the body will run down along the surface of it, and with greater velocity, in proportion as one end of the plane is more elevated above the horizon. When a plane is inclined to the horizon, and a body is laid upon it, the action of gravity is not entirely, but partially counteracted by the plane. From the centre *A* of the body, which is laid upon the inclined plane, *fig. 5*, draw *AG* perpendicular to the horizon, and *AF* perpendicular to the plane. Then the whole force of gravity, which is represented by the line *AE*, is resolved into the two forces, *AF*, and *EF*, whereof *AF* being perpendicular to the plane, is that part of the gravitating power which is lost, or which is counteracted by the inclined plane; and *EF* represents the other part of the gravitating power, which urges the body downwards along the surface of the plane. Therefore the force of gravity is diminished, in the proportion of *AE* to *EF*. But the triangles *A EF*, *EDG*, and *BDC*, are equiangular, consequently similar: therefore *AE* is to *EF*, as *DB* to *BC*; that is, the whole force of gravity is to that part of it which urges the body downwards along the surface of the plane, as the length of the plane is to its elevation.

The extension, which is described by a body descending freely from rest towards the earth, is to the extension which it will describe upon the surface of an inclined plane in the same time, as the length of the plane is to its elevation.

The gravitating force which draws a body downwards along an inclined plane, is only diminished by the intervention of the plane; but its nature is not otherwise altered, so that it still acts constantly; in consequence of which the motion of the body is continually accelerated, and the spaces it describes are also proportional to the squares of the times; but these spaces are shorter than if the body descended freely and perpendicularly; viz. they are to the latter as the elevation of the plane is to its length.

A body descending from a certain height to the same horizontal line, will acquire the same velocity, whether the descent be made perpendicularly, or obliquely, over an inclined plane, or over many successive inclined planes, or, lastly, over a curve surface.

It has been shewn above, that the velocity of a body descending freely in consequence of a constantly acting force, is as the product of the force multiplied by the time; and we have just shewn, that, upon an inclined plane, the force of gravity is diminished in proportion of the elevation of the plane to its length; whence it evidently follows, that the time of the body's running down an inclined plane must be increased in the inverse proportion; viz. that as the force is diminished, so the body is drawn downwards in longer time; that is, less forcibly.

Now, if the times increase in proportion as the force decreases, it evidently follows, that the product of the time by the force is always the same; viz. the velocity which a body acquires by falling from a given height is always the same, whether it falls perpendicularly, or along any inclined plane. And it is evident, that the effect must be the same when the body falls from the same height along a succession of inclined planes, or along a curve; for the whole height may be divided in parts each equal to the altitude of one of the inclined planes, and the same thing may be shewn at the end of each. And as a curve line may be conceived to consist of an infinite succession of inclined planes, the application to it needs no further illustration.

In the preceding explanation of the motion of a body upon an inclined plane, we have supposed the bodies, to be spherical, and the planes, as well as the bodies, to be per-

fectly smooth. But in practice this is not to be expected; for the smoothest bodies, in moving over one another, are, in some measure, affected by friction. The air, likewise, opposes its usual resistance, &c., in consequence of which, the motions of bodies, upon inclined planes, will be found in practice to differ considerably from the results of theoretical calculations. For farther particulars respecting this subject, see the article INCLINED PLANE.

Treating of the descent of bodies, we shall here barely mention a remarkable property of a curve, which, at first sight, can hardly be believed; for it shews that a body, descending from a superior to an inferior place, not in the same perpendicular, will arrive at the lower place sooner by going along a certain curvilinear path, than along a straight one. In short, if two points be given in a vertical plane, but not in the same line perpendicular to the horizon, a body will descend from the upper point of the lower in the shortest time possible, if it be caused to move along the arch of a cycloid, which passes through those points, and whose base is an horizontal line that passes through the upper point.

On this account, the cycloid has been called the line of swiftest descent. See CYCLOID.

When a body is suspended by a flexible string, or by a pin, which passes through a hole in it, and is fixed to a steady support; or, in short, whenever a body hangs down from any point, so as to be capable of swinging about that point, it is called a pendulum, or pendulous body; and as pendulums are of a most extensive use in mechanics, their properties have been investigated with great attention, both theoretically and experimentally. In the examination of the chief properties of the pendulum, which will now be stated, we must suppose the pendulum to consist of a globular body, fastened to the end of a string, the other end of which is fixed to a pin; the string is supposed to have no weight, and to be perfectly flexible, so that the pendulum may move with perfect freedom about the point of suspension. In its natural situation, such a pendulum hangs straight downwards, in the direction of the centre of the earth; but if it be moved out of that direction, and be then let go, it will begin to swing, going backwards and forwards, and will continue that motion for a considerable time. Each of these motions, from one side to the other, is called a vibration, or an oscillation; and the particulars which become the objects of examination in pendulums, are the times in which the vibrations are performed under given lengths of pendulums, the velocities, which the pendulum alternately acquires and loses in the course of vibration, the momenta, &c. The propositions which follow will be sufficient to shew the connection between the vibrations of pendulums, and the other kinds of motion which are considered in dynamics. But farther particulars must be sought for under the article PENDULUM.

If a pendulum be moved out of its perpendicular direction C B, fig. 6, to the situation C A, and there be let go, it will, of itself, descend towards the perpendicular C B; then it will ascend on the opposite side to C D, nearly as far from the perpendicular, as the place from which it began to descend; after which it will again descend towards the perpendicular, and thus it will keep moving forwards and backwards for a considerable time; making the vibrations continually smaller and smaller until it stops; which is owing to the obstruction of the air, and a little stiffness of the pendulum-string; for, without these obstructions, the pendulum would continue to perform vibrations of the same length for ever after.

The body *A* will descend along the arc *AB* with an accelerated motion, in the same manner as if it descended over a curve surface *AB*; for it is evidently the same thing whether a body descends along such a surface, or is confined by the string *CA*, so as to describe the same curve. By the

the time the body A arrives at the lowest point B, it will acquire the same velocity as if it had descended perpendicularly from E to B. (from what has been said respecting inclined planes.) This velocity (abstracting the resistance of the air, &c.) would carry the body A beyond the point B, with a retarded motion, in an equal portion of time, as far from B as A is from it. The body A will then descend again, with an accelerated motion, towards B, and so on. For, since the velocity of the pendulum in its ascent is retarded by the same uniformly acting power, which accelerates it in its descent; *viz.* by the force of gravity; there must be the same time employed in destroying, as in generating it.

That, *ceteris paribus*, the weight of the pendulum cannot alter its time of vibration, may be easily derived from what has been said above, respecting the fall of bodies; *viz.* that, abstracting the resistance of the air, all kinds of bodies will fall from a state of quiescence, through a given extension, in the very same time.

The velocity of a pendulum, in its lowest point, is as the chord of the arc which it has described in its descent.

Thus, the body A, descending from A to B, will, when at B, have acquired a velocity which is proportionate to the chord of the arc A B, or to E B.

In estimating the length of a pendulum, a peculiar circumstance occurs, which is not obviously perceived, and the determination of which demands peculiar attention. When the pendulum consists of a spherical body, fastened to a string, a person unacquainted with the subject might, at first sight, imagine, that the length of the pendulum must be reckoned from the point of suspension, to the centre of the ball. But this is not the case; for the real length of the pendulum is greater than that distance, the reason of which is, that the spherical body does not move in a straight line, but it moves in a circular arc; in consequence of which, that half of it which is farthest from the point of suspension, runs through a longer space, than the other half which is nearer to the point of suspension; hence, the two halves of the ball, though containing equal quantities of matter, move with different velocities, and, therefore, their momenta are not equal. Now, it is, in consequence of this inequality, that the *centre of oscillation* (for so is the point denominated from which the length of the pendulum to the point of suspension must be reckoned,) does not lie between the two hemispheres; *viz.* in the centre of the ball; but it lies within the lower hemisphere, which has the greatest momentum. It evidently follows, that if the ball of the pendulum could be concentrated in one point, that point would be the centre of oscillation; so that the centre of oscillation is that point wherein all the matter of the body, or bodies, that may be joined together to form a pendulum, may be conceived to be condensed. The method of determining the situation of the centre of oscillation in any pendulum, will be found under the article *CENTER of Oscillation*. See also *OSCILLATION*.

In a pendulum thus vibrating about a point of suspension as has been mentioned above, whether it be a body fastened to a string, or an oblong solid like a rod, &c. the same point of oscillation is likewise called the *centre of percussion*; for this reason, that if a body be opposed to the pendulum whilst vibrating, at that point, it will receive the greatest stroke possible. And if the obstacle be opposed to any other part of the pendulous body, the stroke will be less powerful. This point does not coincide with the centre of gravity, as one might at first sight be easily induced to believe; nor does it coincide with the centre of oscillation in all cases. In short, the centre of percussion cannot be said to be the same thing as the centre of oscillation; but is that

point in a body revolving about an axis, at which, if it struck an immovable obstacle, all its motion would be destroyed, or it would not incline either way: so that if at the instant of the impact the supports of the axis were annihilated, the body would remain in absolute rest. The method of determining the situation of the centre of percussion in all cases, will be found under the article *CENTER of Percussion*. See also *PERCUSSION*.

During the preceding illustration of the various species of motion, whether uniform, accelerated, or retarded, and whether rectilinear or curvilinear, the impelling force has been generally considered as if it acted in the direction of the centre of gravity of the body; so that every part of the body might acquire the same velocity; or as if the whole body were concentrated in a single point. But in a great many instances the application of one or more forces is made out of the line which passes through the centre of gravity of the body, or of a system of bodies; in consequence of which that body, or that system, acquires a rotatory motion.

According to the various forms of bodies either single or in connection, and according to the various applications of a force or forces in different parts, a vast variety of cases of this rotatory motion may be easily conceived; and the principal of these cases will be found described in the present work according to the references that follow. In these cases of rotatory motion, the particulars which are principally deserving of mathematical investigation, are the following two points or centres, which we shall barely define in this place.

The centre of gyration, which is that point in a body, or system of bodies, in which, if all their matter were condensed, the same angular velocity would be generated in a given time, that would be generated in the whole body or system, by the same force similarly applied. See *CENTER of Gyration* and *GYRATION*; and

The centre of spontaneous gyration, or of *spontaneous rotation*, which is that point about which a body begins to revolve at the instant in which it is struck by a force acting out of the direction of its centre of gravity. Place a stick upon a smooth horizontal table, with one extremity out of the table. Strike that end in an horizontal direction, and immediately after the stroke, the above-mentioned extremity of the stick will begin to move in the direction of the stroke, whilst its other extremity moves in the contrary direction. Now it is evident, that between those two parts of the stick there must be a point about which those parts begin to revolve; and that is the centre of spontaneous rotation. See *CENTER of Rotation* and *Spontaneous ROTATION*, or *Spontaneous GYRATION*.

The various movements that are produced by the action of forces differently applied, in the endless variety of direction, of combination, of duration, and of power; can only be examined by reducing them into classes, according to the peculiarities which a certain number of them seem to have in common. In this manner we have, in the preceding pages, taken a general view of the whole, and have explained the principal properties of each kind of motion, so far as it seemed necessary to point out their extent and their general connection. But the reader has at the same time been referred to other articles for more ample and more satisfactory information. The only part of the subject which remains to be added for the completion of this article, is the application of the subject to useful purposes; with this view, therefore, we shall now add such general remarks as may suffice to manifest the vast importance of the general application.

Two very remarkable and very extensive objects are answered by the subject of dynamics. It enables the human being to comprehend and to explain the phenomena of
nature,

nature, and it furnishes him with useful machines, by the use of which he becomes capable of accomplishing such wonderful effects, as would otherwise be utterly out of his power.

Sir I. Newton first conceived the grand idea of a general connection between the bodies of the universe. He thought that the celestial objects were actuated and connected by a general and mutual gravitation. Willing to prove the truth of the supposition, he first endeavoured to investigate the laws of such forces, or gravitating powers. One truth naturally developed another truth, until an ample demonstrative theory was formed. His next step was to examine how far the astronomical observations were conformable to that theory; and he was delighted to find an admirable coincidence, which confirmed the truth of the supposition. Subsequent mathematical improvements, farther discoveries, and much more accurate observations, have rapidly advanced the whole subject, so much so, that the present generation is thereby enabled to calculate and to foretell the nicest, astronomical phenomenon; whence immense advantages are derived, especially in navigation.

With respect to mechanical application, the reader may be pleased to consider how limited is the power of the bare limbs of a man; how great are the powers of the natural world; and what astonishing effects the human being can accomplish by employing those natural powers in a proper way. The immense force of the wind regularly applied, gives motion to powerful mills, and to other machinery; it drives very large and heavy vessels across the sea, &c. A stream of water is likewise applied to diverse useful purposes, many of which are so common as to be known to every body. So is the force of steam; the expansive force of gun-powder; the strength of animals; and so forth.

The use of machines, then, is for the purpose of applying natural powers to our advantage, or to perform that which the bare application of those powers could not possibly accomplish. A man, for instance, wishes to remove a stone of a ton weight from any particular place; his strength, unassisted by art, is inadequate to the purpose; but he takes a pole, or lever, which being applied in a proper manner, actually enables him to remove the stone. The vibrations of a pendulum are performed nearly in equal portions of time; therefore, by setting a pendulum in motion, and counting the vibrations, a man might measure time; but the motion of the pendulum requires to be renewed at times, and the counting of the vibrations requires a constant attendance, the performance of which would be an insufferable hardship. But all this hardship is removed by the contrivance of a clock, to which a man applies his power all at once, by raising a weight, or winding up a spring; then the power thus imparted to the spring, or weight, is gradually communicated to the pendulum, so as to keep it in motion during a day, a week, a month, and even a longer time. The other parts of the mechanism serve to reckon and to indicate the number of vibrations, under the denominations of seconds, minutes, and hours.

The number of machines that have been invented, that have been used, and that are actually in use, is really immense, and new ones are daily constructed. But all those machines consist of certain parts or simple mechanisms variously combined and connected with each other. Those simple mechanisms are commonly called the *mechanical powers*, and their number is not above six or seven. They are the *lever*, the *wheel and axle*, the *pulley*, or *system of pulleys*, the *inclined plane*, the *wedge*, and the *crew*.

Several writers on mechanics reckon the balance amongst the mechanical powers; but other authors do not; for in

fact, there is no power gained by the use of the balance; and this gain of power undoubtedly is the characteristic property of the mechanical powers. There are some who exclude the inclined plane from the number of mechanical powers; whilst others consider it as one of the principal, and reckon the wedge and the screw as only species of it.

In each of those simple mechanisms, a force or power is applied at one end, in order to overcome a resistance at the other end. Thus with a lever, a man thrusts the end of a pole under the weight B, *fig. 7*, rests part of the pole, or lever, upon a firm obstacle, or prop, or fulcrum C, and applies his hand to the other end A of the lever. Then by lowering the end A of the lever, the weight will be raised, (supposing that the power of the man and the weight of B are not too disproportionate.) Now in this case the man's hand is the force or moving power, the weight B is the resistance which is to be overcome, and the pole is the lever, or the mechanical power, by which the man is enabled to raise the weight; which effect he could not have produced by the immediate application of his natural strength.

Instead of applying a man's strength to the end A of the lever, a weight may be applied to the same end, which, by a proper adjustment of the lever, may be made to raise the weight B much greater than itself.

If it be asked how it happens, that a small weight at A can lift up a much larger weight at B; the answer is, that by the motion of the lever the weight at A, which acts as the force or power, describes a much larger space than the weight B; and there is this general principle which holds good in all the mechanical powers, and which is demonstrated under the article *Mechanical Powers*; namely, that as long as the product of the weight at A, multiplied by the space through which it moves, exceeds the product of B multiplied by the space through which it moves; A will preponderate, and of course will lift up B. Suppose, for instance, that the weight at A be equal to 40 pounds, the weight B 300 pounds, the length AC twelve feet, and CB one foot. Then, since the arcs which the two extremities of the lever and the two weights describe, are as the distances AC and BC; multiply the weight A, *viz.* 40 pounds, by 12, which is the distance AC, and the product is 480; and multiply the weight B of 300 pounds by the distance BC of one foot, and the product is 300. Now, since 480 exceeds 300, the weight A must preponderate, &c. If the two products had been equal, the whole would have remained balanced and at rest.

The like illustration may be applied to all the other mechanical powers, as well as to machines of all kinds, whether simple or complicated; for in every one of them the following particulars must be indispensably found, *viz.* 1st. One or more bodies must be moved one way, whilst one or more other bodies move the contrary way. One of those bodies, or set of bodies, is called the *power*, and the other is called the *weight*; or they may be called *opposite powers*. 2^{dly}. If the product of the weight of one of those powers, multiplied by the space it moves through in a certain time, be equal to the product of the weight of the opposite power multiplied by the space it moves through in the same time; then the opposite momenta are equal, and the machine remains at rest, or in a state of equilibrium. But if one of those products exceed the other, then the former will preponderate, and the parts of the machine must move in the direction of the preponderating power. In the above computation, however, a deduction must be made on account of friction, imperfection of workmanship, &c. which sometimes amounts to a considerable quantity; but there are no ge-

neral rules by which such deductions may be made with tolerable accuracy.

The complicated machines, which contain two, or more, and sometimes a great repetition of the simple mechanical powers, cannot conveniently be collected under general and comprehensive classes. Their number, their various uses, the different powers which actuate them, their sizes, and their effects, render the particular description of each machine too extensive and nearly impracticable. Yet it is to be wished that all sorts of machines were regularly described and delineated in a sort of general mechanical repository; for though several of those machines may not have answered the purposes for which they were intended, they are nevertheless of use to mechanical persons, who are contriving other machines for similar purposes.

In the examination of machines, it is peculiarly entertaining to observe how different the powers are from the effects of some of them, and by which means those effects are produced. Certain machines are formed to produce a regular effect from the application of an irregular power. Thus at the Albion Mills, (which were erected some years ago near Blackfriars bridge, and were afterwards unfortunately destroyed by fire,) the alternate strokes of the piston of a steam-engine were made to produce the regular rotary motion of grinding-mills. In other machines a regular power is caused to produce an irregular, or an interrupted effect. Sometimes a power once applied acts gently during a considerable period of time; and at other times the accumulation of weak powers is made to produce powerful effects at stated times.

It is not only the production of a certain effect from a particular power, that should be observed in machinery; but the manner by which the object is attained should be carefully examined; for the simplicity of the means, the safety, and the durability of the machine, are the particulars which form the beauty of the contrivance, and upon which the skill of the contriver principally rests.

DYNAMOMETER, (from *δυναμις*, *power*, and *μετρησις*, *measures*, meaning a measurer of power,) is the name of an instrument intended for measuring the muscular strength of men and other animals. An instrument of this kind was, some years ago, invented by Mr. Graham, and was afterwards improved by Dr. Desaguliers; but it was too bulky, and too limited in its use; so that it was soon neglected. Mr. Le Roy of the Academy of Sciences at Paris, constructed, soon after, a much more useful instrument for the same purpose. It consisted of a metal tube about a foot long, placed vertically on a foot like that of a candlestick, and containing in the inside a spiral spring, having above it a graduated shank terminating in a globe. This shank, together with the spring, sunk into the tube more or less, in proportion to the weight which pressed upon the globe at the top of the shank, and the graduation of the latter indicated the quantity of it. Therefore, when a man's strength was to be tried by means of this instrument, the man needed only press upon the above-mentioned globe with all his power, and the graduation of the shank indicated the quantity of that power, *viz.* it shewed the number of pounds weight to which it was equivalent.

Mr. Regnier, at Paris, at the instigation of Messrs. Buffon and Gueneau, contrived another sort of dynamometer. It consisted chiefly of an elliptical spring a foot long, and rather narrow. It was covered with leather, that it might not hurt the hand which compressed it. The strength of this spring was such as to exceed that of any animal to which it might be applied; and it contained an index with a mechanism which indicated how much it was compressed;

or, which is the same thing, it indicated the quantity of the power which compressed the spring. Therefore, when a person wished to measure his power by means of this machine, he was obliged only to compress the elliptical spring with all his force, and to observe the quantity of that force as pointed out by the index of the machine. (See le Journal de l'Ecole Polytechnique, vol. ii.) Both the use and the construction of the last described machine were much extolled; but, upon a strict examination, it does not appear that it was superior to Le Roy's contrivance.

Since the above was made public, nothing peculiarly useful has been offered for the purpose of measuring the strength of animals. Yet upon the whole it seems, that the common well known spring steel-yard, though not intended expressly for that purpose, is the best instrument for measuring the strength of men and other animals. In principle, it is nothing more than Mr. Le Roy's contrivance; but under a much more commodious form. It has a ring at one end, and a hook at the other. By endeavouring to pull those parts from each other, a graduated rod comes out of the external tube, and shews the force which has been applied to it. Therefore, by fastening the ring to an immovable object, and the hook to a man, or horse, &c. by means of a rope or otherwise, the strength of the man or other animal may be easily ascertained. See **SPRING STEELYARD**.

It certainly is a desirable thing to know the various muscular power of men and animals, especially of such as are to be employed for work of various kinds; and upon the whole a pretty good estimate may be obtained from the use of the above-mentioned machine. Yet, it must be observed, that a determination of this kind is influenced by a variety of circumstances, which tend to render the result inaccurate or equivocal. For instance, a man is much stronger than another man in his hands, whilst that other man is much stronger than the former in his legs. One can carry a great weight upon his head; another can pull a great weight after him, that is, drag it over the ground, and so forth. Nearly the same thing may be remarked with respect to other animals. But the most material circumstance is the duration of the exertion, *viz.* certain men, and especially such as are young and well fed, but not much used to work, are capable of immense exertion during a minute, or an hour, or even a day; but they are incapable of enduring a longer duration of labour; whilst others go on with a uniform daisy exertion during weeks and years. The same variety in the length of the exertion takes place in other animals, especially such as are more commonly used for labour, *viz.* horses, mules, oxen, camels, &c.

Fig. 1. Plate XXXVI. Mechanics, represents one of the whippetrees, to which two horses or oxen can be applied, the cover of the mechanism being removed to explain its internal structure. A A is the main whippetree, having a hook at *a* to back it to the plough, &c., and two others to connect it with two short whippetrees B, B, by which the cattle draw; the hook *a* is fastened to a straight bolt *b*, sliding freely through holes in two pieces of iron plate *d, f*; a pin is put through the end of the bolt to prevent it being drawn quite through at *c*; a circular plate of iron is pinned fast upon the bolt *b*, between which, and the fixed plate *d*, a spiral steel spring is placed, which has a strong tendency to elongate itself, and draw the hook to the machine; *b* is a short rack fastened to the iron plate *e*, and turning a small pinion on the back of the index *i*, which points out the divisions on the arc *k*. The divisions are made by suspending weights from the hook *a*; these compress the spring in proportion to their weight, and the rack moves the index *i*; the value of each weight being marked on the arc *k* at the place pointed out by the index;

of course, when the horses are harnessed to the whipletters B, B, and the plough, or carriage, to the hook *a*, the motion of the index denotes the force of their draught.

Fig. 2. is another machine on the same principle as the last, but is contrived to be as to require a very delicate spring, which is found to be more sensitive than a large one, and to keep its elasticity longer: this is accomplished by having the hook *a* formed into two eyes at the other end, to receive the pivots of the lever *b*, whose fulcrum, or fixed centre, is at *d*; at the other end of the lever it is connected by a short iron link *e*, to a second lever *f*, of which *g* is the fulcrum: *b* is the spring barrel, exactly the same as the other machine, but much smaller, being only to weigh about 50*lb*. instead of 5*cent*.; its spindle is attached to the lever *f*, and is moved thereby when the hook *a* is drawn: the spindle of the spring has a rack *i* fastened to it, which moves a small pinion, on whose arbor the index to the dial-plate is fixed: the dial plate is in this machine a whole circle, described in the figure by a dotted circle, with large divisions for hundred weights, and subdivisions for the quarters. By means of the levers the power exerted on the hook is so far diminished, that the small spring of 50*lb*. will serve to weigh a quantity equal to 6*cent*.; and by increasing the spring a little, and altering the levers, by throwing the hooks nearer the centres, and lengthening the levers, it may be made to do for 12*cent*. The mechanism is covered over with an iron box, to defend it from injury.

This machine is the invention of Mr. Robert Salmon, Woburn, Bedfordshire, and they are now manufactured by Mr. Shepherd, implement-maker, Woburn.

This article is also the most proper place to describe a method, employed by Mr. Salmon, to measure the force requisite to give motion to a threshing and flour mill at Woburn-Park farm, belonging to the duke of Bedford. The mill was originally worked by a horse-wheel, adapted for eight horses or oxen, though it is now worked by a steam-engine; but the horse-wheel still remains. It is represented in fig. 3, where A A is the main vertical shaft, having pivots at both ends, one of which works in a brass socket, supported on beams, *a, a*, laid on the ground; and the other in a brass bearing, bolted to a beam, which is framed between two girders, B, B, of the floor above. D is the rim of the wheel, containing the cogs; it is composed of three thicknesses fastened together, and is supported by sixteen arms, F, from the enlarged part of the shaft at E, and braced by sixteen beams, L, extending from the lower part of the shaft to the middle of the arms. The horses or oxen draw from upright pieces of wood, *a, a*, bolted to the arms, F, and braced by long iron bars from the adjoining arms. Eight of the arms are furnished in this manner, for the oxen to work the wheel: they walk upon a circular road at G G, on the level of the ground, while the shaft is sunk in a pit walled round, to give a greater length of shaft, that the oblique braces may have more effect.

The method in which Mr. Salmon applied a dynamometer to this wheel was as follows: a piece of board, *b*, was extended between and nailed to the two uprights, *a, a*, by which the oxen drew; in the middle of the board a large pulley, *g*, was fixed, turning very freely, and upon as small a pivot as was consistent with strength; another pulley, *d*, was suspended from the arm of the wheel near the centre; a small *l*-ft rope was passed over both pulleys, hanging straight down from the pulley, *d*, and terminating in a double hook, and after passing round the pulley, *g*, was tied to the middle of a short round stick. Four of the arms were fitted up in this manner, and two men were placed at each, holding the stick in their hands behind them. Mr. Salmon placed himself in the pit, being provided with a number of weights,

some of which he hooked on the hooks at the end of the rope. He then directed the men to proceed forwards, in the track formed by the feet of the cattle, drawing the rope after them. Their action raised the weights, and caused the wheel to follow; but where the weights were drawn up towards the pulley *d*, Mr. S. added more weight, until it was so adjusted that the wheel moved round with its proper velocity, without the weights rising or falling above any point at which they were placed. The sum of these weights now showed the power required to move the mill; and the motion might be continued as long as was necessary to obtain a fair result. By this method, any sudden jerk or exertion, which the men might make, would not be communicated to the wheel, as it would only draw up the weights, which would descend again, when the men relaxed their strain.

The mill was employed in threshing; and as this is a very unequal kind of work, it was often necessary to hook on more weights, to overcome the resistance occasioned by feeding the machine: for it must be observed, that no more power could be applied to the wheel than the sum of the weights, as it was only through the medium of horses that the men exerted any power at all upon the wheel.

The velocity of the wheel also depended upon the weights, for the heavier they were the quicker it would follow the men, who were directed to move at such a pace, as the wheel seemed to take, that the weights might not descend by their going too slow, or ascend by their going too fast. The wheel's velocity was measured by a watch which Mr. S. had in his hand; and each turn of the wheel was denoted to him, by a nail which was driven in the rim of the wheel striking a piece of tin plate nailed up against the wall. If he found by the watch the wheel was moving too slowly, he applied more weight, or *vice versa*, until the proper weight was found. Mr. Salmon made many experiments in this manner, on the force required to thresh different kinds of corn, of which we shall give the results under **THRASHING MILL**.

DYNASTY, a term in *History*, signifying a race, or succession of kings of the same line, or family. The word is formed from the Greek, δυναστω, or δυναστω, to be powerful, to be king.

We find frequent mention in ancient history of dynasties of Persians, Assyrians, Medes, &c. The ancient Chronicle of Egypt mentioned by Syncellus, gives us an account of three different dynasties; that of the gods, that of the demigods or heroes, and that of men or kings. The two former are represented as continuing thirty-four thousand two hundred and thirty-one years, in order to favour the high antiquity of the Egyptians; the last as commencing with the reign of Menes, the first king of Egypt, and terminating with Nectanebus II. under whom the kingdom was conquered by Artaxerxes Ochus; and this is said to have lasted two thousand three hundred and twenty-four years. Manetho has left us an historical chronology of Egypt, divided into thirty dynasties, comprehending a space of more than five thousand three hundred years to the reign of Alexander; but it is certain, that these were collateral and not successive.

DYOTA, in *Chemistry*, from δι, double, and οτ, ear, a peccan, or circulating vessel with two ears, in shape resembling a man standing with his arms bent outwards, and with his hands on his sides.

DYPTYCHA, or rather ΔΙΠΤΥΧΑ. See ΔΙΠΤΥΧΑ.

DYRAS, in *Antient Geography*, a river which had its source in mount Ota, and discharging itself into the Mediterranean gulf, between Anticyra and Antioch.

BYRNITZ, or **TYRNITZ**, in *Geography*, a town of Germany, in the archduchy of Austria; 17 miles S. of St. Pöten.

DYRRACHIUM, now **DURAZZO**, in *Ancient Geography*, a town of Illyria, with a port on the Adriatic sea, opposite to Brundisium. It was formerly called Epidamnus, but the Romans changed it to Dyrrachium. (Pliny, iii. 26.) According to Strabo, this city was founded by a colony of Coreyraeans. It is mentioned by Cicero, Pliny, Pausanias, Ptolemy, Meia, &c. Its port was much frequented in the time of the Romans, by all those who had occasion to pass from Brundisium to Greece. At the mouth of the Adriatic gulf, the shores of Italy and Epirus incline towards each other; and the space between Brundisium and Durazzo, the Roman passage, is no more than 100 miles: at the last station of Otranto, it is contracted to 50; and this narrow distance had suggested to Pyrrhus and Pompey the extravagant idea of a bridge. The city, being the western key of the empire, was, previously to its siege, A. D. 1081, guarded by fortifications, and also by George Palaeologus, a patrician, victorious in the oriental wars, and a numerous garrison of Albanians and Macedonians, who had, in every age, maintained the character of soldiers. Accordingly, the courage of Robert Guiscard was assailed, in the prosecution of his enterprise, by every form of danger and mischance. His fleet was scattered by an unexpected storm; and the disaster was so ruinous, that both his sailors and soldiers were much dispirited. Unsuccessful in their first naval engagement, a sally from the town, to which they laid siege, carried slaughter and dismay to the tents of the Norman duke. A seasonable relief was conveyed to the town; and as soon as the besiegers had lost the command of the sea, the islands and maritime towns withdrew from the camp the supply of tribute and provision. The camp was soon afflicted with a pestilential disease; 500 knights perished, and the list of burials comprehended 10,000 persons. Under these calamities, the mind of Guiscard alone was firm and invincible; and while he collected new forces from Apulia and Sicily, he battered, or scaled, or sapped the walls of Durazzo. The besieged were equally valiant and industrious in concerting measures of self-defence. A movable turret, sufficient for containing 500 soldiers, had been rolled forward to the foot of the rampart; but the descent of the door or draw-bridge was checked by an enormous beam, and the wooden structure was instantly consumed by ardent flames. In the mean while the emperor Alexius, the founder of the Comnenian dynasty, made a hasty peace with the Turks, and undertook in person the relief of Durazzo. Guiscard, unalarmed, waited in battle-array the nearer approach of the enemy. Alexius, contrary to the advice of his wisest captains, resolved to risk the event of a general action, and exhorted the garrison of Durazzo to assist their own deliverance by a well-timed sally from the town. After the first attack, the army of Guiscard was reduced to 15,000 men. Many of his troops took themselves to flight; but when the Norman duke was on the verge of rum, his wife, Gaita, by her singular valour and address, succeeded in rallying the flying troops, and gave a turn to the battle, which rendered Robert completely victorious over an army five times more numerous than his own. After this decisive battle, the siege of Durazzo was diligently prosecuted. At the dead of night, several rope-ladders were dropped from the walls; the light Calabrians ascended in silence; and the Greeks were awakened by the name and trumpets of the conqueror. Yet they defended the street three days against an enemy already master of the rampart; and nearly seven months elapsed between the first

investment and the final surrender of the place, A. D. 1082. Gibbon's Hist. vol. x.

DYRZELA, a town of Asia, in Pisidia. Ptolemy.

DYSÆ, in *Mythology*, inferior goddesses among the Saxons, being the messengers of the great Woden, whose province it was to convey the souls of such as died in battle to his abode, called *Valhal*, i. e. the hall of slaughter; where they were to drink with him and their other gods *cerevisia*, or a kind of malt liquor, in the skulls of their enemies. The Dysæ conveyed those who died a natural death to Heia, the goddess of hell, where they were tormented with hunger, thirst, and every kind of evil.

DYÆSTHESIAÆ, in *Medicine*, from $\delta\upsilon\varsigma$, *against*, and $\alpha\iota\sigma\theta\eta\sigma\iota\varsigma$, *sense*, implying an imperfect faculty of perception or sensation, is a term employed by Sauvages to designate the first order of the sixth class of his nosology; and by Cullen, as the denomination of the first order of the fourth class in his arrangement of diseases. In both these systems the same diseases are included under the term, viz. those maladies of the organs of sense, which impede their functions: such as cataract, amaurosis, &c. producing *blindness*; the varieties of *deafness*, depraved *taste*, *smell*, and *lo* forth.

DYSART, in *Geography*, a royal borough, in the shire of Fife, Scotland, was incorporated about the beginning of the 16th century; at which time it is mentioned as one of the principal trading towns in the shire. Its traffic declined about the commencement of the last century; but began to recover in the year 1756, and is now very extensive; 36 vessels being employed from this port in foreign trade. About 750 looms are worked here in the manufacture of checks, of which 795,000 yards are annually made. Ship-building also is carried on to a considerable extent: and upwards of 17,000 bushels of salt are made yearly. But the principal trade is the exportation of coal, which abounds in this neighbourhood: upwards of 20,000 tons are annually raised, of which nearly 5000 are sent to Denmark and Holland, whence wood is imported in return. The borough, with the three villages of Porthead, Galaton, and Borland, contain nearly 5385 inhabitants; the lower classes of whom are mostly employed in making nails; some are engaged in the weaving, &c. of check-cloth, and some are occupied in ship-building. The ground on which the town stands, rises gradually from the sea for about a mile in extent, when it slopes again to the river Orr. Near Porthead, on a freestone rock, stand the ruins of an ancient fortification called *Raven's Craig*, the property of which has belonged to the family of St. Clair ever since the time of king James II.—Sinclair's Statistical Account of Scotland, vol. xii.

DYSCINESIAE, in *Medicine, from $\delta\upsilon\varsigma$, and $\kappa\iota\sigma\iota\varsigma$, *motion*, *Impove*, signifying impeded or depraved motions, arising from disease in the moving organs, is the denomination given by Sauvages and Cullen to the third order of the sixth class and the fourth class of diseases in their respective nosological systems. The diseases of *stammering*, *loss of voice*, *dumbness*, *squinting*, and other local disorders of motion, are included under Dr. Cullen's order, to which are added palsy, *hemiplegia*, and *paraplegia* in the order of Sauvages.*

DYSCRASIA. See **CRASIS**.

DYSCÆA, from $\delta\upsilon\varsigma$, and $\alpha\iota\sigma\iota\varsigma$, *I hear*, the same with **DEAFNESS**, which see.

DYSENTERY, the *Flux*, or *Bloody Flux*, *dysenteria*, from $\delta\upsilon\varsigma$, and $\epsilon\pi\epsilon\tau\epsilon\rho\iota\varsigma$, *intestinum*, the *bowels*, is a disease principally characterized by frequent mucous or bloody discharges from the intestines, while the proper fæces are retained, together with griping, and staining at stool, and some fever.

DYSENTERY.

The word *dysentery*; as used by the ancients, had no very precise signification. Originally its import was an *affliction of the bowels* in general, and we find Hippocrates using it, not only to signify all ulcerations, but all hæmorrhages of the intestines (even those which are critical and salutary), and likewise every kind of flux, with or without blood. (Prorrh. 2. et Epidem. lib. ii.) It would seem, however, that, after his time, some of the other Greek authors, whose works are lost, were sensible of this want of precision, and therefore restricted the meaning of the word to an *ulceration of the bowels*, attended with gripes and *teneasms*, (or straining,) and with mucous and bloody stools. For a disease with these symptoms Celsus calls *tormina*, and says it is the *dysenteria* of the Greeks; and Cælius Aurelianus, retaining the Greek name, describes the dysentery much in the same manner with Celsus. (See Cels. De Med. lib. iv. cap. xv.—Cæli. Aurel. de Morb. Chron. lib. iv. cap. vi.) Yet Galen returns to the looser acceptation of the word, sometimes defining a dysentery, an *ulceration of the bowels*, at other times mentioning four species of that diſtemper, all with bloody stools; but of which only one agrees with the *tormina* of Celsus, or the dysentery of the moderns. Arætaus confines the term to an *ulceration of the bowels*. But, although this notion of the constant ulceration of the bowels, in conjunction with dysenteric symptoms, prevailed in all medical writings until the time of Sydenham and Willis; and although it be true, that the bowels are liable to be ulcerated in the true dysentery; yet it has been fully ascertained, by the dissections of the moderns, that ulceration is accidental, and not essential to the disease; and that instances even of fatal dysentery, (consequently of the disease in its most severe and protracted forms,) in which the intestines were found, are more numerous than those accompanied by ulceration. For this assertion, we have the authority of Morgagni, Bonetus, Clegborn, and Pringle; the first of whom alleges, and it is now generally understood, that ulceration takes place only in the advanced or chronic states of the disease.

Dysentery appears to be the same disease under all circumstances of its occurrence, except in the degree of violence; which, as in other diseases, necessarily varies with the season, the constitution of the patient, and the degree of exposure to the exciting causes. Sir John Pringle affirms, that all the epidemic dysenteries, which he witnessed in the army, were the same; and that he was assured by Dr. Huck, and other army physicians, that this disease appeared, in different countries and climates, in Germany, Minorca, America, and the West Indies, with the same symptoms, and yielded to the same remedies; and, farther, that the epidemic described by Sydenham, as having occurred in London, in 1669 and the following years, was similar to the rest, as well as to the sporadic cases which he had met with in private practice, both in England and Scotland. The following is a detail of the symptoms and progress of the disorder.

The dysentery sometimes begins, as Sydenham observes, with cold shiverings, succeeded by heat, and other febrile symptoms; but in other cases these febrile sensations are not felt, but a griping and twisting of the bowels, or stitches in the sides, or only a pain about the pelvis, with a constant fruitless straining to stool, and much flatulence, while the body is costive; sometimes, though more rarely, some degree of diarrœa is the first appearance. In whatever way the disease begins, it soon puts on its characteristic appearances. The disposition to evacuate the intestines becomes more frequent and urgent, but in indulging it, little is voided, except a watery or slimy matter, and the *teneasms* becomes considerable. From this time, until the favourable turn of the complaint, forced and natural excrements seldom

appear, except when a purge operates well, and carries them down, and then they are in the form of *scybalæ*, or hardened, separate balls. When these are voided, whether by the efforts of the constitution, or by the interference of art, a remission of all the symptoms, and more especially of the frequent stools, griping, and *teneasms*, succeeds. These *scybalæ* are of a firm texture, and round shape, having been formed in the cells of the *colon*, or great intestine, where they have lain in all probability from the beginning. The excrementitious discharges most commonly consist of a mucous matter, streaked or mixed with blood, and often with a ferous or watery fluid, and fragments of a membranous appearance, consisting of coagulated lymph, but often taken for abrasions of the internal coat of the bowels: sometimes a pure and unmixed blood is voided in considerable quantity. The *ferum*, sir J. Pringle observes, is perhaps one cause of the irritation, and descends from the higher parts of the intestines, whilst the *mucus* is mostly secreted from the *rectum*, or lower gut, in straining. Streaks of blood, he adds, denote the opening of some small vessels at the end of the *rectum*, but a more intimate mixture is a sign that the blood comes from a higher source. If the disease advances into a chronic form, a purulent, and sanious matter is often discharged, proceeding from ulcerated or gangrenous parts. The stools are all along distinguished by a peculiar smell, different from that of common excrements; it is faint, and not rank at first, but towards the end, when the bowels begin to mortify, the fœtor is cadaverous and intolerable.

When the disease is formed, sickness and vomiting frequently come on, and the appetite is generally lost. Some degree of fever is always present; which is various in its kind. Sometimes it is manifestly of an inflammatory nature; and, especially in warm climates, it is often of a remittent kind, and observes a diurnal or tertian period. Frequently, indeed, a flux in the beginning will have the appearance of the autumnal fever, and the patient will be feverish, with some disorder in the stomach and bowels, for two or three days before the dysenteric lax comes on; but after that, the fever sensibly gives way. This obvious diminution of the fever upon the appearance of the looseness, seemed to justify the expression of Sydenham, when he called the dysentery "the fever of the season turned in upon the bowels." But patients are besides liable to a low fever, which sir J. Pringle says, was commonly brought on by neglect of the case in the beginning, or by the use of opiates and other astringents before evacuations. But the most fatal sort of fever, which so often attends the dysentery of the army, though not essential to it, is the hospital or gaol fever, which at all times infects foul, ill-ventilated, and crowded wards. This fever, combined with the bloody flux, is generally mortal. These febrile states continue to accompany the disease during its whole course, when it terminates soon, in a fatal manner. In other cases the febrile condition almost entirely disappears, while the proper dysenteric symptoms remain for a long time after.

Under these modifications, the dysentery is of various durations in different instances. When the fever attending it is of a violent inflammatory kind, or when it is of a putrid nature, the disease often terminates fatally in a very few days, with all the marks of a supervening gangrene. When the febrile state is more moderate, or disappears altogether, the disease is often protracted for weeks, and even for months, and even then it often terminates fatally. More frequently, especially when occurring out of camps, and military hospitals, it ceases gradually, after proper treatment, the frequency and slimy composition of the stools, the griping and *teneasms*, all ceasing, and natural stools returning. In other

cases,

cases, the disease, with moderate symptoms, continues long, and ends in a diarrhoea, sometimes accompanied with henteric symptoms.

In general the dysentery terminates at the lower extremity of the gut, or, as Sydenham says, "the disease at last is driven to the *rectum*, where it ends in a *teneismus*;" i. e. the colon remains longer diseased than the smaller intestines, and the rectum is generally the last part that recovers. But the same physician observes, that the teneismus remaining at the end of a flux, is not owing to an ulceration of the rectum; but that part he supposes to be the last depository of the irritating mucus of the intestines. But sir J. Pringle explains it more rationally by ascribing this remaining teneismus to the foreness of a part, which has been so much excoriated and inflamed during the course of the disease, and which, by the constant irritation of passing excrement, is still kept from recovering.

It is the sign of a bad case, says the last mentioned physician, when the first vomit and purge do not relieve; when the hectic fever increases; when the disorder of the stomach is obstinate; when the countenance alters much; when the pulse sinks and intermits; when the patient is restless without complaining of gripes. In the beginning a biceps is little to be dreaded; but in the low and advanced state, if obstinate, it is commonly a sign of a mortification. The disease, when fatal, ends in a prostration of strength, a sore throat, or *aphthæ*, involuntary and cadaverous stools.

In the army, he adds, in the most favourable event, those men, who have been sent to an hospital, can be of little more service for the rest of the campaign; for no ailment is more apt to return upon errors in diet, or exposure to cold. Not that these returns are so much relapses into the true dysentery, as they are diarrhoeas, but with more of the dysenteric symptoms than are common in the white-flux.

The proximate cause, or the actual condition of the intestines, upon which the symptoms above detailed depend, appears to be an inflammatory state of the mucous membrane, which lines the intestines, especially the great gut, together with a preternatural contraction of their muscular fibres. The existence of these two circumstances is sufficient to explain the symptoms. The retention of the natural feces in the cells of the colon, especially in an inflamed state internally, will account for the non-appearance of natural excrement, and the constant desire to go to stool, for the pain and griping, and straining; which last will explain the production of streaks of blood, and in part the secretion of mucus, which the inflamed lining membrane so copiously pours out.

Accordingly dissection has generally discovered considerable contractions in the colon, where gangrene had not destroyed the texture and form of the parts; and the proofs and consequences of inflammation were invariably detected. These are a preternatural thickening of the coats of the intestines; internal ulcerations in the colon and rectum; and abrasion or rather corruption of the villous coat into a slimy greenish substance; gangrene of the rectum and colon, sometimes extending the whole length of both; and occasionally a sort of particular appearance, resembling the small-pox, in those parts. The small intestines are generally found inflated, but seldom in a diseased condition in any other respect.

Dysentery is to be distinguished from *diarrhoea*, chiefly by the *teneismus*, or fruitless and distressing efforts at stool, by the absence of natural feculent matter in the discharges, and the smallness of the evacuation and frequent attempts; as well as by the febrile condition, which accompanies these symptoms, in the acute and early stages. From *colicæ* and *cholera*, in both which there is pain and griping, and in the

latter, fever, it is easily discriminated; by the constipation and acuteness of pain in colicæ, and by the profuse evacuations of bilious matter by stool in cholera, without teneismus.

The exciting causes of dysentery have been differently stated by different physicians. The army physicians have attributed the disease to the combination of heat and moisture, or an alternation of these with cold; because it usually appears in camps and in warm countries towards the end of summer and in autumn, after great and continued heats, and at the same time with the autumnal remittent and intermittent fevers. Willis observes, that the summer of 1670 (which preceded the autumn in which the flux was at its greatest height) was remarkably hot; and sir J. Pringle states, that in the summer of 1762, the heat and drought were of long continuance, and in the autumn the dysentery prevailed in London extensively, so that he believes more cases then occurred, than in all the sixteen years that he had previously resided here. He farther remarks, that when, at that period of the year, the men are exposed to night-damps and fogs, especially after a hot day, or lie wet upon the ground, or in wet clothes, part of them will be seized with the autumnal fever, and part with the dysentery, and perhaps some of them will have a disorder compounded of both.

Dysentery, however, is contagious in camps and hospitals. "In the camp," says Dr. Pringle, "the contagion passes from one, who is ill, to his companions, in the same tent, and from thence perhaps to the next. The foul straw becomes infectious. But the greatest sources of infection are the privies, after they have received the dysenteric excrements of those who first sicken. The hospitals likewise spread it; since those who are admitted with the flux, not only give it to the rest of the patients, but to the nurses and other attendants of the sick." This is most conclusive evidence of its strongly contagious nature, under those circumstances. But we have also evidence of the limited extent of the influence of this, as of other contagious *effluvia*. (See CONTAGION.) "In general the contagion does not suddenly spread. For whole towns and camps are never seized at once, from the impurity of the atmosphere, but the infection is carried from one to another by the *effluvia*, or clothes, or bedding, &c. of the tainted person, as in the case of the plague, small pox, and measles." At Niameg, the Jews, who had little intercourse with the rest of the people, escaped the epidemic dysentery. (See Degger. Hist. Dysent. bilioso-contagios. cap. i. § 35.) Dr. Cullen has observed that dysentery is always contagious; he believed that cold never produced the disease, except when the contagion had been previously received; and that a specific contagion was the sole exciting cause of dysentery. (Furr Lines, § 375.)

This position we are disposed to consider erroneous. Sydenham makes no mention of any contagion, attending the epidemic dysentery, which he has denoted; and Willis, who speaks of the same epidemic, expressly asserts that it was not infectious. It is a common disease in this metropolis, in a sporadic form, and during the last autumn (1808) was prevalent to a considerable extent; yet we do not recollect to have once observed it to pass to a second person in any family; while its origin could be often satisfactorily traced to exposure to cold and moisture. In this respect, too, the analogy of CATARRH corroborates the notion of its being under one form contagious, and under another simply the effect of the operation of cold. The common sporadic examples of catarrh, which we witness every day, are so notoriously the effect of this agent, that the disease itself is denominated a *COLD*, by a figure of speech. Yet there can

DYSENTERY.

can be little doubt, that, under the form of INFLUENZA, the catarrh is an infectious disease.

Many writers have ascribed the dysentery to the use of fruit, or to the overflow of bile, or to both these causes. But their opinions have erroneously arisen from the circumstance, that the season of the prevalence of dysentery is usually that, in which fruit is abundant, and bilious diseases occur; namely, the end of summer, and the autumn. Sydenham, however, who considers fruit as a cause of CHOLERA, never mentions it as the occasion of the dysenteries, which were epidemic in London in his time; and DeGner, another diligent observer, expressly says, that fruit had no share in producing the flux which raged some years ago at Nimeguen. Sir J. Pringle is decided in his denial of the effects of fruit in exciting dysentery. He observes that the soldiers could not afford to procure fruit; and besides he states that the worst flux, which prevailed in the army, in which he served in the Low Countries and in Germany, began in the end of June, when there was no other fruit but strawberries, which the men never tasted; and that it nearly ceased about the first of October, when the grapes were ripe, and so plentiful in open vineyards, that the men eat what quantity they pleased. As to the bile, it is certain that occasionally a cholera terminates in a dysentery; but this is very rare, and is often to be attributed to the unseasonable interruption of the discharge by astringents, and strong opiates. Where the bowels are very irritable, any unusual determination to them may bring on dysentery.

Cure.—It has been justly observed, that there are few acute diseases less indebted to the natural efforts of the constitution for a cure, or in which the apparent indications are more deceitful, than dysentery. The constant flux seems to require the administration of strong astringents, and the great pains and gripings in the bowels appear to demand the free use of opiates: and yet these remedies, unless employed with much caution, or corrected by others, tend much more to confirm than to remove the disease. On the other hand, purges and emetics, under such a state of irritation and perpetual discharges, would appear to be inadmissible, and have been condemned; yet later experience has shewn them to afford the chief means of cure.

We shall follow Sir J. Pringle in treating of the method of cure, under three different states of the disease: namely, first, in the *acute* state of the disease, or while it is recent; secondly, in the *chronic* state, or when the disorder is of a bad kind, has continued long, and has much impaired the strength, injured the intestines, and induced a hectic fever; and, thirdly, when the patient, although recovering, is kept low by a *tensusus*, or some other remains of the disease, or becomes subject to frequent returns of a looseness, from the weakness of his bowels.

I. In the *acute* state.—In very strong habits, and where inflammatory symptoms, either accessory, or belonging to the disease itself, ran high, a moderate bleeding may be permitted. This, however, is very rarely necessary, especially in sporadic cases; and the repetition of it may be considered as generally unnecessary or hurtful. The principal object of cure, in a recent case of dysentery, is to obtain a full evacuation of the intestinal canal, by which means the *syphala*, or hardened excrement, or the morbid secretions into the canal, may be removed; at the same time to take care that the inflammatory condition of the mucous membrane, lining the passages, be as little affected by the irritation of the process as possible. This evacuation indeed is sometimes contrary to the inclinations of the patient, who conceives that his bowels are already too much griped and purged; and *a priori* it might justly be supposed, that any additional irrita-

tion, from a purgative substance, would be hurtful, did we not recollect that we thus remove a much greater irritation, the hardened fæces, which actually cause or keep up the disease.

It is desirable, therefore, to adopt the mildest means of evacuation, which are adequate to the full effect. Emetic substances, especially antimonial preparations and ipecacuanha, have been much employed for this purpose, administered in such a way as to act upon the bowels. The *virium ceratum antimonii*, glass of antimony, or vitrified oxyd of antimony melted with wax; was strongly recommended (see Edin. Medical Essays, vol. v.) as a cure for dysentery, and used by Sir J. Pringle, and many other practitioners, with success. It always occasioned vomiting, and generally purging, with which last operation its success was observed to be particularly connected. But the uncertainty and occasional violence of the effects of this medicine have caused it to be generally laid aside by practitioners. A vegetable emetic was introduced by Piso, as a specific against dysentery, namely, the ipecacuanha root. He relied on its purgative quality, however, though he adds, that it still had a better effect when it vomited also. (See Gul. Pison. Hist. Nat. et Med. Indiæ Occid. lib. ii. cap. ix.) Sir John Pringle used this as his first medicine in the commencement of dysentery, and found it most certainly successful, when given in divided doses, of five grains each, at the intervals of an hour. Three doses generally brought on a purging; no drink being allowed until that effect was produced, and then some gruel was taken to promote it.

But since it has been clearly ascertained, that the salutary operation of these and similar medicines, consists entirely of their cathartic effects, and that those substances, which possess a purgative quality only, are equally efficacious and more certain in their operation, the latter are now generally employed. Various cathartic medicines have been adopted upon theoretical principles, or from observation, in the treatment of dysentery. Rhubarb was formerly much used, because its purgative operation was followed by an effect of astringency, upon which principle, by the way, Piso recommended the ipecacuanha; but, on the contrary, it seems desirable that we should use a purgative, which may leave the body open. Among the mildest and most certain means of procuring evacuations from the bowels, are the neutral salts, especially the soluble tartar, or *tartrate of potash*, and the Epsom salt, or *sulphate of magnesia*, well diluted, and with the addition of cinnamon, or peppermint water, in divided doses of a ʒ; or two drachms every hour or two, till an evacuation is procured. The castor oil, *oleum ricini*, *senna*, and *mannia*, have been used with success; and calomel alone, or with rhubarb, is an efficacious medicine: Sir J. Pringle used to administer five grains of calomel with thirty of rhubarb. But he justly observes, “that we are to attend less to the dose than to the effects, which are not to be judged of by the frequency, but by the copiousness of the stools, and by the relief which the patient finds from the gripes and *tensusus* after the operation; and that, as on the one hand, the physician ought to avoid all the rough and stimulating purges, so on the other he is not to spare those of a lenient kind, especially rhubarb, which is commonly under-dosed.” Rhubarb, however, is much condemned by other writers.

But it is necessary to remark, that the cure cannot always be readily effected by purgatives alone. The irritation which they occasion, under the tender state of the internal coat of the intestines, in dysentery, tends, in many instances, to counteract the good effects of the removal of the *fæces*. It has been the custom, therefore, with practitioners in general, to give an opiate in the evening, after the purgative operation

operation was accomplished; to repeat the purgative, at the interval of a day or two, interpolating opiates, especially in the evening of the day of purgation; or to alternate purgatives and opiates, until the state of the bowels become natural. It is singular, that our great physician, Sydenham, recommends the interpolation of cathartics only in the epidemic dysentery, when the disease assumes a more severe form; and used opiates alone for the cure of the milder or sporadic cases of the disorder. This is certainly inconsistent with the observation and experience of succeeding physicians: for even in the mildest instances of dysentery, opium, while it gives a temporary relief to the pain and tenesmus, is observed but to postpone their severe occurrence, and to protract the complaint, which it rather confirms than removes, by retaining "the enemy within the bowels." In the more usual forms of the disease, the general voice of experience has decided, that opiates, given previous to or without purgation, aggravate the disease. Indeed sir George Baker, and some other authors, strongly condemn the use of opiates, until the stools have become natural, in consequence of the full evacuation of the bowels: they affirm that opiates, like other astringent medicines, gives rise to *tympanites*, by retaining the feces and morbid secretions within the intestines.

We are satisfied, however, from observation, and we have no less authority in our favour than the practice of the late Dr. Warren, (see Medical Transactions of the Coll. of Phys.) that opiates may be used, from the first appearance of the disease, with advantage, provided an evacuation be procured at the same time, by the combination of purgative medicines with them. The conjunction of opium with cathartics is an useful practice in extremely irritable conditions of the bowels; it retards, but scarcely diminishes, the operation of the purgatives, the irritation of which it in a great measure prevents. We have known instances of dysentery, which had received but a temporary removal from the alternation of cathartics and anodynes, yield at once to the combination of them, especially of opium with calomel. Dr. Cleghorn, after mentioning two modes in which dysentery begins, observes, "in both cases, when other means have failed, six or seven grains of calomel, with a grain of opium at night, (after the use of the *semicupium*), and a purging apozem, made of senna, manna, and sal catharticum, the next day proved successful, and brought off a prodigious quantity of round, hard, fecal lumps, to the great relief of the patient: nor is it easy to conceive," he adds, "how so much had been collected, or where it had lodged so long, as in some cases I have observed; the patient having eat nothing for two or three weeks that could furnish much excrement, and during that time had taken several glysters and common cathartics, which brought away liquid stools." (On the Diseases of Minorca, chap. v. p. 252.) In such cases, it is clear that the opiate aided, instead of impeding, the operation of the cathartic; probably by relaxing the contraction of the muscular fibres of the bowels, which we have already noticed as constituting part of the disease, and which retained the hardened excrement, in spite of the operation of cathartics alone.

II. But if medicines have been altogether neglected, or improperly or unsuccessfully administered, during the early and acute stage of the disease, the fever becomes more of a hectic form; the pulse more feeble and small; the strength is considerably impaired; and the body more or less emaciated; while the griping and tenesmus remain, and the stools continue small, frequent, and slimy; with various other appearances of the feces, which require attention, as indicating the probable degree and mode in which the intestines are disordered; such as simply slimy or mucous eva-

cuations, those streaked or tinged with blood, or containing ragged membranous appearances, scybala, or purulent and fanious matter.

In this stage of the disease, evacuation of the offending matter from the bowels is still the leading object of medicine; with this difference, that the mildest means are now more requisite, and that it may be particularly useful to soothe the inflamed intestines from the acrimony of morbid and acrid secretions; to aid the operation of laxatives, by means of bland, mucilaginous, or oleaceous fluids; and to procure a respite from pain and spasm by anodynes. For the former purposes, the castor oil has been particularly recommended, or any mild oil combined with tincture of rhubarb. Manna, and the mild neutral salts, sometimes combined with oil or manna, have likewise been successfully employed; and the neutral salts, with mucilaginous diluents, and opiates in conjunction, are well adapted to these purposes. Emollient and anodyne glysters were found beneficial by sir John Pringle in this stage of the dysentery; such as a decoction of linseed, or of starch, or fat mutton broth, in the quantity of from four to eight ounces, according as more or less could be retained. When the irritability of the lower bowels and tenesmus were so great, that those glysters were rejected, the tincture of opium was added. But sir John acknowledges, that the parts were often so tender, as to render it impossible to adopt that practice. And in fact it not infrequently happens, that the introduction of the pipe into the *anus* cannot be borne, in consequence of the inflamed and excoriated state of the *rectum*. In such cases, a pill of opium may be sometimes introduced within the gut with great relief to the frequency of the motions, and to the griping and tenesmus.

The food and drink should be contrived of a bland and demulcent nature. With this view, the diet may consist chiefly of rice or barley gruel, of sago, arrow-root, panada, light pudding, or preparations of milk. Animal broths were at first allowed by sir J. Pringle, when the patients were but slightly feverish; but experience taught him, that a milk food in any form was in general improper. Objections have been made to the use of milk diet in dysentery, in consequence of an observation of the author just named, that some white substances, passed in the stools, and which have been called *corporea pinguis*, were found, in a case examined by Dr. Huxley and himself, to be pieces of *cheese*. But it is much less difficult to suppose, that these cheesy matters were the remains of that indigestible substance, which had lain in the intestines since the commencement of the disease, like the *scybala* mentioned by Dr. Cleghorn, than to believe that an actual cheese-making process goes on in the alimentary canal, from the milk that is swallowed. We cannot but deem a milk-diet the most favourable to recovery, while the hectic fever is kept up in consequence of slow inflammation, or ulceration, in the internal coat of the lower intestines.

For drink, in this stage of the disease, rice or barley-water, toast and water, linseed tea, or a decoction of starch with gum-arabic, seasoned with some simple cinnamon water and sugar, have been employed; and preparations of wax have been long in repute for their virtues in dysentery. Bates recommended a solution of it in spirits, and Diemerbroeck praises it when dissolved in milk. In a spirituous form it is to be strongly deprecated; and the oily and mucilaginous demulcents appear to be on the whole preferable to wax. M. Senac, physician to the French army, informed sir J. Pringle, that after bleeding and administering an emetic of tartarised antimony, he succeeded in curing dysentery by giving one grain of that antimonial, dissolved in a pint of common whey or chicken-water, every day, in divided draughts,

draughts, which served for all food, drink, and medicine, till the patient recovered.

For mitigating the griping pains, and relieving flatulency, stimulant *carminatives*, as they have been called, ought not to be employed. Fomentations or the warm bath are often serviceable for this purpose; but the symptoms are most effectually relieved by a free evacuation of the bowels, from a laxative combined with an opiate. Where morbid acidity prevails in the first passages, with heartburn, the absorbent earths, such as chalk and magnesia, are beneficial.

When the flux continues till the strength is much impaired, and the pulse sinks, while the hectic heats remain, the danger is great: though there are still hopes, as long as there are neither involuntary stools, nor *aphthæ*, nor a hiccup, and while the patient does not complain of great lowness and anxiety about the *præcordia*. If these symptoms are present, the case is most unfavourable, and scarcely admits of palliatives; since opiates have but little effect in easing the pain, or checking the frequency of the stools.

III. But if the general symptoms of the disease are removed, and the patient is chiefly kept low by the irritation of a tenesmus, or by frequent returns of a diarrhoea, from the weakness of his bowels, opiates, astringents, and bitters will be used with advantage. The tenesmus, in this case, is occasioned principally by the increased sensibility and tenderness of the bowels, especially of the *rectum*, which renders the passing of every matter, even the proper secretions, painful. The introduction of a pill of opium, with or without the extract of *cicuta*, is often in such instances particularly useful. Sir J. Pringle recommends a preparation of mutton suet in milk, with a little finely powdered starch, to be taken internally as food, under the same circumstances. When the stomach and bowels are so enfeebled, that a *lientery* is occasioned, the food being carried off imperfectly digested, the astringent vegetable substances, such as logwood, *catechu*, *sinarouba*, &c. with opiates, must be administered. Diaphoretic medicines, by tending to restore the exhalation from the skin, and thus to alter the determination of fluids to the intestines, are also frequently beneficial.

During this astringent course, attention to the diet will still be requisite. It should still be of a light, easily digestible, and nutritious quality, consisting much of milk, vegetable starches, such as sago, salep, and arrow-root, rice, and the common *farinacea*; greens, and other laxative and stultent articles, being sparingly used or avoided. It has been remarked by the best writer on this subject, so often quoted, (Pringle,) that he has often known a cure obtained, when astringents have been of no avail, by a milk and farinaceous diet, without them.

Together with the use of these remedies, exercise in the open air, regularity of life in respect to the hours of eating, sleeping, and rising, and every other means of restoring the functions, should be adopted: and nothing is more conducive to prevent relapses of the flux, or of the diarrhoea, than warm clothing, especially the use of flannel worn next the skin. See Pringle on Diseases of the Army, p. iii. c. 6. Cleghorn on the Dis. of Minorca. Cullen First Lines, § 1067. See also an ample list of references in Cullen's *Nofology*, gen. 4r.

DYSMENORRHOEA, painful menstruation.

In some women, more especially about the period of puberty, the discharge of the catamenia is preceded and accompanied by pain, sometimes in a very violent degree, about the loins and pelvis, and other parts connected with the uterus. The stomach often sympathizes with this morbid condition of that organ, and nausea, loss of appetite, and even vomiting take place; and there is a general languor of

the whole frame, sometimes amounting to actual fainting. This disorder occurs most commonly in delicate females, and the health is usually indifferent in the intervals; occasionally there is a slight discharge of the nature of *leucorrhœa*. Very rarely it has been observed that this pain and disorder have attended every period of menstruation through life.

The patient should be kept quiet, or confine herself to bed, when the period returns; the bowels should be kept gently open, and warm diluent drinks used freely. The two expedients, which afford the most effectual relief, are the use of opium, either internally or by glyster, or both; and the warm bath, or semi-cupium, the good effects of which are partially obtained by fomentations to the lower region of the abdomen, and to the lower extremities. Dr. Hamilton, the present professor of midwifery at Edinburgh, recommends the free use of the inspissated juice of the hyoscyamus, as a preferable narcotic in this painful complaint. He orders from two to four grains every hour, till the pain is mitigated. The earlier the medicine is administered the better, and the smaller the dose of the medicine required to produce relief. Opium, however, has seldom failed, under our observation, to alleviate the disorder. The following are the observations of Dr. Fothergill upon this topic.

Let the patient have by her a few pills of the *extractum thebaicum*, one grain each, made soft with a little of any kind of conserve. She is to take one of these pills the moment she finds the pain attending this discharge coming on. A pill may be taken every hour till the pain goes off; they seldom require more than two of these pills; one is often sufficient, if given early; and it ought to be a constant rule observed in administering anodynes, to give them, when they are plainly indicated, early. It requires much less of an opiate to obviate pain than to quiet it when acute.

When the time is past, a course of chalybeate bitters, in small doses, may be continued till within a few days of the return; and the belly should be kept open by some proper laxative: two or three grains of the *calabaric extracta*, with half the quantity of *calc antimonii illata*, taken every night, will often succeed perfectly well. The anodyne must still be in readiness to take when the pain comes on, and to be taken to such a quantity as to mitigate the pain, be the dose what it may.

This excruciating pain seems to be spasmodic, and to proceed from the extreme irritability of the uterine system: the blood naturally determined hither, in order to its being discharged, by distending the very irritable vessels, occasions the spasm; this produces a constriction of the vessels; they become impervious, and the *nisus* to the discharge continuing, the pain becomes exquisite and general, till the patient, worn out with the struggle, is debilitated and sunk; the fluids are then dismissed, some ease succeeds, but the patient is often so reduced, as not to recover her usual strength before she has another conflict to undergo.

Dr. Fothergill remarks that the *fluor albus* is frequently the consequence of this struggle, and that it would seem as if the uterus itself was so far a sufferer as to be rendered by degrees less fit for fecundation. I think it has been observed by other physicians, he adds, as well as myself, that few of those who have suffered much in the manner here described, have borne children. See *Medical Observations and Inquiries*, vol. v.

DYSODA, in *Botany*, from *Dysodum*, *setidum*, a name given by Loureiro to the *Lycium foetidum*, which he rightly separated from *Lycium*, but which Justu us has called *Scriffia*, and the latter is now adopted. See *SERISSA*.

DYSODIA, in *Medicine*, from *δύς*, and *ὄζον*, *osco*, is a

genus of disease constituted by Sauvages, including the variety of fetid exhalation or bad smells arising from the body, as from sores, bad breath, &c. See his *Nofol. Meth. clafs ix. g. 35.*

DYSOPIA, is the title of a *genus* of disease in Dr. Cullen's arrangement, synonymous with the *amblyopia* of Sauvages, and comprehending those varieties of depraved or imperfect vision, which require a particular quantity of light, a particular distance, or position of the objects. The term includes the *hemeralopes* and *nyctalopes* of authors, or those who are blind except in twilight or in the broad day-light, and also the *short sighted*, &c.

DYSOREXIA, from *dys* and *ορεξις*, appetite, or desire, sometimes used as synonymous with ANOREXIA, or loss of appetite for food. Dr. Cullen has adopted the term, as the title of the second order of his fourth class of local diseases, including the deranged or erroneous appetites and desires, as well as those which are defective; such as *Bulimia*, or canine appetite; *Polydipsia*, or excessive thirst; *Pica*, or appetite for things not eatable; *Satyriasis*, *Nymphomania*, *Anaphrodisia*, &c.

DYSORUM MONS, in *Ancient Geography*, a mountain, which, in the time of Herodotus, separated Thrace, towards the coast of the sea, from Macedonia. It was at a small distance from the lake Prasias, and from a silver-mine, which had sometimes yielded a talent per day. Herod. l. v. 17.

DYSPEPSIA, DYSPEPSY, in *Medicine*, from *dys* and *πεψισ*, to digest, or concoct, a weakness or derangement of the function of digestion. See DIGESTION.

This weakened condition of the digestive power in the stomach is connected with a variety of complaints, which, together or separately, mark its presence in different instances: such as NAUSEA; VOMITING; heart-burn, or CARDIALGIA; pain of stomach, or GASTRODYNIA; FLATULENCE; PYROSIS, or water-brash; &c. which see respectively.

It is also often a prominent feature in what are denominated NERVOUS diseases, in HYPOCHONDRIASIS, and some cases of MELANCHOLY, of all which, in fact, the derangement of the digestive organs is frequently the exciting or proximate cause. It is also generally the precursor of the paroxysm of regular GOUT. See INDIGESTION, and the articles here alluded to.

DYSPERMATISMUS, from *dys*, and *σπερματισμος*, *seminatio*, a slow, impeded, and insufficient emission of the seminal fluid, in the generative act.

The causes by which this impediment is induced may be arranged under a few heads. 1. Diseases of the urethra, which narrow the canal; as thickening of the parietes, strictures, ulcers with elevated edges, caruncles, or excrescences, fungous enlargements of the corpus spongiosum, &c. (See Sharpe's *Critical Enquiry*, chap. 4.) constituting the dyspermatismus *urethrae* of the nosologists. 2. Nodes, or hard tumours, in the corpora cavernosa (D. *nodosus*.) 3. A contraction of the prepuce (D. *preputialis*, or *phymosicus*.) (See Arantius de *Tumor prater natur.*) 4. Mucus lodged in the urethra (D. *mucosus*.) 5. A too rigid extension of the virile member, contracting the canal of the urethra. (See Edin. Med. Essays, vol. i. art. 35.) (D. *hypertonicus*.) 6. A general epileptic convulsion (D. *epilepticus*.) 7. An imperfect extension of the member. (D. *apradnodes*.) (See Etmuller de *Morb. virorum*, cap. 2. p. 469. Veslingii *Epist.* et *Obs. Ep.* 38. Forest. lib. xxvii. obs. 18 and 19.) 7. The fluid being directed towards and flowing into the bladder. (D. *reflusus*.) (See Petit, in *Act. Acad. Chirurg.* tom. i. p. 434.) This reflux of the semen into the bladder Mr. Sharpe ascribes generally to a schirrus, or sometimes a spongy enlargement of the verumontanum, with or without

ulceration, or to an obstruction in some part of the urethra. This species of the disease under consideration is not very uncommon. See Sharpe *loc. cit.* Sauvages *Nofol. Method. clafs. ix. gen. 31.*

DYSPHONIA, from *dys* and *φωνη*, voice, a difficulty of speech.

DYSPNŒA, from *dys*, and *πνῆσις*, I breathe, a difficulty of breathing.

Difficulty of breathing originates from a great variety of causes, and is a symptom connected with a great number of diseases. Whatever impedes the entrance of the air into the cells of the lungs, obstructs the circulation of the blood through them, prevents their free expansion, or narrows the cavity of the chest, will necessarily be an impediment to the act of respiration. When the difficulty of respiration is so great, as to render it necessary for the patient to maintain the erect posture, it is termed ORTHOPNŒA.

1. Among the impediments to the free passage of the air into the cells of the lungs, which occasion dyspnœa, may be enumerated, the thickening of the membranes of the passages from inflammation, and the consequent effusion of mucus, or coagulable lymph, as in CATARRH, and CROUP, in which a frequent cough is excited by the irritation of these secretions, which enables the lungs to dislodge them. In the chronic catarrh of old people, in the *Balsard* PERIPNEUMONY, and in ASTHMA, these mucous secretions are most copious, and, by filling up the cells and tubes of the lungs, occasionally produce actual suffocation. In the paroxysm of asthma, the difficulty of breathing appears to be augmented by a spasmodic contraction of the *glottis*, which still farther impedes the free passage of the air. Inflammation of the lungs, both in the form of PLEURISY and PERIPNEUMONY, is accompanied by dyspnœa in consequence of the congection of blood, and the effusion of serum, blood, or lymph, into the cells of the lungs, which, when the disease is violent, usually ensue; and often destroy the patient by a fatal interruption to the breathing.

The cells of the lungs are compressed, and the admission of air therefore prevented, by tumours, and collections of fluids, in their substance; hence dyspnœa is occasioned by the presence of pus, consequent on acute inflammation of the lungs, in the form of VOMICÆ; and by the presence of tubercles, hydatids, steatomatous, or other tumours, and of serum effused into the cellular membrane, constituting the *anasarca*, or *hydrops pulmonum*. See DROPSY of the Lungs.

2. Whatever obstructs the pulmonary circulation to a considerable extent also occasions dyspnœa. If the blood is prevented from flowing freely back to the heart, a congestion is produced in the lungs, which necessarily compresses the cells and air-tubes; and if, on the other hand, the blood is impeded in its way to the air cells, then it is imperfectly changed by the influence of the air, and the sensation of suffocation, and laborious respiration equally ensue. Polyposy concretions about the heart, aneurysms of the heart or great vessels, ossification of its valves, &c. contribute to produce these morbid states of the circulation. See CARDIOMUS and ANEURYSM.

3. Whatever prevents the free expansion of the lungs necessarily impedes the function of respiration. Thus dyspnœa, often orthopnœa, is a constant attendant on *hydrothorax*, when the water, effused into the cavity of the chest, occupies that portion of the cavity, which the expanded lungs would otherwise fill. (See *Dropsy of the Chest*.) When *venice* burst, and their purulent contents are poured into the same cavity, the elastic produced on the lungs is the same as that of *hydrothorax*, but the dyspnœa is not augmented by this process, since the compression of the lungs,

by the same quantity of matter internally, was nearly the same previously. (See *EMPEMA*.) In a similar way *DROPSY of the pericardium* compresses the lungs, and induces *dyspnoea*: and *BRONCHOCELE*, or swelling of the thyroid gland, by externally compressing the *trachea*, or wind-pipe, sometimes is accompanied with difficulty of breathing.

4. Whatever narrows and diminishes the cavity of the chest, necessarily likewise prevents the free expansion of the lungs, and therefore produces the same effects on the respiration. Hence *dyspnoea* is occasioned by any large tumour, or fluid collection in the cavity of the abdomen, which presses the diaphragm upwards: such as a copious secretion of fat in the *omentum*, and other parts, (see *CORPULENCE*); or scirrhus, sciatomatous, or other solid tumours; the gravid uterus, in the latter stages of pregnancy; *ajistes*, or *DROPSY of the belly*; *TYMPANITES*, or the distension of the abdomen by flatus; *HYDATIDS*, &c.

The *dyspnoea*, occurring from these various causes, will require the different remedies for its relief, which are adapted to alleviate the diseases, of which it is a part; and its nature will be discriminated by an accurate observation of the train of symptoms, with which it may be accompanied, and which characterize those diseases, to which therefore we refer respectively.

DYSTICHIASIS, (from *δυσ*, bad, *σχίσις*, order,) an irregular arrangement of the eyelashes.

DYSURIA, (from *δυσ*, difficultly, and *ουρη*, the urine,) a difficulty of discharging the urine.

DYTISCUS, in *Entomology*, a genus of *COLEOPTERA*, of the aquatic kind, distinguished by having the antennæ setaceous; feelers six in number, and filiform; hind legs formed for swimming, fringed on the inner side, and nearly unarmed with claws. The species are inhabitants of stagnant waters, and from the peculiar structure of their legs are able to swim extremely well; they are seldom observed on the wing, except in the night time, when they fly abroad in search of other waters. The males have a horny concave flap or shield on the fore legs. The larvæ subsist on worms, aquatic insects, and the fry of fish, the latter of which they destroy in vast numbers when first hatched from the egg. They seize their prey by means of their strong forcipated jaws, and destroy it by sucking out the moisture. Linnæus included under the generic name of *dytiscus*, the insects which later writers comprehend under the two genera *dytiscus* and *hydrophilus*. It is understood that Linnæus, aware of the impropriety of uniting those two distinct natural families, intended afterwards to separate them into two genera. Fabricius has since divided them; the character of his genus *hydrophilus* consists in having four filiform feelers; the maxilla bifid; lip horny, and sub-emarginate; and the antennæ clavated and perfoliated; and his *dytiscus* six filiform feelers; the lip horny, truncated and entire, and the antennæ setaceous. Gmelin adopts the genus *hydrophilus* in his edition of the *Systema*.

Species.

LATISSIMUS. Black; margin of the wing-cases dilated, with a yellow line. Linn. Fn. Suec. 768. Fabr. Spec. Inf. *Dytiscus amplissimus*, Müll. *Scarabeus aquaticus*, &c. Frisch.

Native of Northern Europe; the female sulcated, male smooth and polished.

COSTALIS. Black; band on the head; margin of the thorax, and costal streak on the wing-cases ferruginous. Fabr.

The head is black, and marked above the mouth each side with an impressed dot; wing-cases smooth, with three re-

mote punctured striæ. In the female the colours more obscure. Inhabits Surinam.

MARGINALIS. Olivaceous black; margin round the thorax and exterior margin of the wing-cases yellow. Linn. Donovan. Brit. Inf. *Le Ditique noir à bordure*, Geoffr. *Hydrocantharus nigras*, Ray.

Native of Britain, and other parts of Europe.

ROSELLI. Greenish; shield, with the margin of the thorax and wing-cases white, the latter glabrous, with three punctured striæ. Fabr. *Dytiscus dispar*, Roffo.

Inhabits waters in France.

PUNCTULATUS. Black; shield, margin of the thorax and wing-cases white; wing-cases with three rows of dots. Geoffr. *Dytiscus punctatus*, Olivier.

Found in waters in England and Germany. The head is black with a brown frontal spot; body beneath black; legs testaceous.

LIMBATUS. Black; exterior margin of the thorax and wing-cases yellow; the latter very smooth. Fabr.

A native of China, in the Bankian cabinet. The legs in this species are black, with the thighs of the anterior pair ferruginous; the abdomen black.

RUFICOLLIS. Black; front and thorax fulvous; wing-cases with the exterior edge and streak at the base testaceous, Fabr.

Inhabits Siam. The head fulvous with the margin black; wing-cases glabrous; anterior legs yellow. Bankian cabinet.

SULCATUS. Wing-cases brown, with ten longitudinal villous grooves. Linn. Donovan. Brit. Inf. &c.

Native of Europe. The head is black; the mouth and eyes yellow; thorax black, with margin and character on the back yellow; margin of the wing-cases yellowish; body beneath with the legs black.

FASCIATUS. Wing-cases yellow, with two black bands and a black dot at the tip. Fabr.

Inhabits waters in India. The head is yellow; thorax yellow with a black dorsal line, and two small red spots on the back; wing-cases smooth with black future.

STRIATUS. Brown; thorax yellow, with an abbreviated black band; wing-cases finely striated transversely. Linn. Common in waters in Europe.

FUSCUS. Deep brown; margin of the thorax yellow; wing-cases very finely striated transversely. Linn.

Found in waters in Europe. Resembles *striatus*, but is rather less. The head is black; wing-cases imprefred with two striæ of dots; body black; legs ferruginous; thighs black.

LAMIO. Black; mouth, two dots on the crown, and margin of the thorax rufous; wing-cases brown. Fabr.

The head is brown; wing-cases marked with two lines of imprefred dots. Native of Madeira, described from the Bankian cabinet.

CICURUS. Black, smooth; mouth, dot on the crown and margin of the thorax rufous; wing-cases striated with yellow. Fabr.

Found by Vahl at the Cape of Good Hope. The head is deep black, the spot between the eyes large; eyes silvery dotted with brown; thorax with a rufous dorsal line; body black.

VITTATUS. Black, smooth; wing-cases with a yellow marginal silet, and black spot at the base. Fabr.

Described from the Hunterian museum as a native of India. The head is black; mouth yellowish; thorax black; spot at the base of the wing-cases large and oblong.

CINEREUS. Ashy; margin of the wing-cases and half the thorax yellow. Linn. *Le Ditique à corcelet à bandes*, Geoffr.

Common in waters in Europe. The head is black, mouth yellow,

DYTISCUS.

yellow, body beneath black with yellow spots on the sides; legs black and yellow; antennæ yellow.

GRISEUS. Cinerous; wing-cafes with an indented black band. Fabr.

A native of Irdia. The head is yellow with a transverse frontal black spot; thorax grey with two transverse black spots on the back; body beneath yellowish.

STICTICUS. Palish; wing-cafes grey with an oblong impressed lateral spot of black. Linn.

Inhabits Africa. Wing-cafes marked with two very obscure lines of brown dots.

10-PUNCTATUS. Black and glabrous; wing-cafes with five white dots. Fabr.

Native of New Holland, described from the Bankian cabinet. The antennæ are short and ferruginous; head black with the front palish; thorax with a pale marginal spot each side; legs fuscous.

FULIGINOSUS. Black; mouth and margin of the wing-cafes ferruginous; head immaculate. Fabr.

Inhabits waters in Germany. Body black; mouth and legs ferruginous.

BIPUNCTULATUS. Smooth, deep black; head with two red spots behind. Linn.

Native of the North of Europe. The red spots on the head are very minute.

CINCTUS. Head and thorax yellow; wing-cafes black; margin entirely white. Fabr. An American species.

BIPUNCTATUS. Deep black, thorax yellow, with two dots of black; wing-cafes varied with yellow and fuscous. Fabr. D'nov. Brit. Inf.

Found in waters in Germany, and also in England. The head is black, the mouth subferruginous; the thorax yellow, with two black dorsal spots; wing-cafes smooth, glabrous, and fuscous; and body black with ferruginous legs.

FENESTRATUS. Beneath ferruginous, above black; wing-cafes with two transparent dots. Fabr.

Described by Fabricius from a specimen in the cabinet of Schulz, found in the vicinity of Hamburg. The species has been since taken by Panzer in Aultria, and in England. See Marsh. Ent. Brit. The head is black; mouth, antennæ, and two dots at the base ferruginous; thorax black with ferruginous margin.

HYENERI. Smooth, deep black; mouth and margin of the thorax ferruginous; wing-cafes with a marginal yellow line. Fabr.

Discovered in Germany by Hybner.

STAGNALIS. Smooth, black; anterior part of the thorax ferruginous; wing-cafes brown with yellow lines. Fabr.

Inhabits same country as the former.

TRANSVERSALIS. Deep black; anterior part of the thorax ferruginous; margin of the wing-cafes, and abbreviated streak at the base yellow. Müll.

Found in Northern Europe.

CALIDUS. Deep black; wing-cafes as the base and exterior margin ferruginous; sternum advanced and compressed. Fabr.

Native of South America, discovered by Smidt. The head is black; antennæ and mouth dull ferruginous; wing-cafes speckled with yellowish.

HERMANNI. Gibbous; head, thorax, and wing-cafes ferruginous at the base; wing-cafes truncated. Fabr. *Dytiscus tardus*, A.G. Berol.

The head is dull ferruginous, with the orbits of the eyes black; wing-cafes smooth; abdomen ferruginous with black tip. Found in Alsace.

ABBREVIATUS. Black; wing-cafes, with an abbreviated streak at the base, and two dots yellow. Fabr.

Native of Germany.

GIBBUS. Gibbous, ferruginous; wing-cafes black with pointed tips. Fabr.

Taken in stagnant water in Kiel by Schedstedt. The head is ferruginous, and rather blackish at the base; the thorax ferruginous, with the posterior edge black; wing-cafes smooth, the base and margin obscurely spotted with ferruginous; body and legs ferruginous; and the abdomen black at the tip. There is a variety with the head and thorax entirely ferruginous.

ULIGINOSUS. Deep black and glossy; antennæ, legs, and exterior edge of the wing-cafes ferruginous. Linn.

Found in waters in Europe.

ERRORATUS. Testaceous, speckled with black; head and breast black. Fabr.

Inhabits America. The head is black, with testaceous mouth; thorax glossy, smooth, and shining; abdomen and legs testaceous.

AGILIS. Black; mouth, thorax, margin of the wing-cafes, and the legs ferruginous. Fabr.

Native of Germany.

MACULATUS. Black; thorax with pale band; wing-cafes black, spotted with white. Marsh. Linn. &c.

Found in waters in Europe.

ERYTHROCEPHALUS. Ovate-oblong; head and legs rufous. Linn.

Native of Sweden and Denmark.

PLANUS. Ovate-oblong, flat, black; the flanks entirely rufous. Fabr.

Inhabits waters in Denmark. Lund.

VARIUS. Thorax rufous; wing-cafes striated with cinereous and black. Fabr.

Discovered in Patagonia. The head is black; mouth and antennæ rufous; wing-cafes with numerous black streaks, variegated with cinereous and black, and black future. Cabinet of Sir Joseph Banks.

NOTATUS. Fuscous, with yellow thorax, and four black dots; wing-cafes with fuscous yellow striæ. Fabr. *Dytiscus notatus*, Bergstr.

Native of waters in Germany.

BICOLOR. Above deep black; wing-cafes striated; beneath ferruginous. Fabr.

Found in Guinea.

RUFIPES. Black; head and anterior part of the thorax ferruginous; wing-cafes black, with ferruginous striæ. Fabr.

A small species. The body is black; legs rufous.

DEPRESSUS. Thorax ferruginous, with two black dots at the base; wing-cafes fuscous, with ferruginous spots.

Native of Sweden.

DORSALIS. Head, margin of the thorax, spot at the base of the wing-cafes, and unequal margin, ferruginous. Fabr.

Inhabits Kiel, and resembles the following species.

SXPUSTULATUS. Deep black; head ferruginous; wing-cafes with three rufous spots; that at the base larger. Fabr.

A minute species found in the waters of Sweden.

PALUSTRIS. Smooth; wing-cafes with two lateral white blotches. Linn.

Native of Europe; the thorax is ferruginous.

OVATUS. Ovate, fuscous; head and thorax ferruginous. Linn. *Dytiscus sphericus*, Degger.

An European species.

DYTISCUS.

PICIPES. Black; anterior part of the thorax ferruginous; wing-cafes lined with yellow. Fabr.

This is a native of Germany. The head is black; the mouth ferruginous; body black; legs pitchy.

LATURATUS. Black; wing-cafes with a pale blotch at the tip and base. Fabr.

An Italian insect. The body is small, depressed, and black; and the legs pitchy.

CHRYSOMELINUS. Above cinereous, beneath black. Fabr.

A species of small size, found in Germany.

SIGNATUS. Black; head and thorax rufous, with black marks. Fabr.

Native of Patagonia, described by Fabricius from the Bankian cabinet.

12-PUSTULATUS. Testaceous; wing-cafes black, with six testaceous spots. Fabr.

The head and antennæ are testaceous; the thorax testaceous; with the front and posterior margin black.

8-PUSTULATUS. Black; front, sides of the thorax, and four marginal dots on the wing-cafes, ferruginous.

A species of moderate size, found in Sweden.

HALENSIS. Black; thorax rufous; the base black in the middle, with a rufous dot; wing-cafes cinereous, striated with black. Fabr. Hybner, &c.

A small insect, of a flattish form; the head rufous, and immaculate; black streaks on the wing-cafes numerous, confluent, and approximate. The species inhabits Germany.

RUFIFRONS. Black; head, thorax, and margin of the wing-cafes, with a dot at the base ferruginous. Fabr.

Inhabits France.

GRANULARIS. Black; wing-cafes with two yellowish lines; legs rufous. Linn. *Dytiscus minimus*, Scop.

Native of Northern Europe.

CONFLUENS. Black; head and thorax ferruginous; wing-cafes pale, with four black lines on the disk. Fabr.

Inhabits Kiel in Germany. The legs in this species are yellowish.

OBLIQUUS. Ferruginous; wing-cafes with five oblique brown spots. Fabr. *Dytiscus laminatus*, Schulz.

The head, thorax, and body, ferruginous; the exterior fuscous spot binate; legs ferruginous.

IMPRESSUS. Oblong, yellowish; wing-cafes cinereous, with streaks of impressed dots. Fabr. *Dytiscus impresso-striatus*, A&E. Hal.

Native of Europe. The body oblong, and tapering before.

SEMIPUNCTATA. Oblong, ferruginous; head of the base black; wing-cafes dusky, at the tip punctured. Fabr.

Inhabits the East Indies, and is of a small size.

CRUX. Oblong, deep black; the whole body ferruginous with a black cross. Fabr.

Found in Italy. This species is very small, and glossy-black.

GEMINUS. Oblong, deep black; two dots on the thorax, two lines at the base, and dot at the tip white.

A minute species, found in Saxony.

LINEATUS. Ferruginous; wing-cafes brown, with yellowish lines. Fabr.

Native of Alsace.

INÆQUALIS. Ferruginous; wing-cafes black, unequally ferruginous at the sides. Fabr.

The head is ferruginous, with black orbits; thorax ferruginous; behind black; wing-cafes smooth and black; body beneath ferruginous.

Inhabits Sweden.

PYGMEUS. Ferruginous, wing-cafes black; margin ferruginous. Fabr.

Native of Denmark. A small species.

RETICULATUS. Ferruginous; disk of the wing-cafes black, reticulated with ferruginous. Fabr.

Small. Its native place unknown.

CRASSICORNIS. Fuscous; head and thorax yellow; antennæ thick in the middle. Müll. Zool. Dan.

The antennæ of this species are curious; the colour yellow; with the middle joints thickened, and apparently cleft; wing-cafes brown; with the base yellowish.

FLAVIFES. Flat, deep black; base of the wing-cafes, and the legs ferruginous. Fabr.

A small species found in the East Indies.

PICTUS. Ferruginous; thorax black; wing-cafes pale; suture and lateral spot black. Fabr.

Native of Germany. Hybner.

NIGRITA. Deep black and immaculate; antennæ and legs ferruginous. Fabr.

Inhabits Germany. This species is very minute, broad, deep black, and immaculate; antennæ and legs large, and ferruginous.

PUSILLUS. Deep black; thorax and wing-cafes margined with white. Fabr.

Native of Italy.

PARVULUS. Gibbous, black; thorax with a ferruginous band on the fore-part; wing-cafes with ferruginous spots. Fabr.

Inhabits Denmark, and is a small species. The head is black; front and antennæ ferruginous; wing-cafes punctured with numerous rufous spots; body black; legs rufous.

OVALIS. Wing-cafes fuscous, with pale lines; thorax ferruginous; abdomen deep black. Thunberg.

Native of Upsal.

INTRICATUS. Yellowish; above black-green; wing-cafes with excavated striae, edged and tipped with yellow; thorax yellow. Schall. Abh. *Dytiscus semifulcatus*, Müll.

Found in Saxony. In size and appearance resembles the species punctulatus.

VERSICOLOR. Fulvous; wing-cafes with oblong black spots. Schall.

Inhabits Saxony.

SCHALLERI. Black; head, thorax, and legs, ferruginous; wing-cafes fuscous; outer margin rufous. Schall.

Native of Saxony, where it appears to be not very uncommon.

LAMINATUS. Fulvous; wing-cafes striated with black dots; abdomen with two plates at the base. Schall.

A rare species, found in Saxony.

ACICULATUS. Margin of the thorax and wing-cafes, and three spots on the abdomen yellow; wing-cafes with hollow decussating striae. Herbt.

An inhabitant of India.

FUSCULUS. Black; wing-cafes smooth and brown; legs dull testaceous. Schrank.

Found in Upper Austria by Schrank, and by Geoffroy in France.

OCULATUS. Head cinereous; posterior margin, and two triangular spots in front black; wing-cafes piecous, edged with yellow. Herbt.

Inhabits the environs of Berlin, and measures less than half an inch in length.

ORNATUS. Black, beneath piecous; mouth, spots on the thorax and antennæ ferruginous. Herbt.

Native

Native of the vicinity of Berlin, and rather smaller than the last.

UNILINEATUS. Black; divided margin of the wing-cafes, and line half-way down yellowish. Schrank.

Inhabits Germany.

DISPAR. Black, smooth; mouth yellow; wing-cafes variegated, and with the thorax picceous. Herbit.

Inhabits Prussia, and with the ten following species has been met with in the vicinity of Berlin.

SORDIDUS. Black; antennæ ferruginous, with black tips; legs picceous; wing cafes deep-black. Herbit.

AQUATICUS. Chestnut; eyes, wing-cafes, thorax, and belly black; margin of the thorax and band across the middle chestnut; wing-cafes obscurely.

PARVULUS. Beneath picceous; head and thorax fulvous; wing-cafes black; the margin and two striae half-way down yellow. Herbit.

PICCOLUS. Beneath black; head and thorax chestnut; wing-cafes picceous, with an obscure fulvous margin. Herbit.

SIMPLEX. Black; head, margin of the thorax, and wing-cafes, with the antennæ and legs picceous. Herbit.

CAPRICORNIS. Yellowish; belly and eyes black; middle joints of the antennæ much broader; wing-cafes brown with hollow dots. Herbit.

VARIOLOSUS. Yellowish; beneath brown-yellow; eyes black; wing-cafes yell with-green variegated. Herbit.

ORBICULARIS. Black, smooth; antennæ and legs ferruginous; thorax and wing-cafes yellow-brown, pellucid with obsolete black spots. Herbit.

PEDICULARIUS. Smooth; beneath, thorax, and wing-cafes brown; head black; legs picceous. Herbit.

MARGINELLUS. Black; thorax edged with yellow; wing-cafes yellowish, regularly punctured with obsolete blackish spots. Herbit.

SEMINULUM. Black, smooth; wing-cafes pellucid, chestnut tipped with red; legs ferruginous. Herbit.

OBLONGUS. Dull-black; head, antennæ, and legs ferruginous. Herbit.

ZEYLOXICUS. Black; thorax and wing-cafes margined with yellow; sternum unarmed. Gronov.

Inhabits Ceylon.

GLABER. Brown; wing-cafes glabrous; belly and legs ferruginous. Forst.

Native of England.

NEBULOSUS. Livid clouded with black; antennæ and legs ferruginous; belly black, edged with ferruginous. Forst.

Inhabits England, and is the same size as the species uniginosus.

EXOLETUS. Livid; antennæ, head, thorax, abdomen, and legs pale. Forst.

Inhabits England.

DANICUS. Black; outer margin of the thorax, and the wing-cafes yellow. Müll.

This and the twenty following species are natives of Denmark.

MÜLLERI. Wing-cafes pointed, glabrous, and marked with two dots at the tip.

LACUSTRIS. Yellowish; thorax edged with yellow; wing-cafes sprinkled with dots.

PICEUS. Black; body beneath, and margin of the thorax, and wing-cafes ferruginous.

FÆTIOLUS. Ferruginous; above black; exterior margin of the thorax and wing cafes yellow.

COMMA. Yellowish; above brassy-black; wing-cafes with the outer edge and line yellow.

4-PUNCTATUS. Ferruginous; wing-cafes black, with a white band, spot, and four dots.

BIOCOLLATUS. Rufous; wing-cafes brassy, with white spots disposed longitudinally.

ERYTHROMELAS. Black; antennæ and tarsi rufous.

RORIDUS. Yellow; thorax with a black spot in the middle; wing-cafes speckled with black.

RUBRIFES. Black bronzed, polished; antennæ, and legs, tip of the wing-cafes, and two dots ferruginous.

QUADRICOLOR. Ovate, rufous; middle of the thorax black; wing-cafes brown; the lower margin and dot at the base yellow.

CIMICOIDES. Greenish; wing-cafes with a white lower margin, and a few white spots.

VELOX. Ovate, rufous; wing-cafes with eight brown striae.

NANUS. Black; thorax yellow on the fore-part; wing-cafes with an abbreviated groove; legs picceous.

RUFIFRONS. Black; thorax yellow each side; wing-cafes yellow at the base and sides; head and legs rufous.

TRICOLOR. Rufous; wing-cafes yellow, with a common black sinuate spot on the disk.

EYLLIS. Ovate, black; base of the antennæ and legs ferruginous; wing-cafes smooth.

4-PUSTULATUS. Black; wing-cafes with four longitudinal spots; legs rufous.

FLAVICANS. Black; above yellowish; thorax black behind; wing-cafes with black striae and spots.

NEVIUS. Fulvous, with scattered spots of black. Geoffr.

Native of France.

FIMBRIATUS. Brown; wing-cafes yellow anteriorly, and at the outer side. Geoffr.

Same country as the former.

4-MACULATUS. Black; thorax yellow; wing-cafes smooth, with yellow spots and border. Geoffr.

This and the following species are natives of Europe.

UNISTRIATUS. Black; spots, border, and single stria on the wing-cafes yellow. Geoffr.

BILINEATUS. Wing-cafes brown; body beneath fulvous; thorax fulvous with a double black line.

SEMINIGER. Body beneath entirely black; thorax and wing-cafes dull-brown, edged with rufous. Degeer.

NUBILUS. Black; above with grey spots and streaks; legs reddish-brown. Degeer.

HYALINUS. Greenish; wing-cafes hyaline with lateral whitish spots. Degeer.

VIRESCENS. Testaceous, above greenish; outer edge of the thorax and wing-cafes yellow, the latter striated; posterior legs thicker. Degeer.

TESTACEUS. Testaceous, front and posterior margin of the thorax brown, the middle livid; wing-cafes with a livid fufural line and marginal specks. Linn.

NIGER. Black; margin of the wing cafes livid and longitudinally dotted with ferruginous.

BILOBUS. Oblong-ovate; black; mouth bilobate; spot on the crown, thorax, fufural line on the shells, base, and margin yellow.

FERRUGINEUS. Ferruginous; head and posterior margin of the thorax black; anterior part of the two spots between the eyes, thorax, fufural line and margin of the wing-cafes yellow.

FLAVUS. Yellow; mouth, two dots between the eyes,

D Y T

and outer margin of the thorax, and wing-cafes ferruginous.

TRICOLORATUS. Ferruginous; head, thorax, and wing-cafes rusty-brown; between the eyes two ferruginous spots; mouth and edges of the thorax and wing-cafes pale.

DENIGRATUS. Black; mouth, two dots between the eyes, and abdomen yellow; the segments with a black spot each side; wing-cafes brown, with specks, and exterior edges livid.

UNI-PUNCTATUS. Black; antennæ ferruginous; wing-cafes with a testaceous dot each side behind the middle.

BIGUTTATUS. Black; legs, tip of the abdomen, antennæ, mouth, two dots between the eyes, thorax, and wing-cafes testaceous; wing-cafes spotted with brown; thorax with two black dots in the middle.

8-MACULATUS. Livid; thorax greenish; wing-cafes brown-livid, each with four connected livid spots and streaks behind the middle.

LIVIDUS. Livid; head narrow; thorax narrower before; wing-cafes with brown dots disposed in rows.

4-LINEATUS. Black; wing-cafes deeply punctured; brownish with four yellowish branched lines, and outer margins; legs ferruginous.

DENTICULATUS. Piceous; mouth and antennæ ferruginous; shells glabrous, with pale bidentated band at the base; three spots and outer margin, with the anterior part of the thorax and legs pale.

POLITUS. Piceous, glossy, with paler wing-cafes. Marsh. Ent. Brit.

Inhabits England. The antennæ are rufo-ferruginous; head and thorax piceous, the latter paler at the sides; legs same colour as the antennæ.

HUMERALIS. Head and thorax black; wing-cafes with an obsolete ferruginous spot on the exterior margin at the base. Marsh.

Found in England. The head and thorax deep-black and opaque; antennæ filiform, black, and rufous at the base; spot at the base of the wing-cafes variable in size.

MELANOCEPHALUS. Black, and very glabrous; antennæ and legs piceous. Marsh.

Discovered by the bishop of Carlisle in a garden at Ealing. The antennæ are filiform, black, and at the base rufous; legs rufo-piceous.

D Z W

OVALIS. Ferruginous; wing-cafes fuscous with ferruginous margin. Marsh.

This and the remaining species are natives of Britain.

FRONTALIS. Fuscous; margin of the wing-cafes yellowish; head and thorax yellow spotted with black. Marsh.

CONSPERSUS. Griseous; head black, with two red spots behind. Marsh.

PARAPLEURUS. Smooth, black; front and margin of the thorax ferruginous; margin of the wing-cafes yellow with black dots. Marsh.

NIGRO-ÆNEUS. Smooth, dull-brassy; mouth and margin of the wing-cafes brown. Marsh.

ASSIMILIS. Rufous; wing-cafes striated yellow-griseous, with six black spots. Marsh.

INTERPUNCTATUS. Rufo-ferruginous; wing-cafes with numerous black spots placed obliquely. Marsh.

FLAVICOLLIS. Rufous; wing-cafes yellow, testaceous, clouded with black; posterior legs very long. Marsh.

SPARSUS. Oblong-convex, ferruginous, and nitid; back of the thorax, and common disk above dull; wing-cafes with scattered impressed dots. Marsh.

The antennæ, head, and legs rufous-ferruginous; thorax same colour, with sometimes a fuscous spot on the back; wing-cafes fuscous, with paler margin; body beneath ferruginous.

DZAR GURBAN, in *Geography*, a river of Russian Tartary, which runs into the Irutich, 20 miles E. of Semipalatnoi.

DZIEWIENISZKI, a town of Lithuania, in the palatinate of Wilna; 30 miles S.S.E. of Wilna.

DZIWATOW, a town of Lithuania, in the palatinate of Wilna; 4 miles W. of Wilkomierz.

DZOHARA, in *Mythology*, an Arabian goddess, supposed to be the same with Venus.

DZOHL, an Arabian deity, supposed to be Saturn.

DZONMUREN, in *Geography*, a river of Russia, which runs into Angara; 24 miles N. of Irkutsch.

DZURA, a Tartarian village of Russian Siberia, in the government of Irkutsch. N. lat. 56° 4'. E. long. 124° 24'.

DZWINGROD, a town of Poland, in the palatinate of Kaminnic; 20 miles S.W. of Kaminnic.

E.

E, The fifth letter of the alphabet, and the second vowel.

E is a letter that admits of some variety in the pronunciation, in most languages; whence grammarians usually distinguish several E's, or kinds of E. In English, E has two sounds; long, as, *scene*, and short, as *men*. It is always short before a double consonant, or two consonants, as *view*, *Ussing*, *sell*, *debt*, &c. E final has the peculiar quality of lengthening the preceding vowel, as *can*, *cane*; yet there are some instances in which it has not this effect; as *gone*, *give*, *live*, &c. It serves also to modify the foregoing consonants; as *since*, &c. It is also founded at the end of proper names, as *Penelope*, and in monosyllables that have no other vowel, as *the*; but in every other case it is mute. It was formerly used much more generally at the end of words than at present, and had probably a soft sound like the French E feminine; and afterwards was made vocal or silent in poetry, as the verse required, till at last it became universally silent. Camden calls it the silent E. Johnson.

The Greeks have their short and long E, viz. ε and η, epsilon and eta. The Greek η, or H, *eta*, or *ita*, was no original letter; but was added to the alphabet in after times. Of this we have proofs still extant in the ancient monuments; particularly the Farnese columns, brought to Rome from the Via Appia, where the *epsilon*, E, is used in lieu of the H: e. gr. ΔΕΜΕΤΡΟΣ ΚΟΡΗΣ, for ΔΗΜΗΤΡΟΣ ΚΟΡΗΣ. This letter is said to have been added by Simonides.

The pronunciation of the η seems to have been varied; it having been sometimes the same with the Latin E, sometimes with I. Terentianus assures us of the former; and the Greeks themselves for many ages have only used the latter. From the name of an animal of the Lutra species, denominated ΕΝΥΔΡΑΙΕ, that occurs on the Prænestine pavement, the η, *eta*, evidently serves as an aspirate to the υ, *upsilon*; and if this be authentic, the late learned professor Porson concluded, that this inscription affords an additional proof that the η, *eta*, was anciently used and pronounced as we do our H. In reference to this subject, Mr John Jones, author of the Greek grammar, &c. observes, that such letters were formerly aspirates, as they derived their origin from the strong gutturals, which the Greeks borrowed from the Oriental tongues; and hence he traces the origin of the Æolic digamma. (See the letter F.) It is the tendency of every guttural, says this ingenious writer, when become habitual, to soften down in the rapidity of utterance into a mere aspirate; of this he has given several instances. He adds, that the guttural, when softened into an aspirate, is apt to be dilated into a long vowel. Hence the reason why η, *eta*, in the ancient Greek, seems to have been accompanied with an aspirate, as in *ἦρα*, though formerly as in the

ΕΝΥΔΡΑΙΕ on the Prænestine pavement, it expressed the full power of H, as professor Porson has remarked. On the same principle that a guttural softened into an aspirate, the aspirate often melts into a gentle breathing, or becomes in pronunciation quite quiescent. See Dr. Adam Clarke's Narrative of the last illness, &c. of professor Porson, p. 12, &c.

The Latins have an opener E, called *æstivus*; such was the second E, in the word *here*, *maſter*; and another cloſer, as that in the adverb *here*, *yesterday*. This latter E they frequently used promiſcuouſly with I. Thus for *here*, they wrote *heri*; and, in diſerſe places, we meet with *ſibi*, *quaſe*, &c. for *ſibi*, *quaſi*, &c.

The Roman E was likewise sometimes written, by corruption, æ; for which reason, F. Hardoin takes that medal of Gallienus, CALLIENÆ AUGUSTÆ, not to be any satirical medal, as others have imagined: nor to be a dative feminine, but a vocative masculine, *Galliene Auguste*, wrote with the æ.

It has been much disputed how the Latins render the η in their language. The common opinion is, that they render it by an E; as in ΔΗΜΗΤΡΙΟΣ ΒΕΤΑ, ΗΜΕΡΑ, ΟΝΕΡΑ, ΟΝΤΑΡΑΙΟΣ, &c. which they rendered *Demetrius, Beta, Hemera, Theſeus, Theſaurus*, &c. Though there are persons exceedingly well versed in antiquity, who hold that they pronounced it like an i. Lud. de Dieu, one of the most learned grammarians of his age, observes as much in his animadversions on Genesis, vi. 24. Adding, that it is for this reason, that the Hebrews, e. gr. the paraphrast Jonathan, expresses it by a *Hibrek*; מְסָאָרַי, מִי־יִסְרָאֵל. J. Rod. Wetſtein proves the ſame in his learned oration on the true pronunciation of the Greek tongue, from an infinity of inſtances. To this purpoſe he cites a manuſcript Plaſter of the eighth century, where all the η's are expreſſed by i's. In effect Wetſtein ſhews, not only that the Latins pronounced and wrote it as an i, which might happen from its being ſo eaſily confounded in writing with an i; but alſo that they rendered it by an æ, and ai; that it was often uſed for γ and E I; and that in the time of Plato this letter has a kind of intermediate ſound between the ε and ι. See that author, and Voſſius de Idolol. lib. ii. cap. 16.

The French have, at leaſt, ſix kinds of E: the fiſt pronounced like a; as in *emporter*, *orient*, &c. The ſecond, a ſilable mute, in the laſt ſyllable of divers words not pronounced at all; as in *bonne*, *donne*, &c. The third, an imperfect mute, pronounced ſo much like the diphthong *ea*, &c. as in *je*, *de*, *te*. The fourth *e ferme*, or *e masculine*, marked at the ends of the words with an accent C. The fifth is *e ouvert*, or *long e*, having the ſame ſound with ai, as in *merc. fiſſe*, &c. In the middle of words it is ſometimes marked with a

circumflex, and in the end, with an accent \acute{e} . The sixth is an intermediate e , between the *ouvert* and *ferme*; as in *cabaret, lettre, &c.* Some add a seventh kind of e , not reducible to any of the former, as that in *grammarien, bif-torien, &c.* And others admit of only three kinds, *viz.* the mute, open, and shut; but they make variations therein, which amounts to the same thing.

As to the figure of the letter E , we borrow it from the Latins, who had it from the Greeks, and they from the Phœnicians, by Cadmus, who first brought it them. Now the Phœnicians had the same characters with the Hebrews. Accordingly, the form of the ancient Hebrew *He* was the same with that of our E , as may be seen in the Hebrew medals, and the Jesuit Souceit's Dissertation thereon, p. 143. All the difference between them consists in this, that the Hebrews, reading from right to left, turn their letters that way; whereas the moderns, reading from left to right, write their letters accordingly.

The little e was formed of the great one, by writing it fast, and making the cross strokes at top and bottom without taking pen off paper, and then adding the stroke in the middle.

E , on the keys of an organ, or harpichord, denotes the tones, *E, mi, la.*

On the compass in sea-charts, &c. it makes the east point, or wind. E . east; E.S.E. east-south-east; N.E. north-east, &c.

In the calendar, E makes the fifth of the Dominical letters.

Among authors, *e. gr.* stands for *exempli gratia, for instance*. In several dictionaries we find it noted, that the letter E , among the ancients, was a numeral letter, signifying 250, according to the verse.

“*E quoque ducentos & quinquaginta tenebit.*”

But it has already been observed, that this use of numeral letters was unknown among the earliest people. Isidore Hispalensis, an author of the seventh century, says as much in express terms, in the first book of his *Origines*, cap. 3. In effect, it was first introduced in the times of barbarism and ignorance.

EACHARD, JOHN, in *Biography*, was descended from a respectable family in the county of Suffolk, and born about the year 1636. He finished his studies at Catherine hall, Cambridge, where he took his degrees, and was admitted fellow of his college. This was in the year 1658, and in 1670 he published, but without his name, a treatise which passed through many editions, entitled, “*The Grounds and reasons of the contempt of the Clergy and Religion enquired into; in a letter to R. L.*” This work was attacked by Dr. John Owen, on account of the author's representations and uncandid remarks levelled at dissenting ministers. In the following year he published “*Mr. Hobbes's State of Nature considered, in a dialogue between Philautus and Timothy, &c.*” In a short time afterwards he published some further remarks on the writings of Mr. Hobbes, in “*A second Dialogue between Philautus and Timothy.*” Mr. Eachard was a powerful opponent when his weapons were those of wit and raillery, but his talents were ill calculated for serious argument, which caused the remark of Dr. Swift, “*I have,*” says he, “*known men happy enough at ridicule, who upon grave subjects were perfectly stupid; of which Dr. Eachard of Cambridge, who writ ‘The contempt of the Clergy,’ was a great instance.*” Mr. Eachard was chosen master of Catherine hall in the year 1675, and in the following year he was created doctor of divinity by

Vol. XII.

royal command. He died in the year 1697, having twice sustained the honourable office of vice-chancellor of the university. A complete edition of his works was published in 1774, in three vols. 12mo. Biog. Britan.

EADISH. See EDDISH.

EAGER WINE. See WINE.

EAGLE, in *Architecture*, is a figure of that bird anciently used as an attribute, or cognizance of Jupiter, in the capital and friezes of the columns of temples consecrated to that god.

EAGLE, *Aquila*, in *Astronomy*, is a constellation of the northern hemisphere, having its right wing contiguous to the equinoctial.

For the stars in this constellation, see AQUILA and CONSTELLATION.

There are also three several stars, particularly denominated among the Arab astronomers; *Nafir, i. e. eagle*. The first, *Nafir Suhail*, the Eagle of Canopus, called also *Sitarah Jemen*, the star of Arabia Felix, over which it is supposed to preside; the second *Nafir Alhair*, the Flying Eagle; and the third *Nafir Alwake*, the Relling Eagle.

EAGLE, in *Heraldry*, is the symbol of royalty, as being, according to Phœlollratus, the king of birds; and for that reason dedicated, by the ancients, to Jupiter.

The eagle is the arms of the emperor, the king of Poland, &c. It is accounted one of the most noble bearings in heraldry, and, according to the learned in that art, ought never to be given, but in consideration of singular bravery, generosity, &c. On which occasions, either a whole eagle, or an eagle *naissant*, or only the head, or other parts, agreeable to the exploit, may be granted.

The eagle is sometimes represented with one head, and sometimes with two, though never more than one body, two legs, and two wings opened, or stretched out, in which posture it is said to be *spread* or *displayed*: such is that of the empire, which is blazoned a *spread eagle*, fable, diadem'd, langued, beaked, and membered, gules.

The reason why eagles are generally given in heraldry displayed, is partly, because, in that posture, they fill up the escutcheon better, and partly, because it is imagined a posture natural to the eagle, when it plumes its feathers, or faces the sun. However, there are eagles borne in other postures; and some monstrous ones, with human, or wolves, heads, &c. The late authors only say *displayed* to express the two heads; and say *an eagle*, without any addition, when it has but one. The kingdom of Poland bears gules, an eagle argent, crowned and membered, or.

The eagle has been borne, by way of ensign, or standard, by several nations. The first who seem to have assumed the eagle, were the Persians, according to the testimony of Xenophon. Afterwards it was taken by the Romans; who, after a great variety of standards, at length fixed on the eagle, in the second year of the consulate of C. Marius; till that time, they used, indifferently, wolves, leopards, and eagles, according to the humour of the commander.

Several among the learned maintain, that the Romans borrowed this custom from Jupiter, who had appropriated the eagle as his own badge, in commemoration of its supplying him with nectar, while he lay concealed in Crete, for fear of being devoured by his father Saturn. Others hold that they borrowed it from the Tuscaus, and others from the Epirots. The Roman eagle, it must be observed, were not painted on a cloth, or flag; but were figures in relief, of silver or gold, borne on the tops of pikes; the wings being displayed, and frequently a thunderbolt in their talons. Under the eagle, on the pike, were piled bucklers,

and sometimes crowns. Thus much we learn from the medals. See Fefchius in his *Differt. de Insignibus*. And Lipsius, *De Militia Romana*, lib. iv. dial. 5.

Constantine is said to have first introduced the eagle with two heads, to intimate, that though the empire seemed divided, it was yet only one body. Others say, that it was Charlemagne, who, refusing the eagles as the Roman ensign, added to it a second head; but that opinion is destroyed, by an eagle with two heads, noted by Lipsius, on the Antonine column; as also by the eagle's only having one head on the seal of the golden bull, of the emperor Charles IV. The conjecture, therefore, of F. Menestrier appears more probable, who maintains, that as the emperors of the East, when there were two on the throne at the same time, struck their coins with the impression of a cross, with a double traverse, which each of them held in one hand, as being the symbol of the Christians; the like they did with the eagle in their ensigns; and, instead of doubling their eagles, they joined them together, and represented them with two heads: in which they were followed by the emperors of the West.

F. Papbroche wishes, that this conjecture of Menestrier were confirmed by ancient coins; without which, he rather inclines to think the use of the eagle with two heads to be merely arbitrary; though he grants it probable that it was first introduced on occasion of two emperors in the same throne.

The eagle on medals, according to M. Spanheim, is a symbol of divinity and providence; and, according to all other antiquaries, of empire. The princes, on whose medals it is most usually found, are the Ptolemies and the Seleucides of Syria. An eagle with the word "consecratio," expresses the apotheosis of an emperor.

EAGLE, *Aquila, Aves*, in Ornithology. See **FALCO**.

EAGLE-Flower, in Botany. See **BALSAMINE**.

EAGLE, Black, in Heraldry, was an order of knighthood instituted in 1701, by the elector of Brandenburg, on his being crowned king of Prussia.

The ensign of this order is a gold cross of eight points, enamelled blue; in the centre of which are the letters F. R. in cypher; and in the four angles the eagle of Prussia, enamelled black. On collar-days it is worn pendent to a rich collar of gold, composed of round pieces of gold, each enamelled with four cyphers of the letters F. R.; in the centre of the piece is set a large diamond, and over each cypher a regal crown, richly chased, intermixed with eagles displayed, enamelled black alternately, and holding in their claws thunderbolts of gold. The cross is worn on ordinary days pendent to a broad orange-coloured ribbon, which is passed scarf-wise from the left shoulder to the under part of the right arm. The knights also have, embroidered on the left breast of their coats and upper garments, a star of silver, shaped like that of the ensign of the order; and in its centre is an eagle displayed black, holding in his dexter claw a chaplet of laurel, and in the other a thunderbolt, with this motto round it; *Suum Cuique*.

EAGLE, Red, a very ancient order in Bareith, of which the margrave is sovereign. It is established both for military and civil persons, but is generally conferred on officers who have obtained the rank of lieutenants-general. The badge is a medal of gold, of a quadrangular form, enamelled white, upon which is an eagle displayed red. It is worn scarf-wise, pendent to a broad red watered ribbon, edged with yellow.

EAGLE, White, an order of knighthood, instituted in Poland by Uladissau V. surnamed Lokter, in the year

1525, on occasion of the marriage of his son Casimir, to the princess Ann, daughter of Gedimin, duke of Lithuania. This order was revived in 1705, by Frederic Augustus I. king of Poland, in order to conciliate the principal nobility, several of whom inclined to Stanislaus. The badge of this order, worn by the knights, is a gold cross of eight points, enamelled gules, bordered argent, cantoned with flames of fire; charged in the middle with a white eagle, bearing on his breast a cross of the same, environed with the arms and trophies of the elector of Saxony; and on the other side is a cypher of the king's name, with this motto, *Pro Fide, Rege, Lege*. The whole surmounted with a small crown of diamonds. The collar is composed of golden eagles, crowned and chained. On all days, besides state-days, the knights wear the cross at the extremity of a broad blue ribbon scarf-wise. They have it also embroidered on the left side of their cloaks and coats.

EAGLE Island, in Geography, an island in the Atlantic, near the western coast of Ireland, and county of Mayo. N. lat. 54° 17'. W. long. 9° 54'.

EAGLE Island, an island on the N.E. coast of New Holland, so called by lieutenant Cook, in 1770. It is low and sandy, and covered with trees; and abounds with birds, chiefly sea-fowl. An eagle's nest was found upon it, and also that of another bird, of an enormous size, built with sticks upon the ground, and no less than 26 feet in circumference, and two feet eight inches high. The Indians visit this island, probably to eat turtle, many of which were observed upon the island. N. lat. 14° 40'. W. long. 214° 30'.

EAGLE-Owl, in Ornithology. See **STRIX**.

EAGLE-Sea, in Ichthyology. See **RAJA Aquila**.

EAGLE-Stone, in Natural History. See **ETITES**.

EAGLES, in Coinage, a name found very frequently in the ancient histories of Ireland, and used to express a sort of base money that was current in that kingdom in the first years of the reign of Edward I, that is, about the year 1272. There were, besides the eagles, lions, roses, and many other coins of the same sort, named according to the figures they were impressed with. Simon's Hist. Coins.

The current coin of the kingdom was at that time a composition of copper and silver, in a determined proportion, but these were so much worse than the standard proportion of that time, that they were not intrinsically worth quite half so much as the others. They were imported out of France, and other foreign countries. When this practice had been a few years established on the throne, he set up mints in Ireland for the coining of sufficient quantities of good money, and then decried the use of these eagles, and other the like kinds of base coins, and made it death, with confiscation of effects, to import any more of them into the kingdom.

EAGLET, or **EAGLON**, a diminutive of eagle, properly signifying a young eagle.

The eagle is said to prove his eaglets in the brightness of the sun; and if they shut their eyes, he disowns them. In Heraldry, when there are several eagles on the same escutcheon, they are called eaglets.

EAHEINOMAUWE, in Geography, the most northern of the two islands of which Staaten Land, or New Zealand, consists; the other being called Tovy Poenamoo. These islands are situated in the South sea, between the latitudes of 34° and 48° S., and between the longitudes of 181° and 194° W.; and they are separated from each other by a strait, or passage, which is about four or five leagues broad. Eaheinomauwe has a much better appearance than Tovy.

or Tavaï, Pocommoo; for though it is not only hilly but mountainous, even the hills and mountains are covered with wood, and every valley has a rivulet of water. The foil in these vallies, and in the plains, many of which are not overgrown with wood, is in general light, but fertile. Those who visited it with lieutenant Cook in 1770, were of opinion, that all kinds of European grain, plants, and fruit, would flourish here in the utmost luxuriance. The winters are supposed, from the state of vegetation, to be milder than those in England, and the summer was experienced not to be hotter, though it was more equally warm. The country appears to be capable of supplying, in great abundance, not merely the necessaries, but the luxuries of life. In Escheimauwe there were seen no quadrupeds but dogs and rats, the latter of which are very scarce. The species of birds are not numerous; and of these no one kind, except, perhaps, the gannet, is exactly the same with those of Europe. Insects are not more plentiful than birds. But every creek of the sea swarms with fish, which are not only wholesome, but equally delicious with those in our part of the world; the highest luxury of this kind, with which the English were gratified, was the lobster, or sea cray-fish. The forests in this island are of vast extent, and are full of the straightest, cleanest, and largest timber Mr. Cook and his friends had ever seen. The plants were very various, as well as numerous. Of about 400 species, there were not many which have hitherto been described by botanists. There is one plant, which serves the natives instead of hemp and flax, and which exceeds all that are applied to the same purposes in other countries. For other particulars, we refer to the article *NEW ZEALAND*.

EALDERMAN, or *EALDORMAN*, among the Saxons, was of like import with earl among the Danes. Camden's Britan. p. 107.

The word was also used for an elder, senator, or statesman. Hence, at this day, we call those aldermen, who are associates to the chief officer in the common-council of a city, or corporate town. See *ALDERMAN*.

EA-OO-WEE, or *MIDDLEBURG*, in *Geography*, one of the Friendly islands, in the South Pacific ocean, first discovered by Tasraa in Januar 1642-3, and by him called Middleburg. This island, and *Ton-ga-ta-bu*, or *Amsterdam*, are situated between the latitude of $21^{\circ} 29'$ and $21^{\circ} 3'$ S., and between the longitude of $174^{\circ} 40'$ and $175^{\circ} 15'$ W. *Ea-oo-wee*, which is the southernmost, is about 10 leagues in circuit, and of a height sufficient to be seen 12 leagues. The skirts of this isle are mostly taken up in the plantations, and especially the S.W. and N.W. sides. The interior parts are but little cultivated, though, says captain Cook, very fit for cultivation. The want of it, however, greatly added to the beauty of the isle; for here are, agreeably dispersed, groves of cocoa-nut and other trees, lawns covered with thick grass, here and there plantations and paths leading to every part of the island, in such beautiful disorder, as greatly enlivens the prospect. The anchorage, named by Cook "English road," (being the first who anchored there,) is on the N.W. side in S. lat. $21^{\circ} 20' 30''$. The bank is a coarse sand, extending 2 miles from the land, on which are from 20 to 40 fathoms water. The small creek before it affords convenient landing for boats, at all times of the tide; which here, as well as at the other islands, rises about 4 or 5 feet, and is high water on the full and change days about 7 o'clock. Van Diemen's road, where captain Cook anchored, is under the N.W. part of the island, between the most northern and western parts. This island, as well as *Ton-ga-ta-bu*, is guarded from the sea by a reef of coral rocks, which extends from the shore about 100 fathoms.

The produce and cultivation of this isle is the same as at *Ton-ga-ta-bu* or *Amsterdam* (which see); with this difference, that a part only of the former is cultivated, whereas the whole of the latter is. The lanes or roads necessary for traveling are laid out in so judicious a manner, as to open a free and easy communication from one part of the island to the other. Here are no towns or villages, the houses being mostly built in the plantations, which are neatly constructed. The floor is a little raised, and covered with thick strong mats; the same sort of covering serves to enclose them on the windward side, the other being open. Before most of them are little areas, which are generally planted round with trees, or shrubs of ornament, whose fragrance perfumes the air in which they breathe. Their household furniture consists of a few wooden platters, cocoa nut shells, and some neat wooden pillows, shaped like four-footed stools or forms. Their common clothing, with the addition of a mat, serves them for bedding. For further particulars we refer to the article *FRIENDLY ISLANDS*.

EAR, in *Anatomy* and *Physiology*, the organ which, by a sensation peculiar to itself, renders us capable of being affected by sound. By this term we understand, therefore, not only that part which is prominent from the head, but the whole of the organ of hearing. Adapted in an eminent degree to the purposes it is designed to execute, it offers an inviting subject to such as are disposed to investigate the minute mechanism of an organ, which contributes remarkably to some of our most exquisite and refined enjoyments. Whoever has witnessed and attentively observed the distressing effects arising from a loss, or diminution of its sensibility, will readily acknowledge that such deprivation throws us at a distance from our fellow-creatures, and, in the present state of society, renders us more solitary beings than the loss of sight itself. Though the rapid glance of the eye, the immense distance to which it enables us to carry our perceptions, and the extended circle it embraces, have given rise to some of our most pleasurable and magnificent sensations; though it has brought us acquainted with objects which seemed ever placed far beyond our reach; still the more humble sense which we are now considering, the more confined dominion of the ear, has contributed most efficiently to the every-day happiness of life. It enables us to hold communication with our fellow-creatures; to improve and exalt our understandings by the mutual interchange of ideas; and thus to increase the circle, not only of our physical, but of our moral relations. The charms of eloquence, the pleasure resulting from the concord of sweet sounds, inexplicable perhaps as it remains, are other sources of intellectual enjoyment, which contribute to place this sense among the most delightful as well as the most important we possess. Whatever, therefore, by explaining its structure, or examining its functions, can lead us to improve its natural, or restore its disordered sensibility, cannot be a subject of trivial moment. Our more immediate object is to consider the human ear, observing only, that the structure of the organ, being suited to one great end, is in all cases fundamentally the same; its different forms and varieties depending on the peculiar economy and abode of each individual creature. There are some parts, essential to the perception of sound, which are always present, be the sense of hearing delicate or imperfect; there are others which are found only in particular classes of animals. In those which approach nearest to the human form, it differs from that of men only in the relative size of the different parts. The sense of hearing is still perhaps the same, the propagation of sound is subject to the same laws; and we must look for the variety of effect, not only to the organs, but to the centre to which all our sensations tend.

It will be found convenient to make some leading divisions of the subject, under which we may arrange our ideas in more distinct order, and from which we may set forth with greater freedom, when about to examine the powers and structure of the ear. The necessity of such arrangement will be obvious to any one who wishes to distinguish between positive truths, and the probable application of them, to the elucidation of different phenomena. With this view, we shall, in the first place, lay before the reader what may be regarded as demonstrable facts, and then endeavour to explain the application of these, as far as it can be made out by reasoning and probable conjecture. Whatever may be thought of such inferences, the series of facts will remain the same. They will ever form a solid base, however light and imperfect the superstructure raised on it by opinion; however rapidly it may vanish before the illuminating glance of some happier genius, or fall at the touch of more patient and inductive reasoning. These facts consist in a knowledge of the structure of the ear in different animals; in the power possessed by them of perceiving sounds; and further, in the degree of that power enjoyed by man. Of the manner in which this faculty of distinguishing sound is produced, we know but little; and in our endeavour to account for it, we must in many instances take our leave of positive truths, and be contented to trust ourselves to the more doubtful guidance of analogical reasoning and rational conjecture. There is a barrier placed in our road, beyond which nothing is clearly seen: if we pass it, the chance is that we stumble, if we do not fall. We have very little knowledge of the impressions which sounds make on other animals. We know that they hear; and in many instances we scarcely know more. If we could determine that there was a difference in the sensibility, and that this diversity was dependant on one particular structure of the organ, as compared with another, we should gain an important point, and be able to draw some probable conclusions as to the part which each portion of the organ bears in transmitting and modifying sound. We know the degree of perfection in the organ as it exists in man; so we know that many animals, who come near him in its structure, possess powers of nearly equal extent. We are convinced, moreover, that animals, with one part of the organ only out of many, are still capable of being affected by sounds. If, in addition to this, we knew the intermediate gradations of the faculty, as enjoyed by successive classes, when more and more parts are superadded to this simple structure; if we could precisely determine the degree of perfection proportional to each alteration, and improvement in the apparatus, the path would be clear, the barrier thrown down: we should deduce known effects from demonstrable causes; we should go from what is known to what is unknown, without the risk of missing our way: we should be enabled to assign the positive importance of each piece of the apparatus, and mark out clearly its relative functions. As these, however, are at present unknown, and, for the causes mentioned, likely to remain so, we must be contented with the endeavour to explain the phenomena, as we observe them in the more complicated structure, as they occur in creatures who can give an account of their sensations: in short, as we notice them in man. And if we consider the difficulty of accounting for the endless variety of the effects of sound on the human ear, where our knowledge is the most complete, we shall be the less disposed to examine it in other animals, where the variety may be equal; but where our inductions have nothing better to rest on than conjectural supposition. We should have to investigate an obscure subject in creatures, who could not convey to us any ideas of their sensations, or, at least, any such precise ideas as would lead us to well-

founded inferences. The result of all that we can at last draw from our investigation would be this, that in the different gradations we observe a variety of organs, of which some parts are constant, others found only in particular classes, and differing in their conformation even in these. The obvious inference is, that the part universally found is the essential means by which we perceive sounds; that the additional apparatus is intended to facilitate its transmission, or to modify its action. Having gained this step, we again are stopped, totally unable to explain the mode by which this part so constantly met with is enabled to excite in us the idea of a sound. All that we know is this, that there are some ideas, which have admittance only through one sense, which is peculiarly adapted to receive them; and if the nerves, which convey them from without to the brain, are so disordered as not to perform their functions, there is no other way in which they can be perceived by the understanding. In this paucity of facts, we must make the most of those we possess; and for the better understanding them, shall regard them as they concern the structure of the ear, or as they are connected with its power of distinguishing the properties of sounds. This arrangement leads us to consider the method we have chosen to follow, in analysing the functions of the organ. We first take the ear to pieces, if I may use the expression, and describe the delicate and admirable structure of it in man, beginning from without, and proceeding till we arrive at the immediate seat of sensation; we next give the history of its powers, as ascertained by observable phenomena: and, lastly, we endeavour to connect these truths, to trace the progress of sound as affecting the different portions of the ear, and to determine the sum of its action on each; to notice the manner in which the idea of sound is admitted to the brain, and explain the mode in which it becomes modified, during its propagation from without, by the mechanical action of the transmitting parts; and to assign the relative importance of each part, by noticing the effects produced by an alteration or deficiency of them in man, and by considering their conformation in other animals. This comparative view will extend, however, only so far as may be necessary to assist us in explaining phenomena.

Before we can attempt to explain the manner in which the perception of sound is accomplished in man, it will be requisite to give a description of all the parts destined to collect, transmit, and modify the pulses of it, as well as of those on which they are finally impressed. And in thus considering the ear as an organ of sense, we shall include all the parts which are in anywise subservient to its functions, and which, in conjunction with the ear, go to form the whole of the organ of hearing. For the convenience, however, of anatomical purposes, it will be necessary to make a division of the ear into different portions; a division which, though an arbitrary one, will greatly facilitate the description. Of the divisions in common use, we shall adopt, as the most natural, that which makes three portions of the ear: the first including the *external ear*, or *auricle*, and the parts exterior to the *membrana tympani*; the second, the *cavity of the tympanum*, and the parts connected with it; and the last, the parts usually comprehended under the general term of *labyrinth*.

The ears are two in number, and, like all the organs designed to receive the impressions of surrounding agents, are symmetrical, or exactly resembling each other in structure. The description of one, therefore, may with great facility be applied to either; and as the plates represent throughout the formation of the left ear, we shall suppose ourselves to be explaining the structure of the same ear in the following

account. The description of that part of the ear, which is formed in bone, will be found in the history of the temporal bone, under the article CRANIUM; and as a knowledge of it is absolutely necessary in comprehending the following view, we shall, instead of puzzling the reader by continual references, suppose him to be fully acquainted with this previous description. As, in the account of the bony parts of the ear, no reference has been made to the plates designed to illustrate the anatomy of this organ; and as, in the following description, the explanations are scattered, we have thought it best to collect them under one view, that we might the more readily bring ourselves acquainted with the most important parts of its structure. The first plate begins with figures of the external ear, and leads us gradually to the most interior parts; the last plate exhibiting all the parts in their relative positions with regard to each other, and to the rest of the skull.

The formation of the ear, as well as of the eye, is very considerably advanced during the fœtal state; some of the parts possessing, even in the early months, a volume nearly equal to that which they finally attain. After the descriptions of the different portions of the ear in the adult, we shall introduce that of each part, as it existed before birth, as well as of the gradual alterations it undergoes before it arrives at the form it is destined at last to maintain.

The organ of hearing, in its simplest form, consists of the expansion of a nerve, gifted with its peculiar sensitive qualities, over the surface of a delicate membrane. In man and the more perfect animals, there is an additional apparatus connected with this, the design of which is supposed to be that of collecting and modifying those pulses of sound which are finally to be impressed on the nervous pulp. In man this apparatus consists of a piece of cartilage, seated externally to the head, which contracts into a funnel leading to the internal parts. The bottom of this tube is truncated obliquely, and its aperture closed by a firm membrane stretched across it, which separates this external part of the ear from the succeeding, or middle portion of the organ. Beyond, or on the opposite side of this membrane, we meet with a small cavity, hollowed out in bone, which has been termed the barrel of the tympanum. Of the several openings into it, there is one more particularly demanding our attention here. It is the internal aperture of a tube, the other extremity of which opens at the posterior part of the nose, behind and above the palate. By means of this communication, the external air is admitted into this barrel, and equipoises the weight of the atmosphere on the other side of the membrane. Across the cavity there is extended, though by no means in a straight line, a series of little bones, the exterior one of which is attached to the membrane we have just mentioned, the most internal of the set being firmly connected with another membrane, which, in conjunction with it, shuts up the entrance to a still more deepened cavity, called the labyrinth of the ear. This last hollow, excavated as it were in the solid bone, consists of a middle portion of irregular figure, and of different channels, which proceed from it in various directions, and, finally, return, with the exception of one only, to the same chamber. All these passages are lined by a membrane, on which the sentient extremity of the auditory nerve is expanded in different shapes; from thence it is collected into one trunk, and goes on to join a particular part of the brain, and thus completes the communication between the external agent and the sensorium.

External Ear.

Under this name we comprehend that part which projects from the head, and which, folded in various directions, is known

by the name of the *auricle*, or *pinna*, of the ear; and the passage leading from it to the tympanum.

The pinna, itself insensible to sounds, but adapted for the collection of those which are to be transmitted to the tympanum, is placed at the side of the head immediately behind the articulation of the lower jaw. It is of a size varying much in different individuals, of an irregular, ovate, and flattened form, with its broader part above, tapering below; loose and detached from the head behind, and continuous with the skin of the surrounding parts before. Its external surface, directed more or less forward in different subjects, is marked by several eminences and depressions, to each of which a separate name has been affixed.

Beginning our description from the external edge, we first notice the *helix*, which is the elevated convex fold forming the chief part of the outline of the ear. It rises in the middle of the pinna, out of a hollow, termed the *concha*, and, passing forwards, immediately above the external meatus, it makes a turn upwards and backwards, sweeping round to form the circumference of the pinna. Below, the fold is effaced, and gradually lost in the smooth and flattened part above the lobule, which completes the figure of the ear in this part. From this curling in of the external edge of the pinna to constitute the helix, a groove, or furrow, is formed, which separates it from the opposite eminence, the *antihelix*, throughout its whole length. The *antihelix* rises gradually from this depression, forming an elevated semi-circular fold, with its concavity towards the meatus, running lengthwise through the middle of the ear, surrounded nearly on all sides by the helix. Towards the upper end, as it turns forwards, the fold divides into two crura, both of which sink under the inverted edge of the helix, at its upper part: the superior of these forms a less elevated and rounder convexity than the lower, which is pinched up into a narrower ridge. Below, the *antihelix* becomes gradually narrower, and terminates just above an eminence, called *antitragus*, from which it is separated by a slight notch. As the *antihelix* arises in two separate portions above, from under the helix, there is left a shallow depression between them, called *fossa navicularis*.

Anterior to, and below these folds, there are two eminences, called *tragus* and *anti-tragus*. The first of these, continuous with the skin of the face, juts out backwards, in an oblique direction, so as to cover, in a great measure, the opening of the meatus. The projecting edge, the line of which is perpendicular, is nearly straight, and slants off above and below, so as to leave a channel, which separates it from the helix above, and another deeper notch dividing it from the *anti-tragus*, below and behind. This last eminence, which may be regarded as a continuation of the lower end of the *antihelix*, is placed opposite to the *tragus* at the lower part of the ear, forming the inferior wall of the *concha*.

The *concha* is the large deepened excavation in the middle of the pinna, and is surrounded on all sides by the projecting folds we have been describing. Bounded before by the *tragus*, below by the *anti-tragus*, the chief portion of its circumference is made up by the semi-circular sweep of the *anti-helix*, which suddenly shelves off into this hollow. It is divided across unequally by the commencement of the helix, which thus makes a small part of its anterior boundary above. That part of the *concha* above the beginning of the helix is continued into the furrow which separates this eminence from the *anti-helix*: the lower division leads on front into the meatus.

The portion of the ear situated below these parts, is termed the *lobule*: it is flat, and terminates in a soft rounded edge,

edge, varying much in figure in different individuals. It is the part which we see, in most nations, pierced for the admission of ear rings.

The internal surface of the pinna, facing the side of the head, is moulded into eminences and depressions corresponding, in an inverse sense, to those observed on the opposite external surface; but not marked in so striking a manner. The line of its connection with the head is a semi-circular one, with its concavity forwards, formed by the fold of the skin, as it passes between these parts. The convexity of the pinna, behind this line, is caused by the bulging of the cartilage in the part which corresponds to the depression of the concha on the external surface.

The textures, which enter into the composition of the pinna, exclusive of those which we find almost universally distributed, are, common integument, cartilage, muscles, and ligaments. The skin covering the external ear is connected very closely to the parts it surrounds, by a dense cellular tissue, containing scarcely any fat. It is more delicate than in the generality of parts; and is furnished with numerous sebaceous glands, disposed throughout its structure. When the cuticle has been removed by maceration in water, we can distinctly see a vast number of rounded foramina, of different sizes; these are the excretory ducts of glands, from which the greasy substance that covers the ear is secreted: they are particularly large and distinct in the concha. The skin alone, covering a close cellular tissue, filled with a delicate fat, composes the lobule of the ear, which does not appear to suffer any irritation from the continued pressure of a foreign body, as an ear-ring, in its substance. On the internal surface and edge of the tragus, the skin is furnished with a few fine hairs, which project over the entrance of the meatus.

The cartilage on which the figure of the whole pinna, excepting the lobule, depends, has been necessarily described in considering the shape of that part, and we have only to notice any alteration in its form, which may be observed after the removal of the integuments. When this has been effected, we may perceive that the figure is broken in upon before by a deep notch, occupied by a ligament, between the upper edge of the tragus, and the opposite portion of the helix. Behind, the united extremities of the helix and anti-helix, instead of forming a continued rounded outline, terminating smoothly in the lobule, appear as a pointed projecting process, separated from the body of the cartilage by a small interval, which, when covered by skin, appeared only as a groove. Between this process and the anti tragus, a tolerably strong ligament is extended. In the distinct cartilage, we observe, in a more striking manner, the eminences and depressions corresponding, in an inverse sense, to those on the external face, some of which were scarcely perceptible before the removal of the investing parts. We see now, also, the cartilage sending in a process, which goes to form a part of the commencement of the meatus externus, as we shall have occasion to mention hereafter. The texture of the cartilage of the pinna resembles that of the nose and trachea, and has, by an eminent and much to be lamented anatomist, been described under the name of fibro-cartilage, as distinguishable, by its structure and properties, from the cartilages entering into the composition of joints. It is flexible and exceedingly elastic, so as to assure, by constantly preserving the ear open, a ready admission to all sounds, the reflection of which into the meatus is still further favoured by its form.

The cartilage is fixed to the side of the head by three ligaments: an anterior one, arising from the root of the zygomatic process of the temporal bones, and terminating in the base of the tragus, and the neighbouring part of the con-

vexity of the helix: a superior one, arising from the aponeurosis covering the skull, and fixed to the upper part of the convexity of the concha; lastly, a posterior ligament attached by one extremity to the mastoid process of the temporal bone, by the other to the protuberance of the posterior part of the concha. They would appear to be nothing, perhaps, but a dense cellular substance.

The muscles of the external ear may be divided into those which move the whole pinna, and those which act partially only on the divisions observed on its external surface. In the first of these classes, which we shall consider here, though it cannot be regarded as entering into the construction of the pinna, we enumerate some small muscles, which are, however, very manifest in a muscular subject, and which appear to have derived their names from their situation, with regard to the ear. They are, the *attollens auriculam*, the *anterior auricula*, and the *retrahentes auriculam*.

The *attollens auriculam*, temporo-auriculare of Chaussier, is a thin flat muscle, situated on the side of the head, immediately above the external ear. It is the broadest of the muscles of the ear, and of a triangular shape: the upper portions of its thin and scattered fibres arise in a curved line from the external surface of the aponeurosis of the occipitofrontalis, rather below the rounded origin of the temporal muscles; from these points they converge in their approach to the ear. (not in corresponding lines, however, from all parts, the anterior fibres being directed more backwards than the posterior ones are forward,) and terminate in a flat tendon, which is fixed to the eminence on the inner side of the pinna, answering to the fossa, which is observed between the crura of the anthelix. This muscle lies immediately under the skin, and over the temporal fascia, from which it is separated by cellular tissue. It will elevate the pinna, and, perhaps, by stretching the part to which it is attached, tend to open the passage of the external meatus.

Anterior auricula, *zygomato auriculare*. This very delicate muscle, allied in form to the one we have been describing, but much smaller in its dimensions, is situated on the temple, immediately before the ear. It arises from the same surface of the aponeurosis as the former, in that part of it which lies over the middle of the zygoma. Its origin is not always, however, distinct, nor easily determined. It proceeds from thence backwards, and a little downwards, and becoming tendinous as it reaches the ear, passes on under it to arrive at the inner side of that part of the helix, which has been described as dividing the concha into two unequal portions. It is covered immediately by the skin, and lies over the temporal fascia and artery. Its action will be to draw that part of the helix forwards.

Retrahentes auriculam, *mastoido-auriculaires*, appear as small narrow muscles, affixed, by tendinous origins, to the external and hinder part of the root of the mastoid process, immediately over the attachment of the sterno-mastoideus. From thence they pass transversely towards the ear, and become fixed to the protuberance corresponding to the hollow of the concha. They are hardly to be reduced to any description which shall answer, in every instance, as they vary in number and origin in different subjects. They are covered by the skin, and separated from the temporal bone by cellular tissue. They will stretch the concha, and draw the pinna backwards.

From its connection with these muscles, the auricle can be moved upwards, backwards, or forwards; and by their combined actions in any of the intermediate directions. It is doubtful if they have much power over the tube of the meatus, though they may exert their influence in opening the hollow of the concha. In removing the skin, to gain a

view of these muscles, considerable caution is requisite; as they are delicate in some, and not in every case easily distinguished from the surrounding parts. To see them more distinctly, the ear should be drawn in different directions, so as to put them on the stretch; and they should be studied immediately as they are dissected, as they soon become confused and indistinct. The muscles we have mentioned as acting on the different eminences of the pinna, are placed at different points on its surface: they are extremely small, so that some anatomists have denied altogether their existence. The *tragicus* derives its name from the tragus on which it lies: placed on the external face of this eminence, which it almost entirely covers, it may be described as arising at its basis and terminating at its summit by tendinous extremities. It is of a triangular shape, with the base below. Where the anti-tragus forms its greatest projection there is attached to its exterior surface a small muscle called *anti-tragicus*: its fibres proceed obliquely upwards and backwards, and terminate at the lower and posterior edge of the anthelix, in which they are fixed in the angle of that slit which we have described as existing in the cartilage between this last eminence and the anti-tragus. It is broader below, and tapers gradually to a tendinous point above. The ligament which we have mentioned as filing up the interval noticed above, lies externally to this muscle, which is covered by skin on its internal surface. The *major helcis*, a narrow slip of muscle, arises from the edge of the projecting helix immediately above the tragus: it mounts a little forward, gradually lessening in size, and is attached to the external edge of this eminence just where it begins to make its turn backwards. The *minor helcis* lies on the heap as it begins to arise from the hollow of the concha, its fibres pass forwards and terminate on the edge of the helix opposite the end of the inferior crus of the anthelix. These muscles lie on the external surface of the pinna: there is still another arising from the inner side, called the *transversus auriculæ*. It is placed between the convexities answering to the hollow of the concha and the groove between the helix and anthelix. Its fibres are short, and can scarcely be distinguished as muscular: they occupy nearly the whole length of the space corresponding to the rising of the anthelix, so that the perpendicular measurement of this muscle is considerable, though its transverse one is short. The more regular and more distinct of these muscles are the *tragicus* and *anti-tragicus*. The distinct action of each of them has been described by different anatomists, and may be collected by reflecting on their attachments. The motions they produce, however, are at the best extremely obscure, and in most instances not discernible. Their only actions can be those of approximating, or drawing asunder the different eminences of the ear, and the extent of such movement we believe to be extremely minute. This has been supposed to arise from the opposition made by the elasticity of the cartilage to the actions of these small muscular powers, which, it will be readily seen, do not exert their influence through the medium of moveable articulations, but act immediately on a resisting body, in which there is a constant tendency to preserve one customary form. The integral action of these muscles seems to be principally directed towards altering the form and dimensions of the concha, around which they are partially distributed. We shall have occasion to consider the uses of both the orders of muscles we have been describing, when considering the functions of the external ear in their relation to the sense of hearing. In the mean time it must be allowed, that in man the action of many of these muscles is extremely confined, and, in the majority of instances, scarcely per-

ceptible. Whether this may arise from our habit of compressing them by our mode of dress, or from being seldom called into action in the quiet and regulated intercourse of civilized life, is perhaps a matter of but little moment: our wants require accuracy, more than acuteness of sense. There are, however, numerous recorded instances, as well as living examples of persons in whom this power of moving the external ear has been manifest and decided. We are told also, that among the more savage nations, whose predatory habits are such as to render a watchful caution liable to every coming sound necessary both for their preservation and support, there does exist a considerable power of moving the ear in different directions. The rapid movements of it in brutes, and the various directions of its opening in animals of different habits, have been the subject of frequent observation. The minute form and paleness of the proper muscles of the human ear render the dissection of them exceedingly troublesome, more especially if the subject be not strongly muscular: indeed, unless in these favourable circumstances, our labour will be in vain; we shall to no purpose seek to distinguish them from the surrounding substance, to which, by their paleness, they are nearly allied.

The pinna in the fœtus possesses nearly the same external characters as in the adult. Its size does not bear the same proportion to the other parts of the ear as it afterwards reaches; it being of all the organ the part which is the least advanced before birth. In the adult male the auricle is observed to be more rounded and full, as well as somewhat thicker than it is in the female. The natural distinctions of the ears are derived chiefly from their size and situation. They are described to be, in Europeans, smaller than in the inhabitants of many other climates; amongst whom we have accounts of their reaching a prodigious size. It is well known, that in savage nations they stand off farther from the side of the head; and in the idols of ancient Egypt they are constantly figured as being placed much higher than we now observe them. That such a representation was not the effect of ignorance, but of design, is deducible from the finished workmanship we observe in the rest of their construction. Allowing then that it is taken from nature, it will be no more remarkable than the variety we notice so frequently in domestic animals, as to the situation of the external ear. The four-footed mammalia are the only animals besides man who are provided with a projecting pinna: it is not constant, however, even among these, being deficient in many of those who live either in the water or under ground. Its varieties of figure and position are familiar to all, and we have only to add, that they are provided with strong muscles adequate to move them in every necessary direction.

Meatus Auditorius Externus.

Having completed our description of the pinna of the external ear, we proceed next to consider the passage leading from it to the tympanum. The external meatus extends from the concha to the membrana tympani, by which it is separated from the next cavity, or that of the middle ear. It takes its course immediately between the mastoid process and the glenoid cavity for the reception of the condyle of the lower jaw. The general direction is at first upwards and forwards, it then makes rather a sudden turn downwards and backwards, and is continued nearly in an horizontal line till it reaches the membrana tympani. Considered in the whole of its course it would appear as forming a convexity pointing upwards, and a corresponding concavity directed downwards and forwards. A section carried at a right angle to its axis presents an oval rather

than a rounded opening. It gradually diminishes in size as it proceeds from the concha, being narrowed for about the middle third of its course, and enlarging again as it approaches the tympanum. Its usual length is rather less than an inch; and it is always shorter above than below, behind than before, on account of the oblique direction of the membrana tympani. In considering the parts which enter into the construction of the sides of the meatus, our attention will be called to a solid or bony portion, a cartilaginous plate, incomplete in parts, its vacancies being filled up by the interposition of a fibrous structure, and, lastly, the common lining of the whole. The bony portion has been already described with the temporal bone, it occupies about one-half of the length of the meatus. The cartilaginous part of the tube is continuous with the base of the tragus, and the lower and anterior part of the concha as before mentioned. It is formed by a broad plate, proceeding inwards from these points, gradually decreasing in breadth, and curling from below upwards and backwards in such a manner as not to form a complete circle of cartilage, but to leave a vacancy between the circumvolved edges towards the upper and posterior part, which is filled up and completed by a fibrous expansion. The cartilaginous tube thus constructed terminates in an oblique line, the lower part of which projects inwards in a pointed form, and is fixed either immediately or by the intervention of fibrous tissue to the rough edge observed at the inferior part of the termination of the bony meatus. When the membrane, which completes the tube from above, has been cut through longitudinally, so as to give one the liberty of making the cartilaginous plate flat, it appears of a triangular shape, its base towards the pinna, its apex towards the head, which, when folded up, will form the obliquely truncated tube we have been describing. It will be seen from this that the pinna and the cartilaginous portion of the meatus are formed by a continuous piece of cartilage, which in the pinna lies extended by the side of the head, and gradually contracts into a tubular meatus. Near to the tragus there is a considerable cleft in this cartilaginous plate, filled by a fibrous substance: farther in, we find it again divided transversely by another cleft, which does not however run to the full extent of its breadth. Besides these two, we sometimes meet with a third vacancy; and they are all known by the name of incisures (*incisure*). It is on this account, as well as from its being an incomplete tube, that it has been compared to the construction of the trachea. The fibrous substance, which occupies the interstice of the second incisure, has been described by Santorini as being covered by muscular fibres, which have retained his name; the *musculus incisure majoris Santorini*, *musculus meatus auditorii Dongias*. Its action would be to contract the length of the tube. The fibrous portion, in conjunction with the skin, forms the upper part of the tube, where they complete the vacancy left between the edges of the cartilage. The fibrous plate is not very apparent, but may generally be distinguished from the skin which lines the whole of the tube within. It is continued to the temporal bone, stretching itself on each side as it advances inwards, and serves to connect the oblique edge of the cartilage to that part. Between this expansion and the skin lining the meatus we meet with numerous blood-vessels enclosed in cellular tissue. The whole of the external meatus is covered by a production of skin, which dips into it after having invested the pinna, and becomes reflected over the membrana tympani at the bottom of the conduit. It varies somewhat in appearance, as well as in structure, in different portions of its passage; and may be described generally as being con-

siderably thinner the nearer it approaches to the tympanum. It is covered, more especially towards the pinna, by a fine down, interperied by a few longer hairs of an equally delicate appearance.

Towards the commencement of the bony meatus, we observe, on removing the cuticle, the skin to be pierced by numerous small openings lying close to each other, which are the outlets for the ceruminous secretion we shall presently notice. They are more particularly observable at the termination of the cartilaginous portion, where they form a zone of minute foramina. As we arrive at the membrana tympani, we find the skin become extremely delicate; and where it is produced over that membrane, it is diaphanous: whether it is only the cuticle which is thus produced, or whether the true skin also goes to form this external layer, is not perhaps exactly ascertained. It adheres but loosely to the cartilaginous portion; as we proceed inwards, it becomes most closely and intimately united with the membrane covering the bone, so as not to be separated from it. Still farther in, and where it covers the membrana tympani, it is separable without any difficulty, so as to be detached in the form of a bag accurately complete at its bottom, so that if the membrana could be removed from within, this bag would still obstruct the communication between the cavity of the tympanum and the internal meatus in the most perfect manner. It is of great sensibility, which has been ascribed to the thinness of the cuticle in these parts.

In the cellular tissue which intervenes between the skin and membranous parts of the meatus, we find a considerable number of small rounded and oval bodies, which are the ceruminous glands of the meatus: we find them, also, but not so closely studded, between the skin and the cartilaginous portion of the tube: they each open by a peculiar excretory duct into the meatus, and give the porous appearance we before mentioned. They furnish a yellow matter of some consistence, extremely bitter and of an oily nature: it is known by the name of cerumen, or the wax of the ear. It acquires in many persons considerable hardness if suffered to accumulate, and forms a solid body obstructing the meatus. The use of this secretion is supposed to be that of affording some defence to the sensible covering of the meatus, as well as to bar the access and nesting of insects.

In order to obtain a correct knowledge of the figure of the meatus, we must make sections of it in different directions, or we may with ease procure a cast of it in common plaster. The sections should be made transversely in different parts of the tube to gain a view of its shape and area, or longitudinally in the perpendicular and horizontal directions, to ascertain its extent and curvatures. It is by these last sections also, that we are enabled to observe the proportions which the bony and cartilaginous portions bear in the construction of the meatus, its connexion with the concha, the openings from the ceruminous glands, and, lastly, if the section be carried on through the petrous part of the temporal bone, the relative bearing of it to the internal part of the organ. Such sections will be found eminently instructive, are easily executed, and require no particular directions for their performance.

The meatus externus in the fœtus possesses the same proportional length as in the adult. Its area also does not materially differ, excepting that it is comparatively larger towards its internal extremity from the magnitude of the circle for the membrana tympani, to the circumference of which it is affixed. The structure of the tube, however, offers some more remarkable differences. The cartilaginous portion is nearly the same, only the incisures are larger and
more

more apparent, and the fibrous part occupies perhaps a greater part of the circle. The bony part, as has been already described, is absolutely wanting; we have then only to examine here what supplies the deficiency. Above, the internal lining alone is observed, as forming the provisional sides of the meatus; below, in addition to this, we can plainly perceive a peculiar membranous sheath formed of strong parallel fibres which arise from the ring of the tympanum, and terminate in the cartilaginous part of the meatus. It is this expansion of thick membrane which makes the division between the meatus and the glenoid cavity, which in the adult is formed in bone; as the formation of the bone proceeds from within, it becomes gradually lost. The animals who have no external ear, and still possess an external meatus, are birds, and cetacea. In the former class the tube is short and chiefly membranous, in the latter it is very long, proportionably small, and inflected in various directions.

The middle Ear, or cavity of the Tympanum.

The middle division of the ear is bounded externally by the membrana tympani, which separates it from the external meatus, and internally, by the parts called the labyrinth: it lies under the union of the squamous with the petrous portion of the temporal bone, over the fossa jugularis, with the mastoid process and its cells behind, part of the glenoid cavity and the Eustachian tube before. The irregularity of its form will admit of no exact description of its figure, the walls of which, it will be sufficient to observe, are made up on both sides by bone. It is only towards the meatus that we observe any considerable deficiency in this bony case, where it is interrupted by a large circular opening, which is, however, shut up by a membrane stretched across it, called, from its situation, the *membrana tympani*. In this cavity our notice will be claimed by a variety of objects, which we believe to be subservient to the transmission and modification of those sounds which have impinged on the membrane from without. Here, however, it will be necessary again to refer the reader to the description of the bony part of the organ, as, without a correct knowledge of that part of the subject, the study of this will be at last but incomplete and unintelligible. In the present place, we have to notice the membranes closing the different openings, the Eustachian tube, the connections of the ossicula, the muscles employed in moving them, and, lastly, the membrane which lines the whole of the cavity and the parts connected with it.

The *membrana tympani* is distinct from the linings of the external meatus and the cavity of the tympanum, from both of which, it may be separated by maceration in water. It has been already mentioned as closing the internal end of the meatus, where it lies in an oblique direction, stretched across the bony circle in the external side of the tympanum. Its obliquity is such, that it forms a very acute angle with the lower portion, and an equally obtuse angle with the upper side of the bony external meatus, to which latter, indeed, it is at first nearly parallel. The plane of its external surface, however, does not lie exactly opposite to the lower half of the meatus, but it is directed rather forwards, the internal surface looking proportionably backwards. The dimensions of the membrane are rather larger than the circle to which it is fixed, which allows, therefore, of its relaxation, and of its being drawn into a wide cone, the apex of which is directed towards the cavity of the tympanum, thus forming a hollow surface towards the meatus, and a corresponding projecting surface in the tympanum, which latter is strongly united to the descending handle of the malleus, the motions of which it must in all cases follow. The *membrana tympani* is closely fixed round its circumference to the bony

circle which embraces it. It has, however, been a matter of dispute among anatomists, whether there existed, in a natural state, any deficiency in this union, at any part which would allow of the passage of air or any other fluid from the meatus to the cavity of the drum. The most exact researches of later days have, we believe, ascertained, that no such opening does exist in the natural structure of the parts. There can be no doubt, however, that there is occasionally a communicating foramen which allows of the passage of air, or smoke, through this intercepting membrane. The existence of it is proved beyond contradiction, in those persons who have had the power of expelling, by the external meatus, the smoke of tobacco collected in the mouth, which must have passed by the Eustachian tube into the cavity of the tympanum. We have been informed also, that in some of the northern Americans, this phenomenon has been observed pretty generally. The foramen has been particularly described by Rivinus, whose name it long bore. Whether it exist, however, or not, it would seem that the reflection of the skin over its external, and the membrane of the cavity of the tympanum over its internal surface, would effectually close any deficiency left between the *membrana tympani* and the bone. The membrane itself is dry, and when these reflections are removed, totally transparent. It appears to possess no vessels carrying red blood in its healthy state in the adult, though in cases of inflammation, and in the fetus, it is sensibly vascular. It differs in structure from any of the other membranes with which we are acquainted, preserving its peculiar appearance long after the other animal parts of the body are dissolved by putrefaction. Joined to this firmness and transparency, Mr. Home has of late considered it as possessing muscular fibres, which pass in all directions from the bony rim to the handle of the malleus. In the elephant this structure, he says, "is visible to the naked eye, as it is even in the human tympanum, when examined under favourable circumstances. When viewed in a microscope, the muscular fibres are beautifully conspicuous, and appear uniformly the same throughout the whole surface; the muscular fibres appear only to form the internal layer of the membrane, and are most distinctly seen when viewed on that side." Its probable use we shall have to consider hereafter. The *membrana tympani* thus formed, completely establishes a barrier between the external meatus and the cavity of the tympanum; preventing the entrance of air or other fluids. The *membrana tympani* of the fetus is more slanting in its position than that of the adult, and it is covered externally by a thin layer of white sebaceous substance, called by some *pseudo membrana*, by others *membrana* or *lamina mucosa*. This seems to consist merely of the secretion of the ceruminous glands, as the whole meatus is more or less covered by a similar whitish substance. It may be separated from the outer surface of the *membrana* in a distinct circular piece.

The *Eustachian tube*, or trumpet, is a canal formed partly in bone, and partly in cartilage and membrane, extending from the cavity of the tympanum to the upper part of the pharynx, behind the posterior opening of the nares; its direction, viewing it from the tympanum, is obliquely forwards, inwards, and downwards: about two inches in length, contracted and of a circular form at its commencement in the tympanum; it becomes gradually larger, with its sides flattened into an elliptical canal, as it approaches the pharynx, into which it opens by a transverse mouth with an elevated margin around it. The bony portion of the tube forms the third next the tympanum, the remaining two-thirds being made up of cartilage and membrane. The first of these commences in the anterior and superior part of the tympanum, and passes on in the very substance of the temporal bone, to join the other

portion. In this course it lies under the channel which contains the tensor tympani, and externally and above the canalis caroticus, from both of which it is separated only by a thin bony plate. The other two-thirds, regarded as an whole, resemble a flattened cone, whose apex is continuous with this bony portion, into the irregular edge of which it is firmly implanted. From this origin, the tube passes obliquely forward, attaching itself to the neighbouring bones, and when arrived opposite the internal ala of the pterygoid process, enlarges suddenly just before it terminates in an open mouth. The cartilage, which enters into the composition of this part of the tube, forms its internal side, or that next the mesial plane. It is of a triangular shape, and constitutes at first not only the inner side of the tube, but also the superior part of its external side. The tube has, from this appearance, been described as if made up by two plates of cartilage united longitudinally at their superior edges, of which the external plate is narrow, and the deficiencies supplied by membrane, whilst the internal plate is continued from the fauces to the tympanum, forming throughout the inner half of the wall. This external plate is not always found, and in such case it is the membranous portion which completes the circumference of the tube without. It is constructed chiefly by the membrane lining the tube strengthened by some fibrous expansions arising from the adjacent bones and enveloping it closely. The Eustachian tube is lined internally by a continuation of the mucous membrane of the pharynx, which gradually loses its redness as it approaches the cavity of the tympanum, becoming also more evidently delicate in its texture. This tube establishes a communication between the tympanum and the external air, which thereby gains access to the cells formed in the substance of the malleus process, and already described as opening into the upper and posterior part of the cavity. This air, however, or any other fluid, cannot penetrate into the internal ear, as the openings between them are closed by membranes in the living subject. The foramen rotundum is shut up by its peculiar membrane, which resembles the membrana tympani in appearance: its plane is not parallel but oblique, in regard to the latter, as may easily be supposed if we consider the direction of this opening. The foramen ovale also is closed by its membrane, to which the base of the stapes is firmly affixed, the latter not filling up the whole of the opening, but leaving a narrow border in which the transparent membrane is apparent.

From the consideration of the barrel of the tympanum, we proceed to that of the parts which it contains. These consist of three small bones, called the *ossicula auditus*, some muscles concerned in moving them, and a nervous cord crossing the cavity transversely.

The figure of the ossicula has been already the subject of a particular description; and we have here to examine the relations which they bear to the tympanum, and to each other, as well as their modes of connection; we then observe the possible degree and extent of their motions, as resulting from these connections. With an accurate understanding of these points, we proceed to examine the muscles or moving powers which can be brought to act on them, and attend more particularly to the spots at which they make their appearance in the tympanum, and the relative situation of these points with regard to the bones; as it is from them alone that we can estimate the line of direction in which they act. Possessing a correct knowledge of these facts, we may calculate the probable effects of their combined or individual action on the bones, and consequently on the parts connected with them, the

membrana tympani and the membrana fenestræ ovalis. The handle of the malleus is attached, throughout the whole of its length, to a line in the upper half of the membrana tympani; the lower point of it being fixed to the apex of the cone we have described in the centre of it, from whence the attachment is continued to the circumference. Above, the neck of the malleus is tied to the bony ring of the tympanum; its head lying in a hollow of the superjacent bone, to which it is fixed by a strong ligament descending from above, and passing to its inner surface. Anteriorly the long process is admitted into a fissure of the bone, from which it cannot be removed in the adult. The direction of the long axis of the malleus will be thus nearly perpendicular, and that of its long process horizontal. In this situation, its double articular surface is directed backwards and inwards, the whole of its neck and head being above the frame supporting the membrana tympani; so that when viewed from without that opening, we can see its handle only. The articular surfaces of the incus lie closely embracing the corresponding surfaces of the malleus, to which it is attached by a capsular ligament, allowing some freedom of motion: its short leg is directed backwards and a little downwards, so that its point rests in a small hollow at the commencement of the malleoid cells, in the same horizontal line with the long process of the malleus: it is further fixed in this spot by two distinct and strong ligaments, which effectually prevent its starting. The long leg descends in a line nearly parallel to that of the handle of the malleus, but behind it, and removed farther inwards from the membrana tympani; it does not, however, extend so far down into the cavity of the tympanum. From this position all that we can see of the incus below the circle of the tympanum is the inferior part of its long leg, as it turns inwards to be connected with the head of the stapes, to which it is united by a loose capsular membrane. This last bone, as it lies in the fenestræ ovalis, has the long axis of its base nearly at right angles to the descending crus of the incus, and the manubrium of the malleus, and consequently parallel to the long process of that bone: the base has its convex edge uppermost, and is fixed firmly to the membrana fenestræ ovalis: from the narrow strip of membrane left between it and the rim of the fenestræ, it can have but a very circumscribed and inconsiderable motion. Such are the relative positions and connections of these bones; and if we examine their possible motions, we shall find them limited to very narrow bounds. It will be found that they have but little action among themselves, their motions being chiefly restricted to changes producible on the membranes of the tympanum. Of their individual action we shall say nothing; as, from their connections, we can hardly suppose one bone to be moved, without influencing the motions of the whole, which we shall therefore consider in combination. The axis of motion of the integrant bones is in a line drawn from the point of the short leg of the incus to the commencement of the long process of the malleus; so that if the parts of the bones lying below this line be drawn inwards, the parts above must be carried outwards, and *vice versa*. From the connections, however, of the head of the malleus and the base of the stapes, their motions in these directions can describe but very minute portions of a circle. The incus, having no muscles, would appear in this instance to be perfectly passive, rotating on its short leg as the stapes acts with advantage on its long process, or the malleus on its articular base. Besides this motion inwards and outwards, we are disposed to admit of a slight motion of the bones backwards and forwards, in which, however, they do not move in parallel lines, there being two centres of motion, one in the point of the short leg of the incus, the other in the head of

the malleus, the revolving points being the manubrium of this bone and the long leg of the incus. But from the peculiar obliquities of their articular surfaces, which may be readily understood by examining the bones, if the handle of the malleus is drawn forwards, the long leg of the incus will be carried backwards, and communicate its motion to the head of the stapes: if the stapes be drawn backwards, it will carry with it the long leg of the incus, consequently to which the handle of the malleus will be carried forwards and a little outwards. These motions are, however, still more limited than the former, in which the integrant bones are carried on their axes either inward or outward, and even by minute research scarcely determinable.

The muscles which can be brought to act on the ossicula are four in number; three belonging to the malleus, the tensor tympani, externus mallei, and laxator tympani; and one attached to the stapes, the stapedius.

The *tensor tympani* arises from the upper side of the cartilaginous portion of the Eustachian tube, just under the opening in the sphenoidal bone, for the passage of the arteria meningea media; from thence it runs backwards towards the tympanum, forming a rounded fleshy belly, terminating in a tendon: during this part of its course, it lies enveloped in a strong membrane, in a canal formed for its reception above the bony portion of the Eustachian tube: arrived at the extremity of this canal, its rounded tendon emerges into the tympanum, passing through a contracted circular opening at the end of the bony channel. On coming through this hole, it turns over its external edge, and goes towards the membrana tympani, in a line directed horizontally and a little backwards, to be inserted into the short process of the malleus, as it lies turned towards the internal part of the tympanum.

The *externus mallei*, in shape like the *tensor tympani*, arises by a small origin from the exterior edge of the spinous process of the sphenoidal bone, from which it runs backwards and a little outwards towards the fissure in the genoid cavity, along which its tendon proceeds, and becomes fixed to the whole length of the long process of the malleus, as it lies in its particular groove at the anterior part of the cavity of the tympanum.

The *laxator tympani* is the smallest of the muscles of the malleus: it rises from the superior and posterior margin of the bony ring of the tympanum, from which point it descends to be fixed by a tendon into the handle of the malleus, near the root of its short process. The upper extremity of this little muscle lies in a fold of the membrane of the tympanum, just where it begins to be reflected over the membrana tympani, and as it descends it passes a little forwards.

The *stapedius* arises in a small cavern in the petrous portion of the temporal bone, near the aqueduct of Fallopius; passing through this, its tendon emerges into the tympanum through a small circular hole, over which it turns and passes forwards and a little downwards and outwards, to be inserted into the posterior part of the neck of the stapes.

The action of this last muscle and the *tensor tympani* is not in the direction of their fibres, but in a line which forms an obtuse angle with them, their powers acting by the intervention of a bony pulley. By observing the situation of this point in its relation to insertion of the tendon of the *tensor tympani* into the malleus, and bearing in mind at the same time the connections of the ossicula, we shall find that the effect of its action will be to draw the *membrana tympani* inward, by which means it becomes proportionally tense. At the same time, by the joint rotation of the malleus and incus on their axes, the long leg of the latter will be drawn inwards, and somewhat forwards; and,

from its connection with the stapes, must depress that bone, but more particularly the anterior end of its base, in the *membrana fenestra ovalis*. The action of this muscle is the most extended of any of the four, and the most easily determined by examination. The point at which the tendon of the *stapedius* appears is situated rather above a plane, which should be drawn through the base of the stapes, and more internal than its neck; so that it must proceed a little downwards, as well as forwards and outwards, to arrive at its insertion. Its action would appear to us to be that of drawing the neck of the stapes towards this pulley; and in effecting this, it will necessarily draw with it the long leg of the incus, thereby carrying the handle of the malleus a little forwards and outwards, and relaxing in a slight degree the *membrana tympani*. The other effect of its action will be the depressing of the posterior end of the basis inwards, and drawing its anterior end proportionally outwards. For reasons, however, before mentioned, this can produce but little visible effect on the membrane of the fenestra ovalis, which will allow but of little motion in the base of the stapes. The possible effects of the action of this muscle has been a fertile field of conjectures, which we fear are not yet reduced to truths.

The *externus mallei* will draw the handle of the malleus forward and upward, and will consequently stretch that half of the membrane which lies beyond the malleus, and relax that part which lies between the handle and its origin; at the same time, it will cause the long leg of the incus to rotate backwards, and carry with it the head of the stapes. It may possibly thus exert some power over the membrane of fenestra ovalis.

The *laxator tympani* is described as drawing the handle of the malleus upwards and backwards, and thus relaxing that part of the membrane which lies between its insertion into the malleus and its origin. It will stretch the part of the membrane lying on the anterior side of the malleus, and become in some measure the antagonist of the former muscle.

The action of the muscular fibres of the tympanum, as described by Mr. Home, would be to bring the broad cone of the *membrana tympani* into a plane surface, and thus antagonize the *tensor tympani*, if the handle of the malleus could be affected by their action.

We have thus endeavoured to give the reader some account of the motions of the ossicula, the greater part of which are demonstrably evident on the recent ear of the adult; the others are so slight, as to oblige us to calculate rather on their probable, than assert their real degree. The general conclusion as to their actions will be, that they are all to be referred to the possible changes they can produce on the membranes of the tympanum, which consist in their being rendered tense or relaxed. The degree to which this is effected by their intervention does not appear to be within the reach of experiment in the living subject; the examination of such points in the dead must be necessarily liable to error. The effects of different degrees of tension or relaxation, in modifying the pulses of sounds, will be considered hereafter.

An object met with in the cavity of the tympanum yet remains to be noticed, which, though not subservient to any purposes perhaps immediately concerned with hearing, must not be passed over. On looking into the tympanum, we observe a small nervous cord crossing it transversely, called from its situation *chorda tympani*. On tracing it from behind, we find the nerve entering the tympanum at the base of the small pyramidal eminence, whose apex gives passage to the tendon of the *stapedius*; from thence it passes obliquely across between the long leg of the incus and the

manubrium of the malleus, to which last it is so closely attached, that it cannot move without interesting the nerve at the same time. As it crosses it, however, near its upper end, and not far from the axis of motion, it cannot be drawn much in the motions of this bone. Having passed it a little above the insertion of the tensor tympani, it increases in size, takes an horizontal course forwards, and goes out of the cavity in company with the tendon of the externus mallei.

The facial nerve, in its passage through the *aquæductus Fallopii*, gives off two small twigs, which supply the tensor tympani and stapedius: during its stay in the same channel, it sends off also the nerve we have been describing, which, after its exit from the anterior side of the tympanum, forms a junction with the lingual branch of the inferior maxillary nerve.

The whole cavity of the tympanum is lined by a mucous membrane, which we have mentioned already as gaining access to the ear through the Eustachian tube; from the opening of which, it may be seen spreading in all directions. Internally, it covers the membranes of the fenestræ; externally, it passes over the *membrana tympani*, forming its inner layer, and it is between these the handle of the malleus is confined in its situation. Behind, it enters the mastoid cells, which it lines throughout. Before, passing from the Eustachian tube, it is reflected over the glenoid fissure, the opening of which it closes towards the tympanum, surrounding in this place the long process of the malleus, and the *chorda tympani*. In the middle of the tympanum it is seen passing over the *officula*, forming between them and the walls of the tympanum numerous membranous processes of considerable breadth. It thus completely covers the cavity of the middle ear, and the parts connected with it, having but one aperture of communication with the external air by means of the Eustachian tube. It appears to be a mucous membrane, analogous in structure to the membranes lining the sinuses, and like them, defends the parts it covers from the immediate contact of the air. When inflamed, or in the scætal state, it is of a marked red, and resembles precisely the surface of other mucous membranes, which it resembles likewise in its offices. It is extremely sensible, by which character it may be still further distinguished from fibrous periosteum.

The *membrana tympani* is so delicate in the fœtus, as not to allow us to make any distinction into layers. As it becomes firmer after birth, its direction is less oblique, and it is removed to a greater distance from the internal side of the tympanum. The Eustachian tube increases gradually also in size as well as length, as the dimensions of the cranium are enlarged. The *officula* and bony walls of the tympanum undergo but trifling alterations, as the reader will have observed in the description of those parts. The mucous membrane pours out less of its secretion as the age advances: so that after the second year, we seldom see in the healthy state any of that whitish mucus which fills the tympanum in the fœtus, at which period the membrane is vascular and spongy.

The work of demonstrating to the adult ear the positions and structure of the parts we have been describing, is one of considerable nicety and labour. The most useful views, perhaps, are those which shew the relative situations of the important parts, with regard not only to the tympanum, but to the whole apparatus of the organ; and these may be obtained by sections of the cavity in various directions. We shall mention only a few of the most useful here, as when by means of these the inquirer has obtained a correct knowledge of their relations, he will readily execute any further sec-

tion without the assistance of written directions. We will first suppose him to have removed from the skull, by two transverse sections, the parts more immediately connected with this organ. If then a fine law be carried in a plane, which shall extend horizontally from some part of the lower half of the external meatus to the lower edge of the internal meatus, he will obtain, in the upper section, a view of all the more important parts of the tympanum, without in any way injuring the situation of its contents, as he will have passed below the point of the handle of the malleus, and consequently the base of the flapes. He will be able to observe the tendons of some of the muscles, and the points at which they emerge, most of the openings of the tympanum, and the direction of its membranes. Having studied this, he will learn what is yet wanting to complete the view of the subject, and proceed either on the same, or any sections, to remove such parts as obstruct his researches. The most useful perpendicular section, is one carried in the direction of a plane passing perpendicularly through some part of the interior half of the meatus, towards the middle of the *fella turcica*. In this instance the *officula* will escape, and each half of the section contain parts of considerable interest. To obtain a view of the obliquity of the *membrana tympani*, we remove longitudinally the anterior half of the meatus, down to the bony circle which supports it: in the same piece we may open into the tympanum from before, and by dividing the Eustachian tube through the whole of its length, gain a view of its general direction and structure. The *officula* should be studied in their scætal state, at the latter period of which time they are perfect in form, and can be removed without danger of breaking. Another method of obtaining a knowledge of the relative situations of the bony parts of the structure of the internal, as well as middle ear, is by taking casts of them in easily fusible metals. The bone is encased in a covering of plaster which surrounds every part but the opening of the external meatus: it is then heated red, and the heat continued till smoke no longer issues from the meatus: at this period some fluid metal, consisting of equal parts of lead, tin, and bismuth, is poured into the opening, and the whole thrown into water. The plaster and surrounding bone are, after this calcination, easily removable by any sharp instrument, and the metallic cast exposed, representing accurately and completely, if the operation has been successful, all the cavities of the ear in their relative situations and proportions. On account of the difficulties of the investigation arising from the minuteness and delicacy of structure, we have thought it necessary to give these few introductory hints as to the best mode of prosecuting the examination of the ear: and although we may fail in our first attempts, the successful execution of them will be afterwards readily obtained, when directed by the acquired skill and corrected knowledge of the inquirer.

In our short comparative notice of the external ear, we found man possessed of parts which were deficient in some other classes of animals: in the present case we shall find some of them approaching him more nearly in the structure of this organ, inasmuch as they have a tympanum exterior to the part which receives the auditory nerve, though varying much in construction from that of the human ear. The *membrana tympani* is found in some of the reptiles, and more particularly in those which inhabit chiefly the surface of the earth. In birds it is remarkably large: in the cetacea, and other orders of mammalia, it resembles much that which we have been describing in man. The cavity of the tympanum is wanting in all those creatures who possess no *membrana tympani*; consequently, in the classes of insects, worms, fishes, and most of the serpent tribe. We find it in those reptiles

reptiles who are furnished with this membrane; in birds, where the cavity is increased by its continuity with the cells of the cranium; in cetacea and the other mammalia, in whom, however, it is not so large as it is in the human subject. The Eustachian tube is found only in those animals who are provided with the cavity and membrane of the tympanum, to which it would appear, therefore, to be subservient. It has no existence in the serpent tribe, who are furnished, however, with an ossiculum. The ossicula are not found in the three lower classes or in some of the aquatic reptiles. In the other creatures belonging to this last tribe, and in the two upper classes, they are always to be seen. In the more perfect animals, as we call them, they are more in number, have articulated junctions, and are provided with muscles which act by their intervention on the membrana tympani. The fenestra ovalis is observable in all the animals in which we can distinguish an organ of hearing, with the exception of the spinous fishes and the genus *Sepia*. In those who have no ossiculum, it is closed by a membranous or cartilaginous operculum, whilst in the contrary case it is more or less shut up by a bone adapted to its opening. The fenestra rotunda is deficient in all those creatures who do not possess that part of the internal ear called cochlea. There is some appearance of it in birds who have the rudiments of the cochlea: in the mammalia it is always conspicuous, but the largest in those animals who are furnished with the proportionally largest cochlea.

The internal Ear or Labyrinth.

We have now carried our researches from without, to the most internal part of the organ of hearing, designed for the reception of the terminations of the auditory nerve. The best mode of prosecuting our inquiries will be, first, to bring ourselves acquainted with the bony labyrinth; then with the membranous parts it contains, or the additional apparatus on which the nerve is spread; and, lastly, to trace the distribution of the nerve to the intimate recesses of these most delicate parts. The bony cavities communicating with each other, into which this nerve is admitted, are known altogether by the name of *labyrinth*, and have been divided into three portions; a middle one, named *vestibulum*; the common centre of the different cavities which compose the labyrinth; an anterior division communicating with it, called the *cochlea*; and a posterior one, consisting of the *three semicircular canals*. The detailed description of these has been already given in that of the temporal bone, to which the reader is referred before he begins the study of the soft contents of the labyrinth. By a careful attention to what is there described, he will readily inform himself of the relative situation of the contained parts, as well as their form and connections, as these delicate parts are all exactly adapted to corresponding surfaces in the surrounding bony case. It has been found that all the cavities we have above-mentioned are lined by a fine membrane differing in its nature from that which forms the lining of the tympanum, and little known to us, until of late years. This ignorance of its form and structure is the more to be wondered at, if we recollect but for an instant the acknowledged genius and industry of those eminent men who have made the ear the subject of so many elaborate researches. Till lately, all that we knew of the contents of the bony labyrinth, consisted in some vague ideas respecting certain *zone sonora*, as they were termed by Vallava, connected with the semicircular canals, and a *septumnerveum* dividing the vestibulum into two halves. The loose descriptions, however, which were given by different anatomists of these expansions, lead one to suspect that they were far from possessing any

thing like a correct knowledge of the membranous labyrinth, as it has been since described by Scarpa. From repeated investigations of the organ of hearing in different classes of animals, he was induced to suspect that there existed in man a membranous labyrinth included in the ossific one. He had ascertained the existence of it in fishes, reptiles, and birds: and was led by analogy to expect a similar apparatus in the human ear. After numerous trials, he fully confirmed his rational conjecture, and was enabled to observe the great similarity which it bore to that he had remarked in the former classes. He discovered also an additional part, consisting of a membranous sacculus placed in the cavity of the vestibulum, the probable use of which we shall have hereafter to consider. In examining the soft contents of the labyrinth, we shall begin with those contained in the bony semicircular canals. Each of these bony channels encloses another membranous tube, which is perfectly distinct from the perioticum, and which should be considered as the proper semicircular canal. These membranous tubes are of less diameter than the bony case in which they lie, from which they are separated by a delicate cellular tissue, forming the medium of connection between them. Each of the canals, at the part from which it commences in the vestibule, dilates into an oval bag, which is known by the name of *ampulla*, corresponding precisely in form to the dilatation we have already described in the beginning of each bony canal. It contracts again into a narrower tube as it proceeds, still accommodating itself to the form of its bony case; and after making its semicircular curve, returns again to the same membranous sac in the vestibule from which it commenced. These little canals are cylindrical, and pellicled as well as their ampulle, which appear as small oval expansions of the membrane, just before the canal communicates with the sac common to them all. One of these ampullæ lies in the sinus ellipticus of the anterior or superior bony semicircular canal; another is contained in the fovea orbicularis of the inferior bony canal. The third ampulla is enclosed in the sinus infundibuli-formis of the exterior bony canal. The membranous canals proceeding from the two first of these ampullæ, after making their circuit, unite and form one common canal, communicating with the *alveus communis* in the vestibule. The exterior membranous canal takes a solitary course throughout, and returns as it departed, by its own proper channel. We have now traced these canals from their ampullæ, back again into the vestibule, and have to describe the cavity which forms the common centre of communication between them all. In the fovea *æliptica*, which lies nearly opposite the fenestra ovalis, there is placed an oblong transparent membranous bag, which crosses the vestibulum transversely; the largest end of this little sac lies in the fovea we have just mentioned; whilst the other extremity, contracted a little in size, stretches towards the posterior canal. It is from this *alveus communis*, as it is termed by its first discoverer, Scarpa, that the membranous canals proceed, and it is back again into it that they open. The ampullæ of the superior and external canals commence from that part of the sac which lies in the fovea *semieliptica*; the ampulla of the posterior canal having its origin in the smaller portion of the bag: from these points the membranous canals proceed in the manner we have described, and open again by two apertures into the middle portion of this sac, thus completing the free communication which we observe between each particular tube. These cavities are all filled by a limpid fluid, which increases so much the natural transparency of the membranous investment, that it may escape the eye of a person who was not prepared to find it.

On making an opening into the vestibule in the recent subject, if the sac is left entire and turgid, it has the appearance of a bubble of air, so perfectly pellucid are the membrane and its contents. Independently of this, we find in the vestibule another membranous sac of a rounded figure, which is placed in the fovea hemispherica of this cavity. It is also transparent, and forms altogether a sphere, one half of which is buried in the corresponding fovea, the other projecting into the vestibule. The first of these halves adheres so strongly to its containing hollow, as not to be separated from it without laceration: the projecting half is received into a corresponding depression in the membranous alveus communis, without, however, in any manner, communicating with its internal cavity. This spherical sac is closed on every side, and is distinct from all the other membranous receptacles of the labyrinth, being filled with its proper limpid fluid. In the fœtus, during the early months, the investment is so firm as not to collapse, when the fluid has been let out by a lancet.

We here finish our account of the membranous contents of the canals and the vestibules; and to complete the description must examine the soft parts which go to complete the construction of the cochlea. It has already been mentioned, that the lamina spiralis of the cochlea was composed of different substances. One, a bony plate forming the part next the central modiolus, requires no further description; it is the part which completes the lamina spiralis that we have now to examine. It is found to consist of two substances, one of which approaches the nature of cartilage, the other being perfectly membranous. The first of these, which is termed the *zona coriacea*, from the firmness of its texture, is attached to the edge of the bony lamina spiralis which it accompanies in its circumvolutions, and where the ossific plate ceases, this coriaceous part is still continued round the modiolus to the apex of the cochlea. The margin of this coriaceous part, which is fixed to the bony lamina, is pierced by numerous canals, proceeding in a radiated direction throughout its substance, which are continuous with those canals which lie between the plates of the bony lamina, and which have been already described as adapted for the reception of the auditory nerve. The external edge of this part is somewhat transparent, and when subjected to the microscope exhibits a series of reticulated cells, filled with a limpid fluid, in which we can perceive numerous white filaments, which are the ultimate expansions of the nerve. The other portion of the septum is membranous, and appears to be a duplicature of the periotem lining the feals of the cochlea reflected from the plates to complete the deficiency of the lamina spiralis, which it encloses in its fold. In other words, the periotem, which covers the two plates of the bony lamina spiralis, is continued from its edge over the zona coriacea, and meeting at the termination of this, coheres, and proceeds to be reflected over the internal parietes of the cochlea. And as both the ossific and coriaceous parts decrease in breadth as they approach the apex of the modiolus, it will follow that this membranous portion forms a greater part of the septum in proportion as the lamina spiralis advances to its termination.

We here conclude our description of the labyrinth, but before we proceed to consider the distribution of the auditory nerve, it will be proper to take notice of the fluid contained in the different divisions we have been following, and which, from the constancy of its appearance, would seem to execute no trivial part in conveying sounds to the nerve with which it is in immediate contact. It has been ascertained by numerous and indisputable examinations, that the labyrinth is filled by a fluid, as well as the membranous re-

ceptacles which it encloses, from which it will appear, that the membranous labyrinth itself, with its contents, may be said to float in the water of the bony labyrinth: which will be the more readily admitted, if we consider that the same occurs in the ear of some other classes of animals, as fishes, reptiles, and birds. It is also very observable in the human ear, on account of the great difference between the diameters of the membranous semicircular canals and their bony case. In the vestibule it has been often demonstrated occupying the space between the fenestra ovalis and the membranous sacs, long before these sacs were known to exist in their present form. With regard to the feals of the cochlea, the fact of their being turgid with fluid was long since admitted, and the lamina spiralis has been described as lying "inter duos aquæ rivulos demersa." The aqueducts, which communicate with the cavities containing this fluid, have been already described; we have here only to add, that they are lined by a continuation of that delicate membrane which invests the internal surface of the labyrinth, of which we deferred the mention till we had considered all the parts which it covered. We find it, if we begin from the vestibule, lining the whole of that cavity, dipping into the semicircular canals, entering into the vestibular scala of the cochlea, and passing through the opening of the infundibulum at its termination, descending through the tympanic scala to the foramen rotundum. It is the same membrane which lines the aqueducts, and terminates in an expanded shape under the dura mater, covering the petrous portion of the temporal bone. Of the peculiar structure of this membrane, as well as of that which forms the membranous receptacles, we know scarcely any thing. It supplies the place of periotem, and we have throughout mentioned it under that name: it would seem, however, to differ from it materially in one character, namely, that we suppose it to be the secreting surface from which the fluid of the labyrinth is poured out. The membranous canals and their sac appear to be of a similar structure, though perfectly distinct in situation. The only difference observable between the structure of the membranous labyrinth in the fœtus and the adult is, that in the former case it is most evidently vascular, whilst, in the latter, it is too delicately thin to allow of the existence of red blood-vessels. The early development of the ossific labyrinth in the fœtus, and the perfection which it reaches long before the usual period of birth, have been elsewhere noticed; we introduce the mention of it here, only, as it is in the fetal ear, that we must seek with the best chance of success to examine the membranous and other soft parts which it contains. Before we attempt this delicate investigation, we must obtain a correct knowledge of the ossific labyrinth, and the relative positions of its different cavities, in order to remove the bony parietes, without injuring the subjacent parts by random, or ill-judged efforts. With such knowledge but few directions are necessary, without it the most minute would be given in vain. To gain a view of the membranous structure, we begin by laying open the vestibule from the foramen ovale so as to bring into sight the sinus of the foramen rotundum and the commencement of the cochlea. This is easily effected in a fœtus of three or four months, where the labyrinth is already evolved, and the removal of the bony parts is neither a work of difficulty nor labour. We have this advantage, also, that at this early period the tunics of the membranous receptacles are much more compact and firm, than we observe them at after times; and in addition to this, we always find them involved in a mucous wrapping, which adds much to their firmness, so that the membranous semicircular canals, when exposed to the air and cut transversely, still preserve their truncated tube open. It is after cautiously

cautiously removing the osseous covering, that the pipe of an Aneſ's ſyringe has been introduced into one of the ampullæ, and from thence the membranous canals and their common ſac have been filled by a coloured fluid, proving beyond doubt the manner of their communication. This ſac may be preſerved entire even in opening the veſtibuſe of the adult from the fenestra ovalis, or we obtain another view of it by cautiously cutting away the cochlea, ſo as to gain an inſight into the veſtibuſe from the part which it occupied. All theſe investigations ſhould be made in the moſt recent ſubjects, as the membranes of their fluid ſoon loſe their transparency, and become inextricably confuſed. It is, perhaps, from examining them in this ſtate, that anatomists, prior to Scarpa, have given us ſuch vague and unintelligible accounts of their ſtructure. The mode of obtaining a proof of the exiſtence of a fluid in the labyrinth, has been moſt excellently deſcribed by Meckel in his "Differatation de labyrinthauris contentis," to which we ſhall refer the reader who wiſhes for a minute and particular account of his manner of proceeding. He preſferred the making a ſmall opening into the cochlea, from which a fluid immediately burſt, and then by preſſing the baſe of the ſtapes againſt the fenestra ovalis, he was enabled at will to force out more of its fluid contents; the ſame fact occurs if we make the opening into one of the bony ſemicircular canals. By freezing alſo ſeveral recent ears, he decidedly obſerved an icy cake in the labyrinth formed by the congelation of the water it contained. To obtain a view of the zona mollis of the cochlea, we make ſections of this body in different directions, or carefully remove its ſides, beginning at the fenestra rotunda, and following the ſcala to its termination in the infundibulum. It need only be added, that from the tenuity of the parts to be examined, the inveſtigator ſhould be provided with magnifying glaſſes of conſiderable power.

Having thus ſtudied the apparatus deſigned for the reception of the auditory nerve in man, we proceed, before we complete our deſcription of the organ, by tracing its extreme diſtributions on theſe ſoft parts, to give a ſuccinct account of them as they have been ſeen in other claſſes of animals. The *cray-fiſh* and the *ſepia* have been found to poſſeſs only a veſtibuſe; and the animals of all the other claſſes have the additional apparatus of ſemi-circular canals. And it may be worth our noticing that in all of theſe, the membranous ſemi-circular canals regularly ſwell into an ampulla, in the part at which the auditory nerve is admitted; that all of them are filled with their peculiar fluid; communicate freely with a common ſac in the veſtibuſe, and are immerſed in the water of the labyrinth. *Fiſhes*, however, and *reptiles*, have this peculiarity, that their membranous receptacles are found to contain certain ſolid bodies, *lapilli*, or *officula*, as they have been termed, which are ſuſpended by a great number of nervous fibrillæ. Again, the more perfect animals are provided with the elaborately conſtructed cochlea, and the fenestra rotunda.

We ſhall take up our deſcription of the *auditory nerve* at that part of it where it enters the internal meatus; its connection with the encephalon will be found in the hiſtory of the brain; the foramina, through which it penetrates to gain admiſſion to the ear, are deſcribed under the article CRANIUM. The auditory nerve lies in the internal meatus, in a twiſted form, and rolled up, as it were, in different bundles, which, when unravelled, give the nerve the form of a flattened band of fibres. At the commencement of this twiſted appearance, we obſerve a ganglion-like ſwelling, which gives origin to three branches, differing conſiderably in ſize.

The *largest* of theſe, as it arrives at the *macula cribroſa*,

divides into numerous threads, which pierce the pyramid of the veſtibuſe, into which they enter, appearing, to uſe the words of Scarpa, "barbulæ albidiffimæ quam ſimiles." Theſe divide into two portions, one of which is received into the membranous ſac of the *alveus communis*, over which it firſt expands in a fan-like form, occupying about two-thirds of its length. Soon after this expansion begins, we loſe ſight of the nervous fibres which penetrate the ſac, and ſeem to terminate in a delicate nervous pulp, ſpread over the inner ſurface of this membranous inveſtment. The other portions of this *barbula* take their courſe towards the ſuperior and exterior canals, the ampullæ of which they embrace with this expanded ſurface: after which, they penetrate the membrane, and appear as a ſoft nervous pulp on the inner ſide. The *leſſer branch* penetrates through a ſingle foramen in the bone from the meatus; which, however, is ſubdivided into numerous ſmall canals, before it opens again at the baſe of the ſolla orbicularis of the poſterior canal: in conſequence of this diſpoſition, we ſee the nerve emerging in numerous fibrillæ, remarkable for their whitenefs, which are ſpread over the ampulla of this canal, which they ſubſequently penetrate, and terminate, as the other branch, in a nervous pulp on its inner ſide. After minute inveſtigation, Scarpa was unable to trace this pulp beyond the ampulla into the membranous canals. The *middle branch* of theſe three paſſes almoſt immediately after its ſeparation from the others, through a foramen, or *macula foraminuloſa*, correſponding to the bottom of the ſacculus ſphericus, into which it enters, and the internal ſurface of whole membrane it covers with a nervous pulp, which is more oſtenſible at the part by which the nerve penetrates. This diſtribution has been compared, and not unaptly, to the expansion of the optic nerve into the retina.

The auditory nerve having given off theſe branches, goes direct towards the baſe of the *cochlea*, where its fibres become untwitted a little, and penetrate the *tractus ſpiralis foraminuloſus* on every ſide, in the direction of the axis of the modiolus; a tolerably large cord in the middle of the nerve paſſing into the hole in the baſe, and running through its length, till it arrives at the infundibulum, and the laſt half turn of the cochlea. The nervous fibres, which paſs through the external circle of the tractus ſpiralis, penetrate the firſt turn of the ſcala; thoſe which paſs through the next circle of the tractus arrive at the ſecond turn of the ſcala. The fibres having penetrated in this way through the ſmall canals, arrive at the external ſuperficies of the modiolus contained in the ſcala tympani, and paſs on till they arrive at the lamina ſpiralis: here they change their direction, which was before parallel to the axis of the modiolus, and follow the plane of the lamina ſpiralis, which they penetrate, and between the laminae of which they radiate in minute penicillous filaments, extending on through the zona mollis, where they are finally loſt, as before noticed. Thoſe which provide the ſecond circle of the tractus ſpiralis have to take a longer courſe before they arrive at the ſcala tympani of the ſecond turn, where they are diſtributed in the manner above deſcribed, receding from the modiolus, and terminating in the moſt minute reticulated filaments in the outer edge of the ſubſtance of the zona mollis. This diſtribution of the nerve through the ſpiral lamina of the cochlea is very conſpicuous, when viewed through a microſcope, and ill more diſtinct, if the cochlea be macerated for a few hours in a mixture of ſpirit of wine, and nitrous acid, which will be found to increaſe the transparency of the osſeous lamellæ. The nerve which paſſed through the centre of the modiolus, is found to ſupply the laſt half turn in the ſame manner as the other branches did the turn below.

We have omitted the mention of the arteries, and other vessels of the ear, as they possess no peculiarity of disposition, and will be better described elsewhere. It is sufficient to remark, that the whole of the organ is well supplied with vessels and nerves from the most contiguous trunks, the veins of the internal ear communicating with the lateral sinuses.

We thus complete the first great division of the subject, having given a detailed history of the human ear, and a brief account of it as it exists in other animals. Before, however, we shall attempt to exhibit what is at present believed, with regard to the functions of this apparatus, we think it proper to give a short account of the powers of the human ear in distinguishing the varieties of sound; after which inquiry, we shall be better prepared to take a survey of its physiology, as far as it is at present understood.

Description of the Plates in which the Anatomy of the Ear is represented.

PLATE I.

Fig. I.—A well-formed left ear of a male, drawn from life. It has a more rounded shape, is thicker, and is marked by stronger features than in the female.

a to *e*, the helix, forming the external circumference, or fold of the auricle.—*u*, the upper end, or beginning of this border, sloping into the concha; *b*, part of the edge which is lost in the skin of the face; *c*, *d*, that part which is prominent from the head; *e*, the lower end of the fold, which terminates in the lobule of the ear.

f to *m*, the antihelix, forming a plait, or fold, in the external ear.—*f*, *g*, the upper end of it dividing into crura, sinking under the edge of the helix; *h*, the junction of the crura, or processes *f* and *g*; *i*, *k*, the lower end of the antihelix, continued at *i* into the concha, and at *k* into the antragus.

l, the tragus covering the entrance to the external meatus.

m, the antragus.

n, the lobe of the ear.

o, the furrow between the helix and antihelix.

p, the oval, or boat-like depression between the crura of the antihelix.

q, the concha.

r, the beginning of the meatus auditorius.

Fig. II.—A well-formed female ear, drawn from life. In its most perfect form it possesses a more lengthened and delicate shape than the male.

Fig. III.—A representation of the muscles which move the external ear, or auricle. They are exhibited as seen from behind, or from that surface which is turned towards the skull, in order to obtain a more complete view of the whole at one glance: there is less objection to this, as the muscles are not attached immediately to the bone, but to the aponeurotic and cellular sheath which covers it.

a, *d*, *e*, the cartilage of the ear, as seen from that side which looks towards the cranium.

f to *p*, the attollens aurem.—*f*, *g*, *b*, *i*, the upper end of this flat and delicate muscle, the fibres of which converge; *l*, *m*, and terminate in a tendinous expansion; *o*, *p*, attached to the prominence corresponding to the hollow between the crura of the antihelix.

q to *t*, the anterior auris.—*q*, *r*, the anterior portion attached to the aponeurosis of the occipito frontalis: it grows narrower at *s*, and is inserted tendinous into the prominence at the back of the beginning of the helix *t*.

u to *x*, two retrahentes aurem.—*u*, *v*, *w*, *x*, the upper and larger of these two; it consists of two or three portions of muscular fibres, *u*, *v*, *w*, and is inserted by an evident

tendon into the bulging part of the pinna, corresponding to the hollow of the concha; *y*, *z*, the inferior and smaller of these muscles, directed obliquely under the other.

Fig. IV.—There was considerable difficulty experienced in executing this figure, both from giving the relative situation of the parts clearly and correctly, and from the necessity of choosing such a point of view as would enable one to gain a sufficiently perspicuous view of the most important points, without giving any erroneous idea of them by the strong fore-shortening of the picture.

The external ear is seen fore-shortened straight from before. *b* to *d*—*b*, *c*, the meatus externus, as it appears detached from the bone; *b*, *c*, its two curvatures: the first, *b*, upwards and forwards; the second, *c*, downwards, and in some degree backwards; *d*, *d*, the oblique direction of its internal end, which is seen as closed by the membrana tympani.

e, the membrana tympani stretched on its bony ring, and bulging inwards.

f, *g*, *h* the malleus.—*f*, the handle or process attached to the membrana tympani; *g*, the long process; *h*, the head.

i, *k*, the incus.—*i*, the short leg or process; *k*, the long process.

m, the stapes.

V H A *m* *n* *p*, the labyrinth.—*n*, *p*, the cochlea; *n*, its beginning, its termination at *p*; *m*, the vestibulum. V, the bony case of the anterior, or smaller of the semicircular canals; H, the posterior, or largest semicircular canal; A, the outer, or smallest canal.

This figure, exhibiting the most important parts of the ear in their several relations to each other, holds a middle place between the figures of the external ear and the more intricate ones of the internal parts, to which it naturally leads us.

The remaining figures of this plate, together with the two first of the following one, represent the parts contained in the middle division of the ear, or the cavity of the tympanum: all these parts are shewn in their natural connections with each other, as well as individually. It appearing, however, scarcely possible to give the true form of these fine and delicate parts, with sufficient fidelity and clearness, of their natural size, there are representations of them as magnified to four times their natural diameters. The figures IV, 8, 9, 10, 11, XII, XIII, of this plate, and I, II, of the second, shew them of their natural size. In figures V, VI, VII, VIII, IX, X, XI, we see them magnified to four times their proper dimensions. The form of these parts varies from many causes: we have chosen that which appears the most general and the most perfect.

Fig. V.—The labyrinth and ossicula auditus, four times their natural dimensions. Although the labyrinth is not shewn so completely in this figure as in those of the following plate, it was represented here in order to shew the connection between the different bony portions of the ear, that when we meet with the views of the labyrinth, we may be previously acquainted with the relations they bear to the surrounding part. Independently of this object, the figure before us exhibits the mutual connections of the ossicula, the order in which they are placed, and the general line of their directions. On these accounts it should be studied before we proceed to the following figures.

a to *e*, the malleus in full view.—*a*, the long process; *b*, the shorter process; *c*, the handle, or process attached to the membrana tympani; *d*, the neck; and *e*, the head of the malleus.

f to *i*, the incus.—*f*, the body of the incus; *g*, the short leg; *h*, the long leg, or process; *i*, the small epiphysis of this leg articulated with the stapes.

k to *n*, the stapes.—*k*, the small head of the stapes; *l*, the anterior crus; *m*, the posterior crus; *n*, the basis, connected with the membrane which closes the fenestra ovalis.

o to *M*, the labyrinth.—*o* to *r*, the first turn of the cochlea; *s t u v*, the second turn; *w x*, the half turn, or third; *y*, the foramen rotundum, of a somewhat triangular form; *z z*, the vestibulum; A B C D, the anterior, or superior of the femicircular canals.—A, the ampulla, or sinus ellipticus; B C, its curvature; and D, its junction with the inferior or posterior canal; E F G H, the inferior canal.—E, its ampulla, or fovea orbicularis; F G H, its peculiar curve, and the connection of the united canal D, with the exterior femicircular canal; I K L M, the exterior canal.—I, the ampulla, or sinus infundibuliformis; K L, the direction of its curve; M, its termination in the vestibulum.

Fig. VI—The malleus, drawn in such a situation as to gain a view of the long process *a a*, and the smooth cartilaginous surface ***, for articulation with the body of the incus.

Fig. VII.—A longitudinal section of the malleus, being the anterior half of the last figure, reversed so as to shew the greater and smaller medullary cells.

Fig. VIII—The malleus, in the same position as in *fig. V*, but separated from the incus; *a, b, c, d, e*, mark out the same spots as in that figure; ***, the articulating surface.

Fig. IX.—The incus, in the same position as in *fig. V*, its parts being noted by the same letters; ***, the articular surface adapted to the head of the malleus.

Fig. X.—The stapes: this side of it is, when in its natural position, directed downwards; *a b*, the head of the stapes; *c*, the neck; *d*, the anterior crus, straighter and thinner than the posterior *e*, which is thicker and more curved; *f*, the basis.

Fig. XI.—The stapes seen from above; *a*, its cartilaginous surface, articulated with the small epiphysis of the incus; *b*, its anterior; *c*, its posterior crus; *d*, the basis, with its sloping sides. The view we have here of the stapes is a perpendicular one, as in the line of its axis it will be found to differ in form from that in *fig. V*, in the proportion that the latter differs from a perpendicular aspect.

Figures 8, 9, 10, 11, shew the bones of their natural size.

Fig. XII.—The temporal bone of an adult, from which so much of the bony meatus has been removed as to enable one to gain a view of the muscle called externus mallei.

a to *d*, the temporal bone.—*a*, the squamous portion; *b*, the zygomatic process; *c*, the glenoid cavity for articulation with the lower jaw; *d*, the mastoid process.

e e, the circumference of the meatus broken off, in order to obtain a plainer view of the cavity of the tympanum *t k i u*.

f, a portion of the petrous portion of the temporal bone.

g h, a portion of the sphenoidal bone.

i, the foramen rotundum, closed by its proper delicate membrane, which separates the cavity of the tympanum from the cochlea.

k, l, m.—*k*, the malleus; *l*, the incus; *m*, the stapes.

n o p, the laxator tympani.—*n*, the upper extremity attached to the rim of the meatus, lying in a fold of the internal lining of the membrana tympani; *o*, its fleshy portion; *p*, the tendon fixed to the handle of the malleus.

q r s, the externus mallei.—*q*, its origin attached to the

spinous process of the sphenoidal bone; *r*, its fleshy portion; *s*, its tendon inserted into the long process of the malleus.

t, the tendon of the tensor tympani as it is seen emerging from its canal.

u, the tendon of the stapedius as it passes from out of its bony cavity.

Fig. XIII.—A continuation of the former figure; but in order to shew the tensor tympani and the stapedius, some more of the bony parietes have been removed.

a b c, the Eustachian tube.

d e f, the tensor tympani.—*d*, the tendinous origin attached to the tube; *e*, the fleshy belly; *f*, the tendon affixed to the short process of the malleus.

g h i, the stapedius.—*g*, its tendinous origin; *h*, its threao-like belly, which lies in a bony canal; *i*, its tendinous end, attached to the posterior part of the neck of the stapes.

PLATE II.

The figures in this plate, with the exception of the two first, are intended to represent the structure of the internal ear, or labyrinth; and are, as well as all the foregoing ones, taken from the left ear, in order not to increase the intricacy of a delicate subject by the confusion which must arise from the change of side.

Fig. I.—The outline of the temporal bone of a child, with the ossicula in their natural size and situation.

a to *d*, the temporal bone.—*a*, the squamous portion; *b*, the zygomatic process; *c*, the petrous portion; *d*, the mastoid process.

e e, the bony ring, in a groove of which the membrana tympani is affixed.

The malleus, incus, and stapes need not be marked, as they have been already sufficiently distinguished in the preceding figures in *Plate I*.

Fig. II.—This figure represents the ossicula, from the opposite side to that in which they were seen in *fig. I*.

a, the squamous part of the temporal bone; *b*, the zygomatic process; *c d*, the bony ring; *e*, the malleus; *f*, the incus; *g*, the stapes seen from its basis.

Fig. III.—The bony case of the labyrinth seen from below, magnified four times.

1 2 3 the cochlea.—1 1, the first turn; 2 2, the second turn; 3, the incomplete third turn; *a, a, a*, small canals for the nerve of the sacculus sphericus; *b b b*, the tractus spiralis foraminulosus for the passage of nerves and vessels; *c*, the opening of a canal in the middle of the base of the modiolus, through which a nerve passes to the infundibulum; *d*, an opening in the beginning of the cochlea, for the passage of the membranous aqueduct.

e, maculae cribrosae for the passage of nerves to the ampullae of the superior and exterior canals, and the alveus communis.

f, an oval opening for the nerve of the ampulla of the posterior canal.

g, opening of the aquaeductus vestibuli.

g to *q*, the bony case of the femicircular canals.—*g h i*, the posterior canal; *k l m*, the superior canal; *o p q*, the exterior canal; *g, k, o*, the parts containing the membranous ampullae.

Fig. IV.—The bony case of the labyrinth, one half of which has been regularly removed throughout, in order to exhibit the internal characters of the bone.

a to *h*, the upper half of the cochlea.—*a a*, the thickness of its external crust in a fetus of eight months; *b c d*, the lamina spiralis; *b c*, the scala vestibuli; *e f g h i*, the scala tympani.

tympani. In this figure we see only the bony lamina spiralis. *b*, its commencement, or broadest part; *d*, its termination in the little hook, or *hamulus*; *k*, the opening of the infundibulum, where the two scalæ communicate; *l*, the opening for the aquæductus cochleæ.

m to *q*, the under half of the vestibulum.—*m*, the thickness of its case in the fœtus; *n*, the fovea hemisphærica; *o*, the fovea semielliptica; *p*, the projecting ridge between them, terminating in the pyramis vestibuli; *q*, the opening for the aquæductus vestibuli.

r, G, K, L, the canals divided each into half.—*r*, the thickness of their case in the fœtus; G, the posterior; K, the superior; L, the exterior semicircular canal; *1*, the opening of the large end of the posterior canal; *2*, the opening of the large end of the superior canal; *3*, the opening common to their conjoined tubes; *4*, the larger end; *5*, the more contracted opening of the external canal.

Fig. V.—The labyrinth laid open in the same way as the last figure, with the soft parts it contained.

a to *e*, the lamina spiralis viewed from above.—We can scarcely distinguish on this side the distribution of the nerve, which is visible on the under surface; *a a a*, the first turn; *b b*, the second turn; *c d e*, the third turn of the lamina; *d e*, its unconnected edge, through which the two scalæ communicate. Comparetti has described the lamina as consisting of four different substances, or zones, as they are termed: *1*, the bony zone, or strip; *2*, the flexible coriaceous, or leather-like zone; *3*, its vesicular zone; *4*, the membranous zone attached to the cupola.

f, the facculus sphericus, lying in the fovea hemisphærica of the vestibule.

g, space between this last and the alveus communis.

h, the alveus communis, or membranous sac, communicating with all the canals, with the fan-like expansion of the nerve over it.

i k i 3, the membranous posterior canal—*i*, its ampulla; *k*, the radiated expansion of the nerve over it.

l m, the superior membranous canal.—*l*, the ampulla.

n 5, the exterior canal communicating at each end with the alveus communis. Soemmering gives each of these canals the name of cartilagineo-membranous canal, "knorpelg häutiges bogenrohr."

Fig. VI.—The soft contents of the labyrinth removed from their bony case, of their natural size, and in their natural situation; *a a*, the spiral plate of the cochlea; *b*, the facculus sphericus; *c*, the alveus communis; *g*, the posterior; *k*, the superior; *l*, the exterior semicircular canal.

Fig. VII.—Another view of the labyrinth laid open.

a b c, the cochlea. In order to expose the zona mollis, the exterior bony case has been removed.

d e f, the vestibulum.

g to *q*, the semicircular canals.—*g h i*, the posterior; *k l m*, the superior, *o p q*, the exterior canal.

1 2 3, the lamina spiralis seen on its under surface; *3*, the two faces of the vestibule, which, viewed from this, appear as one common bag.

t u, the membranous posterior canal.

v w x, the superior membranous canal, uniting with the last at *x*.

y z, the exterior membranous canal.

This figure exhibits the distribution of the auditory nerve on the labyrinth; the large branch going to the cochlea, the three lesser branches to the vestibule and canals.

Fig. VIII.—The natural size of the parts containing what we see exhibited in the last figure.

Fig. IX.—The larger half of a recent cochlea of the left

ear, divided perpendicularly through the modiolus, and magnified to four times its size.

a, the external shell.

b, the modiolus.—*1 1*, the first turn; *11 11*, the second turn; *111 111*, the third turn ending in the cupola.

c to *i*, the lamina spiralis.—*c d*, the beginning of it; *e*, a portion, which by its direction is seen on its under surface; *f*, the lamina at the commencement of the second turn, where we see its upper surface; *g*, the lamina coming round; *h*, the beginning of the third turn; *i*, its termination in the infundibulum.

1 to *7*, the under and smaller scala, or the scala tympani. The arithmetical order of the figures denotes its progress upwards.

d to *h*, the larger scala, or that of the vestibulum. The alphabetical order of the letters points out its gradual rise towards the top of the cochlea.

7, the point where the scalæ meet.

i G, the infundibulum cut across.

n n, the longest diameter of the cochlea.

Fig. X.—A perpendicular section of the bony cochlea. *1, 11, 111*, its turns.

a to *c*—*a*, the cupola of the cochlea; *b*, the modiolus.

d, the bottom of the meatus auditorius internus.

e f g h i, the bony lamina spiralis; *g h*, the hamulus.

1 2 3 4 5, the scala tympani.

k l m n, the scala vestibuli.

Fig. XI.—The ampulla of the posterior semicircular canal magnified to twenty times its natural size, to shew the radiated expansion of the nerve.

a a, the ampulla; *b b*, the portion joined to the alveus communis; *c c*, the canal into which it contracts; *d*, its opening; *e*, the point where the nerve appears as a white spot, from which it radiates in all directions, *f f f*.

Fig. XII.—The shape of the area of these tubes.

Fig. XIII.—The fan-like expansion of the nerve of the alveus communis, magnified by a power of twenty; *a, b*, two arterial twigs.

PLATE III.

The relative size and position of the organ of hearing, with regard to the skull in the adult.

a, the right os nasi.

b to *h*, the frontal bone.

d to *i*, the cribriform plate of the ethmoidal bone.

k to *o*, the parietal bone.

p to *u*, the temporal bone.—*t u*, the squamous portion; *p q u*, the petrous portion; *q r*, the mastoid part.

v w x z, the sphenoidal bone.

1, the canal for the carotid artery.

2, the passage for the auditory and facial nerves.

3, a suture for a communicating branch between the second branch of the fifth pair of nerves and the facial nerve.

5, the opening of the aquæductus vestibuli.

On the left side, by the removal of some of the petrous portion of the temporal bone, we are enabled to distinguish plainly the external meatus passing under the membrana tympani, the bony ring supporting this membrane, and the oblique direction of the latter. We see also the ossicula, the cochlea, the vestibulum, and, lastly, the three semicircular canals.

The Powers of the human Ear in distinguishing Sounds.

In prosecuting the second division of our subject, we shall soon be struck with the consideration, that the ear discriminates all the different qualities of sounds, not only by its structure,

structure, but by a judgment corrected by experience, assisting most materially in forming our conclusions as to some of its qualities. We here then make a distinction of powers, and should first examine those arising from the mechanical construction of the organ; and afterwards, those depending on the correction of judgment: we should not, however, investigate the latter, until we have examined what proportion the subordinate parts of the organ bear in producing these effects; supporting our theory by the few facts we can draw from the source of comparative anatomy. After such inquiry, observing the difficulty of adapting phenomena to mechanical structure only, we should be the better able to determine what share judgment bears in their production. As the line of distinction between these powers is not, perhaps, clearly ascertained, and as the degree of them, taken conjointly, has been more frequently the subject of observation and experiment, we shall give the simple history of the powers as deduced by observable phenomena, referring all examination of causes till we have gone through the received opinions, as to functions of different parts of the organ.

We are not to enter here on the theory of sound, which will be considered at length in another place, but briefly mention the varieties distinguishable by the organ of hearing. They may be classed, sufficiently for our present purpose, into those dependent on the greater or less frequency of the vibrations; on the quantity, force, or momentum of the vibrating parts; and on the greater or less simplicity of each sound: observing that, in all these cases, we are to include the variations as to the duration of the sound, the distance at which it commences, and the direction in which it comes.

On the first of these causes depends the *tone* or *pitch* of a sound, as to its being grave or acute; and the degree of discrimination which a good ear possesses in this respect has been the subject of frequent observation and experiment. On the second cause depends the *loudness* or *softness* of a sound, which the ear can accurately distinguish, as far as intensity is concerned; but the difference between a loud sound coming from a distance, and a soft one pulsating from a nearer point, is not perhaps to be determined with an equal degree of correctness. As to *simplicity of sounds*, the ear is so organized as to seize readily on the differences between one simple sound and another; but it can determine only vaguely the differential proportions between two noises. If, at the same instant, many noises arrive at the ear, the loudest will drown the weakest, and make of it but a simple noise; but if they succeed each other, the ear can discriminate as to their intensity and duration, but not as to tone. Noise is a multitude of simple sounds, which the ear cannot separate from each other, and which excite in this confused junction the idea of one sound only. But where simple sounds succeed each other, the ear appears to partake of each separate vibration of the sounding body, and discriminates with great accuracy: nay more, if simultaneous simple sounds, arising from the vibration of different sounding bodies, strike the ear, it can perceive them all distinctly. It has not, however, this power of discernment to any very nice degree, excepting in persons exercised in music: for although the ear can make the difference, sounds are so analogous, their gradations so imperceptible, that an ear not corrected by judgment would still confound them. To pursue this at present would lead us beyond our intention, which is to state the power, without entering into its cause. Extremely sensible also is the faculty of the ear in distinguishing the quality, as well as the degree of tone. We know from experiment, that a musical ear can distinguish nearly eight octaves as to pitch; but it can also still perceive any variety

of quality in the same note, or the difference arising from the law which governs each separate vibration, and which constitutes the difference between instruments of different kinds, or different instruments of the same kind, or even the same instrument differently employed. It will thus distinguish clearly the character of the same note, given out by various instruments. The flute and the oboe may be in perfect unison, as to the pitch of the note, and as to its strength; still there will be always something between these equal sounds, which will not allow the ear to confound them: there will be a peculiar difference as to clearness, softness, and other qualities, which a discriminating ear will instantly seize. We can distinguish very accurately also the modulations of voice and articulated sounds; and some nations distinguish in their pronunciation certain letters, between which an ear unused to the sound can perceive no difference. Every articulate word is a different modification of sound, by which, when we reflect for an instant on the varieties of language, we see that the mind may be furnished with distinct ideas even to an infinite variety. There is another difference in the powers of the ear, which consists in its being most delicately susceptible of some of the qualities of sounds, whilst it is dull in perceiving others. It has, for instance, been observed, that a person capable of perceiving sounds so low as to be totally unperceived by another in his company, has yet been far from having a correct ear in discriminating musical sounds. And the converse of this holds equally good: the musician, who can distinguish the slightest variation of tone, has been insensible to sounds clearly perceived by a bystander. As an instance of accuracy of judgment arising from sensibility to sounds, we shall mention an anecdote, told by Dr. Darwin, in his *Zoonomia*. "The late blind justice Fielding walked for the first time into my room, when he once visited me, and, after speaking a few words, said, this room is about 22 feet long, 18 wide, and 12 high; all which he guessed by the ear with great accuracy."

Having stated thus shortly the power of the human ear in distinguishing the qualities of sounds, we shall make a few remarks as to its faculty of determining the *distance* and *direction* from which they proceed. Its power of determining the duration of a sound is obvious; that of distinguishing distance and direction is not so clearly defined, although every one is sensible of the existence of them. First, as to *distance*: it will appear from experiment, that a delicate ear will distinguish, with considerable accuracy, the distance from which a particular note begins to vibrate. A sound, just audible at 240 feet, was distinguished as being nearer at 40 feet than at 42, and at 38 than at 40; such a power of discrimination must be allowed to be considerable, and to prove sufficiently that the human ear is a very delicate judge of distance, as determinable by loudness of sound. It cannot, however, always be depended on; and perhaps the distinction which the ear makes between the roughness and smoothness of a sound is the best criterion by which it judges of proximity or distance; sounds becoming perceptibly smoother as they are remote, and proportionally rougher as the sound commences at some nearer point. The manner in which judgment influences this power will be considered further on. It has been found also by a rough experiment, that the ear can distinguish the *direction* of two similar sounds, proceeding from points which subtend an angle of about five degrees. Of such spaces there are more than a thousand in an hemisphere, so that the ear can receive an impression of about a thousand different directions. By other experiments it would appear, that an horizontal difference of direction is not perceptible within the points sub-

tending an angle of eight degrees, or the perpendicular difference within those subtending ten degrees of elevation. Even this depends in a great measure on the force of a sound; for unless it be of some strength, though we can distinguish the general direction, we can by no means bring it within such nice measurement.

The education of the ear to the nice discrimination of these differences, as well as to those of musical sounds, together with the effects of attention in increasing our sensibility of the pulses of sound, come to be considered after we have given the theory of hearing, as it is effected in the peculiar organ allotted for its accomplishment.

Functions of the individual Parts of the Organ of Hearing.

In order to discover what part of the ear is more immediately concerned in the perception of sounds, we shall exhibit a very short comparative review of its structure in those animals in whom an organ of hearing has hitherto been discovered.

In *cray-fish*, and the *sepia*, the organ is most simple, consisting of a small cavity or vestibule and a single membranous tube, and in the latter genus the sac includes a small solid body or lapillus: in the interior of this receptacle the auditory nerve is expanded. The *spinous fishes*, in addition to the hollow of the vestibule and membranous bag containing the lapilli, are provided with semicircular canals. The *cartilaginous fishes* have the vestibule, the sacculus for the lapilli, semicircular canals, and a fenestra ovalis, defended by an operculum composed of a membrane and the skin, whilst in the *osseous fishes* the whole organ is enclosed by bone. To the labyrinth of the *serpent* tribe, which is very similar to the internal ear of the cartilaginous fishes, there is added an ossiculum closing the fenestra ovalis. In one of this order, the genus *cæcilia*, and in almost the whole of the four-footed *reptiles*, a membrana tympani is connected with this ossiculum. In the other classes of *birds* and *mammalia*, we find an external passage leading to the membrane, and in the last of these an external cartilaginous auricle is annexed.

The obvious inference drawn from this view will be, that the whole of the apparatus, external to the labyrinth, is not absolutely necessary to the perceiving of sounds, because many creatures we know are susceptible of the impression, who are entirely destitute of these parts of the organ. We suppose, indeed, that the additional apparatus is intended to collect and modify the pulses of sound in their progress towards the labyrinth, to give force to the slightest tremors, and to regulate the intensity of the strongest. Whatever be their office, it is proved beyond a doubt, that for the simple perception of sound a membranous tube, or bag connected with the pulp of a nervous trunk, is fully sufficient; and whatever be the variation in the shape of these, we shall find them in all cases fundamentally the same. We say nothing of the manner in which the sensation of sound is excited in the lesser insects and worms, as we cannot perceive any organ set apart for this purpose, though we know that they are, for the most part, sensible to its impression. Among these creatures which have been subjects of repeated observations, we may remark, that from the osseous fishes up to man, we always find the membranous semicircular canals connected with a common sac in the vestibule. As to the cochlea, it is clear, that from its being found in perfection only in the class of mammalia, it is by no means requisite for simple hearing.

We conclude then, that the *labyrinth*, whatever be its form, is the most important part of the ear, inasmuch as it contains those soft parts immediately connected with the sense of hearing; and by giving an account of the manner

in which sound is supposed to be impressed on those parts in man, any one may readily deduce the effects it would have in every other instance.

The pulses of sound, having arrived at the membranes of the fenestræ, are communicated to the aqueous contents of the labyrinth, and from them spread in every direction to the membranous receptacles supporting the auditory nerve; and not only will the fluid external to the membranous sacs and their canals partake of the vibration, but also the whole of their gelatinous fluid contents, and consequently the nervous pulp which is immersed in them. The nerves of the ampullæ, of the alveus communis, and the sacculus sphericus, will all be excited by the tremor, and convey to the brain their peculiar sensations. As to the cochlea, we have described it as consisting of two scalæ, or hollow spiral cones communicating with each other at their apices, the base of one opening into the vestibule, the other being terminated by the membrane of the fenestra rotunda: they are both filled by the aqueous contents of the labyrinth, which will communicate the vibration to the delicate filaments of that portion of the nerve distributed to the zona mollis. And here we cannot but curiously notice the care which nature appears to have taken, that this nervous pulp should suffer no injury from rude and unexpected shocks, by including it in an elastic membranous receptacle floating in an aqueous fluid, as well as containing one within itself. There has been many an idle dispute concerning the immediate seat of hearing, before the structure of the organ had been the subject of successful as well as minute investigation. It has been placed exclusively in the canals, in the vestibule, and in the spiral lamina of the cochlea; the inferreces, however, furnished by a comparative review of this organ, will prove that it can be attributed in preference to no one particular division of the nerve, the whole of which is sensible of the impression. If we might hazard a conjecture, drawn from the same source, it would be, that the nervous pulp of the membranous ampullæ, and the sacs in the vestibule, is the most immediately concerned in the simple perception of sounds; as to this part of the structure there is an analogous formation in all the classes of animals.

It has been ascertained by common observation, that sounds can be impressed on the nerve, not only when propagated through the medium of the air, but that they affect it most powerfully when conveyed by the medium of the solid parts surrounding it. In those animals, whose labyrinth is completely cased in bone, this must necessarily be the only way in which sounds can be communicated; the reason why in man, as well as in other animals who have a membranous opening, acted on by external air, the labyrinth should be hollowed out of most compact bone, is not easily determinable. It has been conjectured, that the sounds rebound from the bony channels to the nerves they surround; also, that we judge of the direction of sounds by means of tremors communicated to the solid parts continuous with the labyrinth. This is rendered the more probable, as we cannot but suppose, that animals who possess this organ in its most simple state, judge with some correctness of the direction of the point from which the sound proceeds. Whatever be the direction of the sound in the open air, when it enters the winding meatus externus, it must necessarily follow the course of that channel, and will in every instance be propagated to the tympanum and labyrinth in the same line of direction. However acute we may suppose the sensibility of the ear to be, we cannot conceive that under such circumstances it could distinguish the angular difference of direction, but that every sound would appear

to come from the same point; which we know not to be the case. How far the external ear is concerned in producing this effect, we shall briefly notice in the sequel; and to render ourselves the better judges, shall state then what share the solid parts have been supposed to take. It appears sufficient here to observe, that the nerve can be impressed, and can distinguish direction without the apparatus of the external ear.

Speculations as to the reasons of the particular form of the *femicircular canals*, we conceive, in the present state of our knowledge respecting this organ, to be but a waste of labour: their use we believe to be perfectly unknown. One fact we shall mention, which is, that in the osseous fishes, whose labyrinth is enveloped wholly in bone, we observe them to be particularly capacious, and describing portions of large circles. With respect to the *cochlea*, the obvious point which would first strike us, is, that by means of it the expansion of the auditory nerve is very considerably increased in the animal who possesses it: we observe, also, that it is proportionally larger in quadrupeds than it is in man. Its relative importance to the organ cannot be precisely determined, but it would appear that its existence in the perfect state in which we see it in quadrupeds and man, is not necessary for any of the nicer perceptions of sound. Birds, in whom it is found of a simple construction, in no wise approaching to the elaborate one of the other class, have a delicate feeling of all the qualities of sound. This is proved by their learning to sing with great correctness, and when their vocal organs permit them, by their imitating very accurately the human voice in all its tones and articulations. That the *cochlea* is not necessary for that correctness in hearing, which constitutes a musical ear, is thus fully ascertained. Whether it increases the sphere of the perception, enabling animals who possess it, to hear those low and gentle tremors, which would not affect an ear without this part, has not been at present ascertained, nor from the difficulty of the investigation do we see any probability of effecting it. We omit the different opinions respecting the use of the decreasing lamina spiralis of the *cochlea* in modulating sounds, or its office of perceiving exclusively some of their particular qualities, as we can see no foundation whatever on which to build them: and shall conclude this account of its negative properties by remarking, that although it is rational to suppose that some important purpose is answered by the construction, we have as yet no data from which to draw a conclusion as to its extent.

The *fenestra rotunda*, and its membrane, are found only in animals who possess a *cochlea*, one of the scales of which the membrane occludes, forming a separation between it and the cavity of the tympanum. Its use is necessarily connected with that of the *cochlea*, and we conclude that it is to transmit to the fluid in that part the tremors which have been communicated to it through the air in the tympanum; we suppose it to be perfectly passive, influencing in no degree the quality of the sound. We noticed, in the description of the nerve of the *cochlea*, that it was most observable in the tympanic scale, with which the *fenestra ovalis* immediately communicates. It is not improbable, therefore, that the impressions conveyed to this portion of the nerve pass through the medium of the *membrana fenestræ rotundæ*; the supposition, though conjectural, carries with it no direct absurdity.

The *fenestra ovalis* is another road by which we suppose sounds to arrive at the labyrinth, and the importance of the opening and its membrane would appear to be considerable, since we find them in almost all animals, though its immediate office is not so clear. In the cartilaginous fishes it has

been considered as performing the part of a *membrana tympani*, there being no parts exterior to it. In other animals the vestibular fenestra is occupied by a bone, between which and the rim of the opening there is apparent, more or less of a membrane.

The cavity of the *tympanum*, we have found very generally, when comparing the varieties of structure, and co-existing with it, certain additional parts, the uses of which we shall now attempt to investigate. In adding this division of the machine, which includes several subordinate parts, it is a matter of no consequence with which individual piece we begin our examination. They are found existing together, and we conclude therefore that they are immediately dependent on each other with regard to their functions, which can scarcely be supposed to be executed unless in mutual combination. Again, the configurations of the different pieces is so exceedingly different, that we are totally at a loss to determine the value of any particular form of parts. Considered in its integral form, it appears as the medium through which sounds are communicated to the labyrinth; and our object here is to ascertain what changes it effects on them during their transmission.

The *ossicula* and the membranes are so immediately connected with each other, that it imports but little with which we next proceed: as, however, an *ossiculum* is found in many animals, where the *membrana tympani*, (if indeed it deserve the appellation,) appears immovable from its structure, we shall first examine the probable office of these small bones, and afterwards that of the membranes to which they are attached, and the muscles which, by their action, have an evident effect in altering their existing states.

There is so striking a variety in the form of the cavity, not only in different classes of animals, but in the different genera of the same class, that we can draw no probable conclusion as to the utility of the particular shape of it in man. Its depth from without inwards is suited to the length of the connected chain of the *ossicula*, all of which are situated in its upper half in the human subject, so that a plane drawn parallel to the base of the flaps is described as dividing the cavity into equal halves. The *fenestra ovalis* is thus placed in the middle of the interior wall, opposite to the centre of the *membrana tympani*, and immediately in the course of coming sounds. The *fenestra rotunda* is directed more downwards, so that the plane of its membrane forms an obtuse angle with that of the *fenestra ovalis*. From this position it has been supposed to be more particularly designed to transmit those vibrations which have been reflected from the opposite bony hollow: and, as it is acted on immediately by the tremors of the air, it has been considered by Scarpa as a second *membrana tympani*. As the *fenestræ* differ in their proportional size in different animals, we cannot suppose any thing very material as depending on that circumstance.

The cavity of the *tympanum* has communicating with it several cells hollowed out in the bony parietes of the skull: in man we have described these as existing chiefly in the mastoid process of the temporal bone. In other mammiferous animals they are irregularly disposed; in the elephant, whose acuteness of hearing is very great, they exist in great numbers, the cells of one side communicating with those of the other. In birds, but more particularly in the nocturnal birds of prey, these cells are extensive, and particularly large; for instance, in the common white owl. The inference drawn from combining these facts will be, that these cells are in some manner assistant in the transmission of sound, and probably increase its force, as we observe them more particularly enlarged in those creatures who are gifted with

the power of perceiving the lowest and most effete pulses of sound.

In every instance where we meet with a cavity of the tympanum we find a *tube* of different diameter and length, communicating with some other cavity in which the external air is constantly passing, so that the tube being pervious, the air penetrates to the part in which it opens. The air thus admitted fills all the cavities we have just now mentioned, as well as that of the tympanum, where its presence would seem to be necessary for the ready transmission of sound. Its importance is best proved by observing what occurs in cases where its tube is by some means closed, and in which the air can no longer gain an access to the tympanum. Deafness always succeeds to a greater or less degree, and the cause of it is ascertained by some marks which we need not dwell on here: it is enough for our present purpose to observe, that where an opening has been again made for the admission of air, the sense of hearing is at first painfully acute. The ear, having lost its habit of perceiving, is so sensible to the sudden return of the sensation as to feel much distress. The sensibility diminishes by degrees, and the ear again accommodates itself to its former mode of action. The opening a new passage for the air, by making a perforation through the *membrana tympani*, is not, however, constantly successful in restoring the functions of the organ for any continuance; the cause of failure is not to be examined here, our object being to prove the necessity for air being admitted into the cavity, and not to estimate the manner in which it should be effected: the organ is not necessarily perfect, because air is found in the tympanum, but it is always imperfect if the access for it is barred. Another use of the Eustachian tube has been supposed to be that of giving admission to sounds when the hearer is anxiously endeavouring to collect them. It had been observed, that a man, attentively listening to any sound, generally keeps his mouth half open, and it was supposed that this was to afford an additional channel for the arrival of sounds to the internal ear. In opposition to this theory it is said, that although we generally open the mouth when in the act of listening with attention, it is not for the purpose above stated, but that in depressing the lower jaw, we necessarily widen the aperture of the external meatus which is closely connected with it, and consequently, that by this action, we facilitate the transmission of sound to the tympanum. Considering the latter use of the Eustachian tube as rather problematical, we shall be contented with assigning to it its more obvious and important office, or that of conveying air to the cavity of the tympanum.

The *ossicula* which cross the tympanum have been supposed to act either as solid bodies, transmitting sonorous vibrations, or merely as subordinate pieces concerned in giving different degrees of tension to the membranes with which they are connected. That they may execute in some extent both these functions is not improbable; because in some animals they are not furnished with muscles, and consequently can have no power over the membrane with which they are connected, in which instance we can only suppose them to continue vibrations they have received. In other instances, however, where we observe a delicate *membrana tympani*, capable, from its construction, of undergoing tension and relaxation, we always find the bones furnished with muscles, which, acting through their intervention, can produce considerable alterations in the state of the membranes. We know nothing as to the difference of perception arising from this different state of the *ossicula*, but from observing them to be provided with muscles only in cases where they can act with effect, we believe, that, in the latter case, their

principal use is not that of transmitting sounds, but of altering the tension of the membranes with which they are connected. In cases of disease of the ear, these bones have been known to fall out, without very materially injuring the delicacy of the organ, provided they did not involve in their separation the destruction of the membrane of the fenestra ovalis. As we suppose their principal office to be allied to that of the *membrana tympani*, we shall consider the latter more particularly before we can draw any inference as to their combined functions.

The *ossicula* are provided with *muscles* which can move them in different directions: the most powerful of these would appear to produce the effect of rendering more tense the membrane of the drum, and by the transmitted motion of the bones increasing the tension also of the membrane of the vestibular, or oval fenestra. By their action they can produce no immediate effect on the membrane of the fenestra rotunda, which they can only influence by the pressure given to the fluid contents of the labyrinth. The importance of their acting thus on membranes occluding the openings to the labyrinth, does not appear to be very great, as in birds, whose delicacy in the perception of sound has been already noticed, the plate of bone connected with the vestibular fenestra, cannot produce any effect of this kind: it is fitted so exactly to the opening, as to be incapable of being in any degree moved in its situation. In these creatures, the muscle acting on their *ossiculum*, can only affect, by its means, the *membrana tympani*, to which we refer also the chief use of the muscles of the *ossicula* in man. That they will also produce an alteration in the membranes of the fenestra is highly probable; but the effects will be comparatively slight, when set by the side of those alterations they will cause in the *membrana tympani*. The importance of their action on the labyrinth is rendered still further of a doubtful nature, when we consider the perfection of the organ, in cases where the bones on which they act have been destroyed. We have observed, that the most powerful of these little muscles will, by their action, increase the conical form of the *membrana tympani*, and render it more tense. It would appear to return, by its elasticity, in some degree, to its former state, as the relaxing power can be brought to act on it but feebly. We conjecture, from this circumstance, that the membrane is always in a state to transmit the pulses of sound; and that it is only when our attention is particularly directed to a low sound, that the membrane is rendered tense: this supposition is, in some measure, strengthened, by observing, that in birds, the muscle which acts on their *ossiculum* can produce the effect of tension only. It is, again, supposed, that in cases of loud and impetuous sounds, the *membrana tympani* in man, at least, and animals similar to him in structure, can be in some measure relaxed. Granting that such is the case, we would observe, that the *membrana tympani* and its muscles are somewhat analogous in function to what we know of the iris: they are to be regarded as the regulators of the intensity of sounds; damping the force of the powerful, and facilitating the transmission of the slight. This leads us to notice some further properties of these muscles, as well as to make some observations on the use of the radiated muscle of the tympanum, as described by Mr. Home. Are the muscles of the tympanum to be considered as involuntary in their actions, or are they dependent in any degree on the will? We believe them to act independently of the will, and to be stimulated by the impulse of sound, in the same manner as the iris acts from the stimulus of light. It has been objected, that in such case, their action would be too late; that the sound would have passed the *membrana tympani* before it could be accommodated to its proper transmission.

mission. The same objection would hold good with regard to the iris, where it may be said that the retina would be impressed before the iris had time to alter the diameter of its aperture. How far the membrane is affected, in the instance of voluntary increased attention, cannot be ascertained: that the external ear is directed more immediately towards the point from which the sound proceeds, is, in all cases, evident. With respect to the action of the radiated muscle of the tympanum we can say but little: it can be but trifling, if we consider the nature of the membrane, and the acknowledged delicacy of the muscle, which, in man, has hitherto escaped our eye. Mr. Home remarks, "that the membrana tympani is stretched, in order to bring the radiated muscle of the membrane itself into a state capable of acting, and of giving those different degrees of tension to the membrane which empower it to correspond with the varieties of external tremors: when the membrane is relaxed, the radiated muscle cannot act with any effect, and external tremors make less accurate impressions. If the tension given by the muscle of the malleus be perfect, all the variation produced by the action of the radiated muscle will be equally correct, and the ear truly musical: if the first adjustment be imperfect, none of the effects of the action of the radiated muscle will be correct." Such is the theory as to the use of the membrana tympani and its various muscles, the ossicula being considered as secondary agents only, and their articulations not designed to regulate the intensity of violent impulses, as communicated through themselves to the fenestra ovalis, but only to act with more correctness and accuracy on the membranes to which they are connected. We believe the transmission of sounds to be performed through the medium of the air in the tympanum, not wholly certainly, but in a considerable degree.

In such a complicated machine as the organ of hearing in man, it is difficult and hazardous to affix the precise power of every individual piece, when we consider, that in no case does it act singly, or uncombined with several others. The relative importance of each is more easily estimated; and we shall conclude the examination of this part of the apparatus, by observing the effects which ensue on their loss. It is, we conceive, proved, by numerous observations, that the integrity of the membrana tympani is not necessary for the perfection of the mechanism of this organ. Many persons, who have been able to drive smoke from the mouth in large volumes through the external meatus, have, nevertheless, retained great accuracy of ear: and it would appear, from some later observations, that the total destruction of the membrane does not necessarily produce deafness, or even any very perceptible defect in the organ. In an instance recorded by Mr. Aitley Cooper, in which the membrana tympani of one ear was totally destroyed, and that of the other nearly so, by disease, it appeared that the deafness was inconsiderable, and that sound was most readily perceived by the ear in which no trace of the membrane could be discovered. This proves that the membrana tympani may be destroyed without any great prejudice as to the power of catching low sounds. Another circumstance is, that, in the same case, the ear was nicely susceptible of musical tones, the individual playing well on the flute, and singing perfectly in tune. The power of accommodating the ear to differing intensity of sound was lost for some time after the destruction of the membrane: it, however, gradually returned; and at the period of examination there was no distress arising from that deficiency. The inference drawn from these observations would be, that the membrana tympani is not materially concerned in giving either delicacy, or correctness of ear, that it may be destroyed without injuring essentially its

functions, its principal use being to regulate "the impressions of sound, and to proportion them to the expectation and power of the organ." In cases where deafness follows the destruction of this membrane, it depends, most probably, from the disease having injured, at the same time, the membranes of the fenestra, in which case, the fluid of the labyrinth would escape, and the auditory nerve inevitably lose its power of perception.

The obvious use of the *external meatus* is to convey the vibrations of sound, propagated through air, to the membrana tympani; and we find it, accordingly, only in those animals who have a proper elastic moveable membrane, as in birds and mammalia. From the inflexions and variations in dimension, in different parts of its course, it is evident that, from whatever point the sound proceeds, it must ultimately strike on the membrane in the direction of this passage, and be continued in the same line to the auditory nerve. The consequence of such formation would be, that the ear would in no case be enabled to determine the direction from which the sound proceeded. The sensibility of its surface, as it approaches the tympanum, is very considerably augmented; and it has been conjectured that, by the wave of sound acting on this part during its passage, notice is communicated to the muscles of the membrana tympani, which are immediately stimulated to action. The different directions of the meatus in animals, as well as the differences in the form and obliquity of the membrana tympani at the bottom of it, are so numerous, and, apparently, irregular, as not to allow us to form any reasonable conjecture as to the utility of their particular figure in the human subject.

The *pinna*, or that part of the external ear which lies without the head, would appear to be in no wise necessary for the perfection of the organ, as far as the perception of sound is concerned, and it can be regarded as an accessory part only, superadded to the meatus in quadrupeds and man. In the generality of quadrupeds the auricle is of a conical form, the apex of the cone terminating in the meatus, appearing thus calculated to collect sonorous vibrations, and transmit them with increased energy to the internal parts. In man we cannot observe so much of this conical form in the concha, nor do we exactly perceive the utility of the different eminences and the intervening hollows. The probable supposition is, that they are concerned in directing towards the meatus, as towards a focus, all the waves of sound impinging on their different surfaces. In order to favour the collecting of sounds, we have found the auricle to be furnished with *muscles* capable of moving it in different directions. In animals, who have it of a larger form, these muscles are considerable both in number and strength, and empower them to direct it with ready execution towards the point from which the pulses proceed. Man, at least in his civilized state, would appear to have much less power in this respect. In the instance mentioned above, where the membranes of the drum were so materially injured, the muscles of the external ear had acquired a distinct power of moving it upwards and backwards, which power was more particularly exerted when the attention was directed to catch an indistinct sound. When the external ear moves, it is most commonly to accommodate its position to the direction of the sonorous rays, to fix itself steadily in order to reflect them, and to straighten the curved direction of the cartilaginous meatus. It is for the latter reason, perhaps, that in man we find no muscle capable of depressing the pinna, as such a movement would necessarily increase its curve, whilst the motion, either upwards or backwards, would tend to make the passage more direct. The pinna has been removed in many instances where no material injury to the power of the organ

was been afterwards observable: for a few days after there has been a slight deafness, but the ear has, in every case, soon recovered all its fineness of perception. Where the canal of the meatus has been covered by a continuation of the skin over it, there being no orifice connected with it, observation has proved also that the functions of the organ were perfect.

Such is the apparatus destined to convey to the sensorium the impressions of sound. We have endeavoured to ascertain the relative importance and functions of the individual parts, and shall now give the sum of their united powers in man, tracing the progress of sound from without. The pulses of sound, which come in contact with the external surface of the pinna, are reflected by its eminences and depressions, but more positively by the sides of the hollow of the concha, and directed into the external meatus, where their energy is probably augmented. Arrived at the bottom of this tube, they strike against the membrana tympani, which we suppose to alter its degree of tension in conformity to their force. The vibration excited by the sonorous waves is continued with them across the tympanum, by means of the air and the chain of ossicula to the fenestra of the labyrinth, and the fluid it contains. The agitations of this fluid are communicated to the nervous ramifications immersed in it, and the nerve conveys to the sensorium the peculiar impression of the sound. Further, that there are passages communicating with the labyrinth, and ending in widened sacs on the interior of the skull, by means of which the motion of the fluid is regulated, and its accumulation to too great a degree prevented. We have observed also, that there remains still another medium by which sounds could be conveyed with some accuracy and force to the nerve, provided the communication was kept up by the vibrations of solid bodies: this we stated to reside in the solid parts of the head. The conclusion, drawn from this review, will be, that the internal ear is alone sufficient to perceive the qualities of sounds, and that the parts exterior to it can only collect, transmit, and regulate the intensity of them.

Having examined the powers of the ear as resulting from structure, we must still look further for the explanation of some other faculties which the perfect organ possesses. We are not to enter here on the advantages which one sense derives from the assistance of others, in correcting its imperfections, or enlarging its powers: we shall suppose such to be proved with respect to the ear, and shall therefore only state the instances in which they may be observed. One of these is seen in the faculty we possess of determining the distance of the sounding body. We mentioned before, that when sounds proceeded with equal forces from the same body, the ear was capable of distinguishing the alteration of distance by the difference of the strength or weakness of the wave. This power we conceive to be acquired by experience, and that it is so, may be rendered further probable by observing that loud sounds coming from a distance, and fainter ones pulsating from a nearer point, provided the tone is the same, cannot be distinguished unless by a judgment derived from other sources. The same may be said of the power of ascertaining direction, which is a secondary faculty depending for its perfection on the assistance of the other senses. It has been supposed by Mr. Gough, and the theory has been supported by some ingenious and conclusive experiments, that the solid parts of the head are the means by which we judge of the point from which the sound proceeds. Having proved, by experiment, that the head is a sensitive solid, and capable of perceiving impulses made on it by sounds much more exquisitely than men generally imagine, he makes some observations on the relative degree of its sensibility in different parts, and adds, "the sensation in

question being but of little use, independently of its connection with hearing, we, for the most part, mistake its true situation, and refer it to the organs of this sense. Seeing, however, that we are convinced, by a delicate sort of touch, what part of the head is affected by the strokes of the sonorous object, and at the same time well acquainted with the form of this member of the human body, we judge accurately what is the situation of the excited portion of it, relative to the centre of the axis of hearing;" which he has supposed to be in an imaginary straight line joining the two ears. We are taught also, by experience, to judge of the lateral direction of sounding bodies according as they strike both the ears with equal or different degrees of force: the perception which determines the position to be before or behind the hearer, is determined in the manner above explained. The discernment of the ear, then, has its bounds, because the sounding bodies are not subject to the touch, and we can determine distance, as well as direction, by judgment only. In the same way we know also the position of a body; and this can only be acquired by exercise. If a deaf man was suddenly to hear, he would be able to judge with correctness of neither: he would be mistaken, if he has not beforehand studied the nature of the sounding object, and the varieties of impression resulting from its different situations.

Although the organ of hearing is double, it does not follow that we must hear a simple sound twice; the two impressions which the same tone makes on them both are received by corresponding parts, and transmitted at the same instant to the sensorium: the two impressions are thus regarded as one, and excite, consequently, but a simple sensation: it is exactly the same as in the case where the object is painted at the same instant on both the organs of vision. The differences of power in the ears of different individuals, would appear to depend on structure as well as exercise. The correct musical ear arises, in a great degree, from original formation, but its exquisite accuracy, as we observe it in persons exercised continually in the science of music, is derived, beyond doubt, from education. The high finish which the organ attains by this constant attention to musical sounds, appears in a most striking light, when compared with the undistinguishing perceptions of the untutored ear. An equality of power in the two ears does not appear to be necessary in order to complete the organ as affected by musical sounds. Instances are every day met with of persons with slight deafness of one ear, who are nicely correct in perceiving every variation of tone. To complete the perfection of the sense in every instance, it seems necessary that the organ should dispose and accommodate its action to the impulse, that it should be on the alert to catch the low tremor of a faint and indistinct sound. It is in such cases that we observe the increased energy of the ear when the attention is particularly called forth. Such are the circumstances and conditions which influence, in a manner, more or less direct, the perfection of the organ of hearing; and we shall conclude by saying a few words on its peculiar pleasures.

The pleasures of the ear consist, independently of those of articulated language, in the succession of sounds according to the laws of harmony. We are not so well pleased with one sound, as with an entire air, which causes joy or sorrow, pleasure or pain, by some unknown change which it is supposed to produce on the organ. Music pleases more as the ear is less exercised to it: tunes simple and unpolished please at first: if we accustom the ear to their effects, we soon seek for more finished and compounded airs, which, at first, were far from pleasing. Music thus becomes a
source

source of new pleasures, ever varying her combinations to suit the educated organ. This can only occur to any high degree in well organized ears; there are some to whom music is ever but a noise. The causes of the pleasure resulting from harmony and melody are very far from being satisfactorily explained, notwithstanding the sagacious conjectures and repeated attempts of the most able metaphysicians, as well as physiologists: we know no more of them than we do of the causes of the pleasures and pains of all the other senses.

The ear, then, is an organ of sense, subjected but incompletely to the will, and unable to withdraw itself from the impression of every impulse of sound: it is on this account, provided with a certain regulating apparatus, which modifies the action of the external agent, and is further assisted by judgment, as acquired from the other senses. Gifted with these powers, and alive to all these pleasures, we once more see this beautiful organ perfect in all its parts, capable of exciting in us, with immeasurable rapidity, that infinite number of ideas which results from the sense of hearing.

In the description of the ear, as far as it is contained under the article CRANIUM, we mentioned the comparative merits of the different authors who had written on that subject. The reader will find some further information as to its functions, in some papers by Mr. Home and Mr. A. Cooper, in the Philosophical Transactions for 1800, 1801, and 1805; in an essay by Mr. Gough, in *Manchester Mem.* vol. v.; and in Haller *Element. Physiol.* vol. v. He will find also a complete catalogue of authors on this subject in the second vol. of Dr. Young's *Natural Philosophy*. See also the article ACOUSTICS for further references to subjects connected with this organ.

Several naturalists and physicians have held, that cutting off the ear rendered persons barren and unprolific; and this idle notion was what first occasioned the legislators to order the ears of thieves, &c. to be cut off, lest they should produce their like.

The ear has its beauties, which a good painter ought by no means to disregard; where it is well formed, it would be an injury to the head to be hidden. Suetonius insists, particularly on the beauties of Augustus's ears; and Ælian, describing the beauties of Aspasia, observes he had short ears.

Martial also ranks large ears among the number of deformities. *Felibien*.

Among the Athenians, it was a mark of nobility to have the ears bored, or perforated. And among the Hebrews and Romans, this was a mark of servitude.

Loss of one ear is a punishment enacted by 5 and 6 Ed. VI. cap. 4. for fighting in a church-yard; and by 2 and 3 Ed. VI. cap. 15. for combinations to raise the price of provisions, labour, &c. if it be the third offence, beside pillory, and perpetual infamy, or a fine of 40*l*.

By a statute of Henry VIII. maliciously cutting off the ear of a person is made a trespass, for which treble damages shall be recovered; and the offender is to pay a fine of ten pounds to the king. 37 Hen. VIII. cap. 6. § 4. In the index to the Statutes at large, it is said, that this offence may be punished as felony, by 22 and 23 Car. II. cap. 1. § 7. commonly called Coventry's act; but ear is not mentioned in that statute.

EAR, in *Botany*, is also applied to a long cluster of flowers, or seeds, produced by certain plants; and usually called, by botanists, *spica*. The flowers and seeds of wheat, rye, barley, &c. grow in ears. The same holds of the flowers of lavender, &c.

We say, the stem of the ear, *i. e.* its tube, or straw; the

knot of the ear; the lobes, or cels, wherein the grains are enclosed; the beard of the ear, &c. great numbers of ears of wheat have been known to arise from the same root.

EAR, in *Conchology*. See AURIS DIANÆ, &c.

EAR, in *Gardening*, a name given to the seminal leaves of plants, or those two green and succulent leaves which first appear from the seed, and are very different, in all respects, from those which follow. Thus in the melon plants, the two first leaves are called ears; and the leaves, with their stalks, which shoot out afterwards, are called knots, and denominated the first, second, and third knot, according to their place, and time of growing. The cutting off every third knot in this plant, is the great means of procuring the finest and largest fruit. *Phil. Transf.* N^o 45.

EAR, in *Music*, denotes a kind of internal sense, whereby we judge of musical sounds and harmony; they who possess this sense are said to have a good ear. And the like distinction we should, probably, acknowledge in other affairs, had we got distinct names to denote these powers of perception by.

Thus, a greater capacity of perceiving the beauties of painting, architecture, &c. is called a *fine taste*. See TASTE.

EAR of Birds. See *Anatomy of BIRDS*.

EAR of Fishes. See FISH.

EAR-ach, in *Surgery*. See OTALGIA.

EAR, running of the, in infants. See INFANT.

EAR, tingling of the. See TINNITUS.

EAR, Jews, in *Natural History*. See AURICULA JUDÆ.

EAR of Corn, and Ermine, order of, in *Heraldry*, so called from the collar, an order of knighthood, instituted by Francis I. duke of Britany, for 25 knights of noble descent. The badge of the order was an ermine on a mount enamelled proper; round the mount the following motto, AMAVIE. The collar was composed of ears of corn interlaced.

EAR-picks, are instruments of ivory, silver, and other metal, somewhat in form of a probe, for cleaning the ear. The Chinese are particularly fond of entertaining themselves with picking and tickling their ears; this they do either for themselves, or interchangeably for one another, and have a great number of instruments of peculiar shapes and structure, invented for this purpose. But sir Hans Sloane very judiciously observes, that the use of them seems very prejudicial; for that, among many people in England who had applied to him on account of deafness, the far greater part were thrown into their complaints by too often picking their ears, and thereby bringing humours, or ulcerous dispositions, on them. *Phil. Transf.* N^o 246. p. 405.

EAR-ring. See PENDANT.

EAR-shell. See AURIS MARINA.

EAR-wax. See WAX.

EAR-wig. See FORTICULA.

EARCH, in *Geography*, a river of North Wales, which runs into the sea near Pwllheli, in Caernarvonshire.

EARED OWL, in *Ornithology*. See STRIX.

EARINÆ VESTES, from *æz, spring*, among the ancient Greeks, a habit worn in the spring, which was made of wool, and dyed green. The custom of wearing green vestments in this season has not been unknown in modern times.

Dempler says, it was customary, in his time, for the king, and nobility of England, to go a hunting in the spring, dressed in green, that they might be of a similar colour with the season.

EARING, in a ship, that part of the bolt-rope, which, at the four corners of the sail, is left open, in the shape of a ring. The two uppermost parts are put over the ends of

the yard-arms, and so the sail is made fast to the yard; and into the lowermost earings the sheet and tackles are seized, or bent at the clew.

EARING, *Third*, in *Husbandry*. See **THIRD**.

EARL, an English title of honour, or degree of nobility, next below a marquis, and above a viscount.

Earls were anciently attendants, or associates of the king in his councils, and martial expeditions; much as comites, counts, were of the magistrates of Rome, in quality of deputies, to execute their offices for them.

Hence, also, earls are called, in Latin, *comites*; in French, *comtes*, counts, &c. The Germans call them *graves*, as landgrave, margrave, palgrave, &c. The Saxons, *ealdormen*; the Danes, *eorlas*; and the English *earls*.

Earl was a considerable title among the Saxons: it is observed to be the most ancient of any of the peerage; and that there is no other title of honour in use among the present nobility, which was likewise used among the Saxons; beside it. The original titles of honour among the Saxons were, *edeling*, *ealderman*, and *degen*, or *degn*. The first appropriated to those of the royal family; the other two to the rest of the nobility; only the thani were afterwards distinguished into majores and minores. Comes in Latin, *alderman* in Saxon, and *earl* in Dane-Saxon, were synonymous. See **ALDERMAN**.

Originally the title earl always died with the man. William the Conqueror first made it hereditary; giving it in fee to his nobles, and annexing it to shires and counties; for the support of the state thereof, he allotted the third penny out of the sheriff's court, issuing out of all pleas of the shire from which the earl took his title. Accordingly, it became usual in creating an earl, to erect a certain territory into a county or earldom, and to bestow it upon the person and his family; and also to give him a fixed salary, commonly about 20*l*. a year, in lieu of his third of the fines. The diminution of his power kept pace with the retrenchment of his profit; and the dignity of earl, instead of being territorial and official, dwindled into personal and titular. But earls are now created by patent, without any authority over, or particular relation to, their counties; and without any profit arising thence, except some annual stipend out of the exchequer, for honour sake. The number of earls being of late much encreased, and no more counties being left for them, several of them have made choice of some eminent part of a county, as Lindsey, Holland, Craven, &c. Others of some town, as Marlborough, Exeter, Bristol, &c. And others, of some village, or their own seat, park, &c. as Godolphin, Bolton, Dauby, &c.

Some earls we have, who are not local, *i. e.* not dignified from any places, but from noble families, *viz.* earl Rivers, and earl Paulet. A third is denominated from his office, *viz.* earl Marshal.

Earls are created by circumscription of sword, mantle, a cap, and a coronet put on his head, and a charter in his hand. Their title is, *most potent and noble lord*. Their coronet has the pearls raised on points, with leaves between.

Their place is next to a marquis, and before a viscount; and as in very ancient times, those who were created counts, or earls, were of the blood royal; our British monarchs to this day call them in all public writings, "trusty and well beloved cousin;" an appellation as ancient as the reign of Henry IV., who, being either by his wife, his mother, or his sisters, actually related or allied to every earl then in the kingdom, artfully and constantly acknowledged that connexion in all his letters and other public acts; from whence the usage has descended to his successors, though the reason has

long ago failed. They also originally did, and still may, use the style of *nos*.

EARL-marshal is one of the great officers of the crown; who takes cognizance of all matters relating to honour and arms, determines contracts that respects deeds of arms out of the realm upon land, and matters concerning war within the realm, which cannot be determined by common law, in which he usually proceeds according to the civil law. He had, anciently, several courts under his jurisdiction, as the court of chivalry, now almost forgotten; and the court of honour. See **COURT of Chivalry**.

He has also some pre-eminence in the court of marshals, where he may sit in judgment against criminals offending within the verge of the court; whence the chief officer under him is called *knight marshal*. Under him is also the herald's office, or college of arms. See **COLLEGE and COURT**.

Mr. Camden, in his discourse concerning the etymology, antiquity, and office of earl-marshal of England, attributes the first use of the word "marescalus" in England to Petrus Blesensis, secretary to king Henry II.; and he says, that the first mention he could find of a marshal on record is in the red book of the exchequer, written, as he erroneously supposes, in the time of that king, not having reference to the reign of Henry I., and that the second mention of marshal is in the first year of king John, and adds, that the marshal had not any precedence in respect of his place, until king Henry VIII. in the 31*st* year of his reign, by act of parliament, assigned him place next to the lord constable and before the lord admiral; and that king Richard II. created the earl of Nottingham (Thomas Mowbray) "earl marshal of England," whereas in former times they were styled only "marshals of England." Camden, however, in a subsequent discourse, concerning the original and succession of the earl marshal of England, and also in his Britannia, receded in part from his former opinion, and allowed the institution of a marshal in England to have been coeval with the reign of William the Conqueror; and this is the generally received opinion. That the term marshal was used as a surname in the time of the conqueror is evident from "domesday," where divers persons under the denomination of marshal are found to hold lands: and, upon the whole, there are so many concurring testimonies of the office of marshal being known in this kingdom almost immediately after the Norman invasion, that there cannot remain the least doubt of its having been brought hither by William I. The earl marshal appears to have been from the first establishment of his office in this kingdom, an officer of great authority and dignity both in war and peace. The office of grand serjeant, and the institution of the high officer who enjoys it, must be alone the king's, who creates him by letters patent under his great seal, and at the same time, for his better distinction and greater state, delivers to him a rod, which he is thenceforth constantly to bear in his hand. This rod was originally made of wood, and like the tipstaff which is carried by the modern marshalsmen: but when king Richard II., in the 20*th* year of his reign, regranted the office to Thomas, earl of Nottingham, and the heirs of his body, that monarch, in order to enhance the grandeur and honour of this new marshal, by the patent of his creation, directed that he and the heirs of his body "earl marshals," should, in the royal presence, and at all other times, bear and carry a rod of gold, tipped at each end with black enamel, and having the royal arms at the upper end, and the arms of the said earl on the lower; ever since which time the earls marshal have borne the like official badge. It is difficult to ascertain the respective periods in which this officer

officer acquired the several styles of "marshal of England" and "earl marshal of England." The earliest patent by which the appellation of "earl" was added to marshal of England, is that of the 12th of January, in the 9th year of king Richard II., granted to Thomas Mowbray, earl of Nottingham, and constituting him earl marshal of England, to hold to him and his heirs male of his body; and yet the style of "comes marcellus" was far more ancient, and probably arose from the persons on whom the office of marshal was usually conferred, being *earls* or *comites*, as or before the time of their investiture; the word "comes" being used in these early ages as a style of office and jurisdiction, and not as a title of dignity. This office though frequently hereditary, hath not been always so; on the contrary, the limitations in the grants that have been made of it vary from time to time. However the limitations in King Edward III's re-grant of the office to Roger Bigod, earl of Norfolk, were more general, *viz.* "to him and the heirs of his body."

Henry Howard, baron Howard of Castle-Rising, and earl of Norwich, was, by letters patent, dated 19th October 1672, constituted "hereditary earl marshal of England," with limitation, in default of issue male, to the heirs male of his grandfather, Thomas earl of Arundel, &c. with remainder to the late earl of Suffolk and his heirs male, remainder to Charles Howard, earl of Nottingham, and his heirs male. On the death of his elder brother, Thomas, duke of Norfolk, earl of Arundel, Surrey, &c. which happened in 1677, he succeeded to the dukedom, and all other his honours and estates.

The office of earl-marshal is hereditary in the family of Howard, and enjoyed by the duke of Norfolk, the principal branch thereof; though, till of late, on account of the religion of the duke of Norfolk, which rendered him incapable of admitting it in person, it was discharged by deputation; but yet it is to be observed, that it was not given out of the name and family of Howard.

EARN, in *Geography*, a river of Scotland, which rises in Loch Earn, and joins the Tay a little below Perth.

EARNEST, called by the civil law *Arrha*, and interpreted to be *emptiois venditionis contracte argumentum*, money advanced, or any portion of goods delivered, to complete or assure a verbal bargain, and bind the parties to the performance thereof.

By the civil law, he who recedes from his bargain, loses his earnest; or, if the person who received the earnest give back, he is to return the earnest double. But, with us, the effect of earnest is more: the person who gave it is, in strictness, obliged thereby to abide by his bargain; and, in case he decline it, is not discharged upon forfeiting his earnest; but may be sued for the whole money stipulated. The property of the goods is absolutely bound by it; and the vendor may recover the goods by action, as well as the vendor may the price of them. And by 29 Car. II. cap. 3. no contract for the sale of goods, to the value of 10*l.* or more, shall be valid, unless the buyer receives part of the goods sold by way of earnest on his part, or unless he gives part of the price to the vendor by way of earnest, to bind the bargain, or in part of payment; or unless some note in writing be made and signed by the party, or his agent, who is to be charged with the contract. With regard to goods under the value of 10*l.* no contract or agreement for the sale of them shall be valid, unless the goods are to be delivered within one year, or unless the contract be made in writing, and signed by the party, or his agent, who is to be charged therewith. Anciently, among all the northern nations, shaking of hands was held necessary to bind the

bargain; a custom which we still retain in many verbal contracts. A sale thus made was called "*handsale*," "venditio per mutuum manuum complexionem." Hence in process of time the same word was used to signify the price or earnest, which was given immediately after the shaking of hands, or instead of it. See CONTRACT and SALE.

EARNING, or YEARNING, a name used in several parts of the kingdom for rent. See RUNNET.

EARTH. See EDDITH.

EARTH, in *Astronomy*, is a primary planet, belonging to the solar system. We shall first treat of its various motions, and afterwards of its figure and magnitude.

There are three principal motions of the earth: a motion of rotation on its own axis; a motion in an orbit round the sun; and a motion of its axis round the poles of the ecliptic. These three motions are all mathematically derived from one single imposition, supposed to be given to the earth at its origin, and combined with the continued action of the sun.

The rotation of the earth on its axis, called its diurnal motion, is the most uniform we are acquainted with. It is performed in 23^h 56^m 4^s. of mean solar time, or one sidereal day.

The earth, or, more strictly speaking, the common centre of gravity of the earth and moon, describe an orbit round the sun, which orbit is of an elliptic form of small eccentricity, the sun being placed in one of its foci. If we suppose the plane of this orbit extended to the fixed stars, it will trace in the heavens a circle called the ecliptic. The plane of the earth's equator, which remains very nearly parallel to itself during the whole of this revolution, is inclined to the ecliptic in an angle of 23° 28'. The points in the earth's orbit, which are intersected by this plane, are called the equinoctial points. See ECLIPTIC.

The motion of the earth in its orbit is very far from uniform; but it is so far regular, that, with the exception of some small inequalities caused by the action of the moon and planets, the radius vector, or line joining the centres of the earth and sun, describes equal areas or sectors of the ellipse in equal times. See ELLIPTIC Motion.

The third motion of the earth, we have to notice, is that which produces the precession of the equinoxes. The motion of rotation having produced a protuberant form in the equatorial regions of the earth, the continued action of the sun and moon on this sun-undulating mass or annulus produces a rotatory motion in the axis of the earth round the axis of the ecliptic; the inclination of these axes remaining the same. This revolution is accomplished in 27,000 years. The reader will find a farther investigation of this motion under *Precession of the EQUINOXES*.

Of the Phenomena caused by the diurnal Motion of the Earth.

The diurnal motion of the earth from west to east causes an apparent motion of the heavens from east to west. A very correct idea of this general motion of the sphere may be formed by inspecting a celestial globe, previously rectified for the latitude of the place; recollecting, however, that the convexity of the one representing the convexity of the other, the constellations are necessarily reversed, those appearing to the right on the globe which are to the left in the heavens.

If the axis of the earth be prolonged each way till it intercepts the heavens, it will there form the two points called the poles, round which stationary points the heavens will appear to revolve. With us the north pole is the elevated pole; and the stars near it will describe small circles, increasing with their distance from the pole, till they arrive at a

certain distance, when a portion of the circle will be intercepted by the horizon. As the polar distance of the stars still increases, they will continue for a longer time above the horizon; still, however, rising and setting north of the east and west points of the horizon, till they reach the equator. At this distance from the pole, they rise exactly in the east, and set exactly in the west; and at their greatest altitude, their distance from the zenith is observed to equal the elevation of the pole above the horizon. As the stars recede from the equator towards the south, they describe still smaller arcs, continue for a less time above the horizon, and rise and set nearer the south point. When they approach this limit, they continue visible only for a few minutes, and no sooner appear on the meridian than they are again carried down by the general motion of the heavens below the boundary of our view. The sun, moon, and planets, appear to partake in great measure of the diurnal motion of the heavens; they describe nearly the same course as a fixed star would do in the same situation. The diurnal motion of the moon, from its vicinity to the earth, differs a little from that of a star, independently of its own proper motion in its monthly orbit. This small difference is called its parallax. See PARALLAX.

The change from day to night is caused by the diurnal motion of the earth on its axis; and the vicissitudes of the seasons, by the combination of this motion with its annual revolution round the sun.

Of the Phenomena which arise from the annual Motion of the Earth in its Orbit.

The annual motion of the earth round the sun is performed in an orbit, the plane of which is inclined to the equator at an angle of about $23^{\circ} 28'$. This orbit, being extended to the heavens, traces there the great circle of the sphere, called the *ecliptic* (which see). The effect of the earth's motion in its orbit is to cause the apparent annual motion of the sun. When the earth is in any one point of its orbit, the apparent place of the sun will be in the direction of the opposite point; and the apparent path of the sun will be similar to that actually traced by the earth; and these two bodies will always be in opposite positions to each other. It was not till astronomy had arrived at a state of great perfection, that sufficient proofs could be collected to ascertain with certainty which of these bodies was really in motion. It appears by arguments which are incontrovertible, and which we shall hereafter enumerate, that there no longer remains any reasonable doubt upon this subject.

The earth's motion in its orbit is not uniform. This is inferred from the corresponding irregularity that takes place in the apparent motion of the sun. This irregularity, which was first discovered by Hipparchus about 140 years before the Christian era, perplexed astronomers for many succeeding ages. The immediate effect of this inequality in the sun's apparent motion is to cause an unequal division of the seasons. Various cycles and epicycles were invented to explain these inequalities; but their true cause was not understood, till the great discovery of Kepler explained it, by assigning to the apparent solar orbit its true elliptic figure; and, moreover, establishing the curious law, observed to prevail likewise in the other planetary orbits, namely, that the revolving body always describes equal areas in equal times. See ELLIPTIC Motion.

The difference of seasons, of climates, and the inequality in the length of the days and nights, all arise from this circumstance, that the plane of the earth's orbit is inclined to that of the equator, which is the plane of its diurnal motion.

If a straight line be supposed always to connect the centres

of the earth and sun, this straight line or radius vector will always trace the ecliptic in the heavens; and the point where it intercepts the surface of the earth, (supposing it a perfect sphere,) will be that over which the sun is vertical. Now it is evident, that, in the upper or north part of the earth's orbit, this line will intercept some point to the south of the equator; and, on the contrary, when the earth is in the lower or southern part of its orbit, this line will intercept some point to the north of the equator: the circle bounding light and darkness being always perpendicular to this line, the circles parallel to the equator will be unequally divided at different parts of the orbit, in the same manner as we observed them to be by the horizon, when we considered the phenomena of the diurnal revolution of the earth.

Fig. 68, *Plat. IX. Astronomy*, is intended to illustrate this. CSC is the earth's orbit projected into a straight line, the eye being supposed in the same plane; the earth being in the upper or most northern part of its orbit, the line SC, joining the centres of the sun and earth, evidently passes through a point, p , whose angular distance from E, the equator, is equal to the inclination of the equator to the ecliptic, or angle ECS. On the contrary, when the earth is at its lowest part of the orbit, the point, p , falls to the north of Q, by the same quantity.

The inequality in the distribution of the seasons, (by which at present the inhabitants of the northern hemisphere of the globe enjoy a greater portion of the sun, by about eight days in the year, than those of the southern hemisphere,) arises from a very different cause, which we shall endeavour to explain.

The great circle in the heavens, called the ecliptic, is in fact the perspective representation of the ellipse in which the earth performs its orbit: all the irregularities, therefore, of the original will be transferred to the circle which represents it; and the four portions intercepted by the equinoctial and solstitial points, though represented each by an arc of 90° , will not be described in equal times, because they do not represent such portions of the ellipse as are originally so described. The point of the ecliptic, representing that point of the ellipse in which the sun and earth are nearest to each other, is called the perigee; and the summer and winter months never can be equal, but in the singular instance of the coincidence of the perigee with one or other of the equinoctial points. The solar perigee does not remain fixed, but has a progressive motion in the ecliptic, which it passes over in about 20,000 years. It is a remarkable circumstance, that this curious coincidence of the perigee with the autumnal equinox took place about the time when chronologists suppose the world to have been created, or about the year 4000 A.C. At that time each hemisphere enjoyed an equal portion of the sun's light and heat; since that time, the northern hemisphere has had gradually the advantage, and the maximum of inequality took place in the year 1250: since that time the advantage has gradually diminished, though it is still very considerable. It will diminish till the year 6472, when the perigee, coinciding with the vernal equinox, will again equally divide the summer and winter periods between the two hemispheres: after which, the southern inhabitants of the globe will enjoy the advantage of having the greatest share of the sun for above 10,000 years.

The Egyptian astronomers are said by some writers to have been the first that maintained the motion of the earth: it was from them, at least, that the Greeks received the idea. Among these latter people, Philolaus of Crotona, a disciple of Pythagoras, was celebrated as being the first philosopher who established the theory of the motion of the earth

earth in a manner more distant than had been done by any other Pythagorean. He lived 450 years before Christ. (Plutarch, de Placit. Philof.) Ariftarchus the Samian, about 100 years after Philolaus, propofed the motion of the earth in clearer and stronger terms, as we are affured by Archimedes, in his *Arenarium*.

Philolaus was alfo followed by Nicetas of Syracufe, who maintained likewife the diurnal motion of the earth, and has been by fome regarded as the firft author of this part of the Copernican fyftem. Cicero, in his *Tufcul. Quæft.*, thus fpeaks of him: "Nicetas, according to Theophrastus, believed that neither the fun, the moon, nor the ftars revolved about the earth; but that the earth, by a rapid motion round its axis, produced the fame apparent effect as if it was immoveable, and the motion exifting in the heavens."

Thus the diurnal motion of the earth feems to have been admitted into the philofophy of the Greeks about 500 years before the Chriftian era, which was probably fome centuries after the fame hypothefis had been adopted by the eastern nations.

The annual motion of the earth is faid to have been understood and taught by Pythagoras, who obtained his knowledge from the aftronomers of India and Egypt. This fuppofition, which places the fun in the centre of the folar fyftem, has been occasionally fuggefted by ancient philofophers, but never univerfally received till after the revival of fciences in modern times.

Notwithstanding Apollonius, a celebrated geometrician of Alexandria in Egypt, maintained this hypothefis, yet we find it afterwards abandoned even by the moft eminent aftronomers; a circumftance that fhould the lefs furprife us, when we reflect how incapable they were of acquiring any juft knowledge of the diftances and magnitudes of the heavenly bodies. Befides, the religious opinions of the heathens prevented the general reception of this doctrine of the earth's motion. For Ariftarchus, being accufed by Cleantes of facrilege, for moving Vefia and the tutelary deities of the univerfe out of their places, the philofophers began to lay afide fo perilous a pofition. Many ages afterward Vic. Cafanus revived the ancient fyftem in his *Doctr. de Pignoran.*; but the doctrine gained little ground till the time of Copernicus.

It was in the beginning of the fixteenth century that this eminent aftronomer revived this doctrine, and gave permanence to a fyftem, which before his time had only been tranfitory and fluctuating. The opinions of Copernicus, however, (fee *COPERNICUS* and *COPERNICAN Syftem*;) were not received without great oppofition; but the arguments by which they were oppofed have gradually yielded to the force of reafon and experience; and, at prefent, we hardly confider the plaineft propofition of Euclid more fatisfactorily demonstrated than the diurnal and annual motion of the earth. Yet it is not uninterefting to retrace thefe erroneous opinions. There is reafon to think, that many of the opponents of the motions of the earth would have changed their fentiments, had they been acquainted with the difcoveries that have been made in the laft century. Tycho, who was the great oppofer of this doctrine, feems to have been influenced by religious motives alone, which at that time deterred many devout individuals from embracing a fyftem, which they thought fo diametrically oppofed to the very words of fcripture. Lactantius, the preceptor to the fon of Conftantine, difcuffes the queftion at great length, in order to prove that there are no antipodes; and laments the folly and impiety of thofe who assert the fphericity of the earth, and maintains that the contrary opinion is eftablifhed both by philofophers and the facred writers.

Kepler, the contemporary of Copernicus, obferves at an early period after the revival of this fyftem, "*Hodierno tempore præstantiffimi quique philofophorum et aftronomorum Copernico adfupplicantur: facta eft hæc glacies: vicinicus fuffragis moribonibus: cæteris pene fola obibat fupervitio, aut metus a Cleanthibus.*"

Tycho and alfo Riccioli bring forward a great many texts of fcripture, to prove the fability of the earth; and the miracle of Jofhua, which caufed the fun to ftand ftill, has been thought by many to be decifive. But the moft approved divines of the prefent day admit a figurative construction, or popular and accommodating ufe, of thefe paffages of fcripture, which, otherwife, it would be extremely difficult to reconcile to the difcoveries of the prefent day. Aftronomers themfelves always fpeak the language of fociety, fo far as to fay, the fun rifes, the fun fetts, the fun moves in the ecliptic, &c.; nor fhould we expect that prophets and infpired writers, if they were again to come among us, would ufe any other language.

Accordingly we may obferve in this place, that the Jefuit Riccioli, though he, at the pope's command, oppofed the motion of the earth with all his might, as fomething contrary to holy fcripture; yet, to frame aftronomical tables, which fhould tolerably agree with obfervation, he was forced to have recourfe to the motion of the earth as his only refuge.

This, De Chales, another of the fame fraternity, frankly confeffes: "*P. Ricciolus:—nullas tabulas aptare potuit, quæ vel mediocriter obfervationibus reponderent; nifi fequendum fyftema terræ motæ;*" notwithstanding that he called in all the foreign and forced affiftances of moveable epicycles, fo that in his *Aftronomia Reformata*, where he undertakes to give accurate tables of the celestial motions, he gives into the hypothefis of the motion of the earth." De Chales *Aftron. Reformat. lib. x. cap. i.* See *COPERNICAN*.

As for thofe who oppofe the motion of the earth, as being contrary to fcripture, and who allege thofe paffages which mention the fun's rifing and fetting, his ftanding ftill in the time of Jofhua, and his going back in that of Hezekiah, we need only refer them to allowed laws of interpretation, applicable to the facred writings as well as to others, and to the customary ufe of vulgar language in the description of fenfible phenomena. By the fun's rifing, therefore, is meant no more than his re-appearance in the horizon, after he had been hid below it; and, by his fetting, an occultation of the fun, which was before vifible in the horizon. When the preacher therefore fays, *Ecclef. i. 5.* "The fun alfo rifeth, and the fun goeth down, and batheth in his place where he arife," he means, doubtlefs, no more than that the fun, which before was hid, is now feen in the horizon; and after being there conspicuous, is hid again, and at length re-appears in the eaft. For thus much only appears to a perfon who views the fun; and therefore thus much, and no more, is expreffed by the facred writers.

In like manner, when in *Jofh. x. 12, 13.* the fun and moon are faid to have flood ftill; all meant by ftation is, that they did not change their place with refpect to the earth. For that general, by "Sun, ftand thou ftill upon Gibeon, and thou moon in the valley of Ajalon," required no more, than that the fun which then appeared over that city, fhould not change its fituation. And from his bidding the fun to keep its fituation, it would be unjuft to infer, that it moves round the earth at reit. Of the meaning of this paffage the interpreters of fcripture have given different accounts. Some, without fufficient authority, have thought it to be an interpolation from the book of Jofhua, long fince loit.

L. A. Others have considered it as a real miraculous event, without pretending to account for the manner in which it was performed; and Dr. Watson, bishop of Landaff, in his "Apology for the Bible," thinks the relation in some measure confirmed by a passage, which he cites from Herodotus. Others again, both in ancient and modern times, have supposed that the passage is capable of a rational explanation, without recurring to a miracle. The book of Jasher, here referred to, they have considered as a collection of poetic songs, in celebration of the extraordinary achievements of the armies of Israel: and that the passage is a sublime exaggeration of an enthusiastic poet, indulging those fervours of rapturous invention conceded to his art. (See Wakefield's Reply to the Age of Reason.) Similar expressions of a bold figurative kind occur in Homer. The learned Bryant, in his "Observations on some Passages of Scripture, &c." suggests that the invocation of the Israelitish deity did not relate to the luminaries in the heavens, but to two idolatrous and probably oracular temples of the sun and moon, for which the two places mentioned were celebrated. Accordingly he renders the passage in the following manner: "May the sun, whose oracular temple is on mount Gibeon, be dumb; and the moon, whose shrine is in the valley of Ajalon, be equally silent." May their oracles cease for ever: their worshippers have been miraculously defeated; and those who joined the standard of Israel have been as wonderfully preserved. This interpretation of the two Hebrew terms, he says, is countenanced by the version of Aquila and Symmachus, and by Arias Montanus, who exhibits the whole passage in the following manner: "Et dixit in oculis Israel, sol in Gibeon sile, et luna in valle Ajalon."

After all, these and similar expressions, are true and proper descriptions of the phenomena, as they appear to us; but as the scriptures were never intended to instruct us in philosophy and astronomy, they do not at all determine by what motions these phenomena are occasioned. And it has been justly observed, that part of the account recorded in the book of Joshua is merely a description of the appearance; Gibeon and Ajalon, and the whole land of Canaan lying in too northern a latitude for the sun or moon ever to be vertical to any part of it; and yet this was a just description of the phenomena as it appeared to Joshua in the place where he then was; and if one part of the account merely describe the phenomena, the other must likewise be understood in the same manner.

Cassiodorus, very pertinently to the same purpose, distinguishes, "two sacred volumes, the one written, called the *Bible*; the other, *Nature*, or the *World*: God having manifested himself by two lights, the one of revelation, and the other of demonstration; accordingly the interpreters of the former are divines; of the latter mathematicians. As to matters of natural knowledge, the mathematicians are to be consulted; and as to the objects of faith, the prophets; the former being no less interpreters, or apostles, from God to men, than the latter. And as the mathematicians would be judged to wander out of his province, if he should pretend to contravert, or set aside any article of faith from principles of geometry; so it must be granted, the divines are no less out of their limits, when they venture to pronounce on a point of natural knowledge, beyond the reach of any not versed in geometry and optics, merely from holy scripture, which does not pretend to teach any thing of the matter.

"For instances, we may quote Lactantius and Augustine; the first of whom rendered himself ridiculous by disputing

from scripture against the roundness of the earth; and the latter, against the antipodes." See ANTIPODES.

But to return from this digression; it is now so long since the motion of the earth has ceased to be a disputed question, that the arguments on each side are nearly forgotten, and those who do not scruple to adopt the hypothesis of the earth's motion, are often less acquainted with the arguments on which it is supported, than they would have been in former times, when their opinions would have often been disputed. Of all authors who have written on this subject, La Place seems to have collected these arguments together in the most popular and perspicuous form. We shall present the substance of them to the reader in as concise a manner as possible, introducing at the same time some additional observations, for the further elucidation of this interesting subject.

When we reflect on the diurnal motion to which all the heavenly bodies are subject, we cannot but recognize the existence of one general cause which moves them, or which seems to move them, round the axis of the earth. If we consider that these bodies are insulated, with respect to each other, and placed at very different distances from the earth; that the sun and the stars are at a much greater distance from it than the moon; and that the variations in the apparent diameters of the planets indicate great alterations in their distances; and, moreover, that the comets traverse the heavens freely, in all directions, it will be difficult to conceive that it is the same cause which impresses on all these bodies a common motion of rotation. But since the heavenly bodies present the same appearances to us, whether the firmament carries them round the earth, considered as immovable, or whether the earth itself revolves in a contrary direction, it seems much more natural to admit this latter motion, and to regard that of the heavens as only apparent.

The earth is a globe, whose radius is only about four thousand English miles; the sun, as we have seen, is incomparably larger; if its centre coincided with that of the earth, its volume would embrace the orbit of the moon, and extend as far again, from which we may judge of its immense magnitude; besides, its distance from us is 23,000 times the semi-diameter of the earth. Is it not infinitely more simple to attribute to the globe we inhabit a motion of rotation on its own axis, than to suppose in a mass so considerable, and so remote as the sun, such an extraordinary rapid motion as would be requisite to revolve in one day round the earth? What immense power would it not require to contain it, and counter-balance its centrifugal force? Every one of the stars presents similar difficulties, which are all removed by the rotation of the earth.

We have seen, that the pole of the equator seems to move slowly round that of the ecliptic, from whence results the precession of the equinoxes. If the earth is immovable, the pole of the equator is equally so, since it always corresponds to the same point of the terrestrial surface; the ecliptic, therefore, moves round these poles; and in this motion carries all the heavenly bodies with it. Thus, the whole system, composed of so many bodies, differing from each other so much in their magnitudes, motions, and distances, would be again subject to a general motion, which disappears, and is reduced to a simple appearance, if we suppose the terrestrial axis to move round the poles of the ecliptic.

Carried on with a velocity which is common to every thing that surrounds us, we are in the case of a spectator placed in a ship that is in motion. He fancies himself at rest, and the shore, the hills, and all the objects placed out of

the vessel appear to him to move. But on comparing the extent of the shore, the plains, and the height of the mountains, with the smallness of his vessel, he recognizes, that the apparent motion of these objects arises from the real motion of himself. The numberless stars which fill the celestial regions are, relatively to the earth, what the shores and the hills are to the vessel; and the same reasons which convince the navigator of the reality of his own motion, prove to us the motion of the earth.

We may here observe, that in all the works of nature with which we are acquainted, the Creator appears to act by the shortest, easiest, and simplest means. Now, if the earth be at rest, and the stars move, the velocity of these latter must be immense; and yet all the purposes thereof might have been answered by a moderate motion of the earth alone.

For the moon's distance from the earth amounts to 240000 miles. Hence, the circumference of the moon's diurnal circle being 1507968 such miles, the moon's ordinary motion must be 62832 miles, instead of 2290 miles, which is really the case; consequently, in each second, a space less than that of the pulse of an artery, the moon, though the slowest of all the heavenly bodies, must move more than 17 miles. Again, the sun's mean distance from the earth is 23750 semidiameters of the earth, or 95000000 miles; consequently, the sun's diurnal path, when in the equator, must be 596904000 miles; and, therefore, in the space of one second, *i. e.* in the twinkling of an eye, he must move more than 6908 miles.

Again, the distance of the sun from the earth, is to that of Mars, supposing the earth, and not the sun, to be the centre of the system, nearly as one to one and a half; to that of Jupiter, as one to five and a quarter; and to that of Saturn, as one to nine: wherefore, as the diurnal space, and all other things described in the same time, are in the same ratio, Mars, in one twinkling of an eye, must fly 10362, Jupiter 36266, and Saturn 62172 miles. Lastly, the fixed stars being yet vastly more remote from the earth than Saturn, their motion in or near the equator must be vastly swifter than that of Saturn.

Besides, if the earth be at rest, and the stars move by any common motion, the several planets must each day describe several spirals running forth to a certain term towards the north, and thence returning to the opposite term towards the south, sometimes narrower, and sometimes broader.

For the distances of the several planets from the zenith alter every day, increasing to a certain point towards the north, and thence decreasing again towards the south; consequently, the altitude of the pole being always found the same, and the planets not returning to the same point of the meridian, they do not describe circles, but spirals. Add, that as the several planets do not retain the same distance from the earth, but are sometimes nearer, and sometimes recede farther from it, at a greater distance, a greater spiral, and at a less, a less is described.

Farther, as their motion is slower when the planet is farther from the earth, the greater spirals are described in lesser times than the lesser; and, as the greatest and least distance of the planets from the earth is not affixed to the same point of the heavens, the planets have moved in different traets every day from the beginning.

Besides, the force by which the stars and planets revolve in their orbits are not directed to the centre of the earth, but to the centres of the several orbits which they describe, or to innumerable imaginary points in the axis of the earth; and these forces, tending to different and continually varying

centres, must likewise increase exactly in proportion to the distances from the axis; whereas the force of attraction is found to decrease.

These arguments are, likewise, strengthened by analogy. A rotatory motion has been observed in several planets, and always from west to east, similar to that which the diurnal motion of the heavens seems to indicate in the earth. Jupiter, greatly exceeding the earth in magnitude, moves round its axis in less than twelve hours. An observer on its surface would see the heavens revolve round him in that time; yet, that motion would only be apparent. Is it not, therefore, reasonable to think that it is the same with that which we observe on the earth? What confirms, in a very striking manner, this analogy, is, that both the earth and Jupiter are flattened at the poles. We comprehend, in fact, that the centrifugal force which tends to remove every particle of a body from its axis of rotation, should flatten the earth at its poles, and elevate it at the equator. This force should likewise diminish that of gravity at the equator; and that this diminution does take place, is proved by experiments which have been made on the lengths of pendulums. Every thing, then, leads us to conclude, that the earth has really a motion of rotation, and the diurnal motion of the heavens is merely an illusion which is produced by it, an illusion similar to that which represents the heavens as a blue vault, to which all the stars are fixed, and the earth as a plane on which it rests.

Thus, astronomy has surmounted the illusions of the senses; and it is not till they have been dissipated by a great number of observations and calculations, that man has at last recognized the motion of the globe which he inhabits, and its true position in the universe.

Moreover, bodies let fall from any considerable height, are found, by experiment, not to fall upon the spot perpendicularly under them, but to the south-east thereof.

The experiment was proposed to Dr. Hook in the year 1679, by a person who suggested, that, if the earth had any diurnal motion, the body would fall to the east of the perpendicular. Dr. Hook, on that occasion, read a discourse before the Royal Society, wherein he endeavoured, *a priori*, to assign what curve a falling body would describe; asserting, particularly, that the fall of the body would not be directly east, but south-east; which was confirmed by divers actual trials. The objection, which supposes, that *e. g.* a ball fired perpendicularly upward in the air should fall westward of the place from which it was projected, on the supposition of the earth's revolution eastward, can have no weight, when it is considered that the gun and ball partake of the earth's motion; and, therefore, being carried forward with the air as quick as the earth and air turn, it must fall down on the same place, describing, in its descent, the diagonal of a parallelogram, whose two sides are proportional to the forces acquired from the earth's motion and the gravity of the ball. Thus, a stone let fall from the top of a main-mast, if it meets with no obstacle, falls on the deck as near the foot of the mast when the ship sails, as when it does not.

Shall we now suppose the sun, accompanied by the planets and satellites in motion round the earth, or shall we imagine the earth and other planets to revolve round the sun? The appearances of the heavenly motions are the same in the two hypotheses; but the second should be preferred, for the following considerations:

The sun will equally appear in motion, and the earth as standing still, to a spectator on the earth, whether the sun really move round the earth at rest, or the earth move round the sun at rest.

For, suppose the earth in T (*Plate IX. Astronomy, fig. 69.*),
and

and the sun in Γ ; the sun will then appear in Υ . And, suppose the sun to proceed in an orbit surrounding the earth from Γ to δ , he will then appear in δ ; and, if he proceed farther to ζ , he will seem to be in Π : and thus will he appear to go on, according to the order of the signs in the ecliptic. Suppose, again, the earth in Γ , and the sun in Γ , the sun will now be seen in α ; let the earth go on from Γ to δ , the sun will appear to the inhabitants of the earth to have proceeded from α to β ; and if the earth proceed to ζ , the sun will appear to have advanced farther from β to γ , and so on, according to the succession of the signs of the ecliptic.

Thus, does the sun appear alike to move, whether he really move or stand still; so that the objection from sense is of no force. But again,

If one of the planets be supposed to have moved a certain space from west to east, the sun, earth, and other planets, together with the fixed stars, will all seem to an inhabitant of that planet to have moved just so far round in the contrary way.

For, suppose a star M (fig. 70.) in the zenith of an inhabitant of a planet placed in T ; and suppose the planet to have revolved on its axis from west to east; in a certain space of time, the sun S will have arrived at the zenith of T , then the star I , then N , then the earth L , and, at length, the star M again. To the inhabitants of the planet, therefore, the sun S , with the earth L , and the stars I , N , M , &c. will appear to have moved round the planet a contrary way.

Thus, to the inhabitants of the planets (if any such there be) the mundane sphere, with the sun, stars, and all the other planets, will, as to us, appear to move round them from east to west; and accordingly, the inhabitants of our planet, the earth, are only liable to the same delusive appearance with those of the rest. Moreover, the orbits of the planets include the sun as the common centre of them all; but it is only the orbits of the superior planets that include the earth; which, however, is not in the centre of any of them, as will be shewn under SUN and PLANET. Again, the earth's orbit being proved to be between those of Venus and Mars, it follows, that the earth must turn round the sun; for, as it lies within the orbits of the superior planets, their motion would appear unequal and irregular; but they would never either be stationary, or retrograde, without this supposition. Besides, from the orbits and periods of the several planets about the sun, and of the moon and satellites round the earth, Jupiter and Saturn, it is evident, that the law of gravitation is the same towards the earth, Jupiter, and Saturn, as towards the sun; and the periodical times of the several bodies moving round each, are in the same ratio to their several distances from them.

Now, it is certain, that, on the hypothesis of the earth's annual motion, her periodical time exactly suits this law, bearing such a proportion between those of Mars and Venus as the several other bodies directed by the same law do bear; *i. e.* the squares of the periods are, in all, as the cubes of the distances from the centre of their orbits. But, supposing the earth too at rest, this law is broken most exorbitantly.

For, if the earth does not move round the sun, the sun must move with the moon round the earth; now, the distance of the sun to that of the moon being as 23750 semidiameters of the earth to 60, or nearly as 396 to 1; and the moon's period being less than 28 days, the sun's period should be found no less than 212775 days, or 583 years; whereas, in fact, it is but one year. Which single consideration Mr. Whiston thinks of weight enough to determine the controversy between the two systems, and to establish the motion of the earth for ever.

Whereas, supposing our earth to have once revolved about the sun in a circular orbit, whose semidiameter were equal to the earth's original distance from the sun six degrees past its perihelion, the annual period would be found exactly and surprisingly equal to the lunar, or the ancient solar year, which were exactly commensurate, containing 12 synodical, or 13 periodical months, *i. e.* 365 days, 4 hours, 19 minutes.

The masses of the sun, and of several of the planets, are considerably greater than that of the earth; it is much more simple to make the latter revolve round the sun, than to put the whole solar system in motion round the earth. What a complication in the heavenly motions would the immobility of the earth suppose? What a rapidity of motion must be given to Jupiter; to Saturn, which is ten times farther from the sun than we are, and to Uranus, which is still more remote, to make them every year revolve round us, at the same time they are revolving round the sun.

This complication and this rapidity of motion disappear, by transferring the motion to the earth; a motion conformable to the general law, by which the small celestial bodies revolve round the large ones which are placed in their vicinity.

The following is an actual demonstration of the earth's motion, drawn from physical causes, for which we are indebted to the discoveries of sir Isaac Newton, and which Dr. Keil takes for conclusive and unanswerable.

All planets, it is demonstrated, gravitate towards the sun; and observations testify to us, either that the earth turns round the sun, or the sun round the earth, in such a manner as to describe equal areas in equal times. But it is demonstrated farther, that whenever bodies turn round each other, and regulate their motions by such a law, the one must of necessity gravitate to the other: consequently, if the sun in its motion doth gravitate to the earth, action and re-action being equal and contrary, the earth must likewise gravitate towards the sun.

Again, the same author has demonstrated, that when two bodies gravitate to one another, without directly approaching one another in right lines, they must both of them turn round their common centre of gravity; the sun and earth, therefore, do both turn round their common centre of gravity; but the sun is so great a body in respect of our earth, which is as it were but a point; that the common centre of gravity of the two bodies will lie within the body of the sun itself, and not far from the centre of the sun. The earth, therefore, turns round a point, which is in the body of the sun, and therefore it turns round the sun.

Besides, if the sun moves about the earth, the earth's attractive power must draw the sun towards it from the line of projection, so as to bend its motion into a curve; but the sun being at least 227000 times as heavy as the earth, it must move 227000 times as slowly towards the earth as the earth does toward the sun; and consequently the earth would fall to the sun in a short time, if it had not a very strong projectile motion to carry it off. There is, indeed, no such thing in nature as a heavy body moving round a light one as its centre of motion. A pebble, as Mr. Ferguson familiarly illustrates this matter, fastened to a mill-stone by a string, may, by an easy impulse, be made to circulate round the mill-stone; but no impulse can make a mill-stone circulate round a loose pebble, for the mill-stone would go off and carry the pebble along with it.

The analogy of the earth, with the planets, confirms this hypothesis: like Jupiter, it revolves on its axis, and is accompanied by a satellite. An observer, on the surface of

Jupiter, would conclude, that the solar system was in motion round him, and the magnitude of that planet would render this illusion less improbable than for the earth. Is it not, therefore, reasonable to imagine, that the motion of the solar system round us is likewise only an illusion?

Let us transport ourselves in imagination to the surface of the sun, and from thence let us consider the earth and the planets. All these bodies will appear to move from west to east, already this identity in the direction indicates a motion of the earth, but that which demonstrates it evidently is the law which exists between the times of the revolutions of the planets, and their distances from the sun. They revolve round it slower, as their distances are greater, and in such a manner, that the squares of the periodic times are in proportion to the cubes of their mean distances. According to this remarkable law, the length of a revolution of the earth, supposing it in motion round the sun, should be exactly a sidereal year. Is not this an incontestible proof, that the earth moves like the other planets, and is subject to the same laws? For would it not be very strange to suppose the terrestrial globe, which hardly subtends a visible angle at the sun, immovable amidst the other planets which are revolving round it, and that the sun should be carried with them about the earth?

The force, which serves to retain the planets in their respective orbits round the sun, balances the centrifugal force. Ought it not likewise to act upon the earth? And must not the earth oppose to this action the same centrifugal force? Thus the consideration of the celestial motions, as observed from the sun, leave no doubt of the real motion of the earth.

The principal argument against the annual motion of the earth, has been the want of an annual parallax in the fixed stars. For let $T A t$ (Plate X. *Astronomy*, fig. 71.) represent the earth's orbit about the sun S , $T X$ the axis of the earth, and $t x$ parallel to $T X$, will represent the position of the same axis at the opposite point t . Suppose $T X$ to be directed towards the star P ; and it is manifest, that the axis of the earth will not be directed to the same star, when it comes to the situation $t x$, but will contain an angle $\angle t P$ with the line $t P$, joining the earth and star, equal to the angle $\angle P T t$, under which the diameter, $T t$, of the earth's orbit, appears to a spectator, viewed from the star P . It might be expected, therefore, that by observing the fixed star P , from the different parts of the earth's orbit, we might judge of the angle $\angle T P t$, and consequently of the proportion of $T P$, the distance of the star, to $T t$, the diameter of the earth's orbit, or double distance of the sun. Yet it is certain that astronomers have not hitherto been able to discover any difference in the apparent situation of the fixed stars with respect to the axis of the earth, or to one another, that can arise from the motion of the earth: though, since the restoration of the Pythagorean doctrine of the earth's motion, they have taken great pains to examine the matter.

The seeming motion of the pole-star, observed by Mr. Flamsteed, was by some mistaken for a proof of its annual parallax; but this phenomenon has since been accounted for in the most ingenious manner by Mr. Bradley, from the motion of light combined with that of the earth in its orbit. See PARALLAX, and the sequel of this article.

The objection to the earth's motion, from there being no discernible parallax of the fixed stars, is answered by observing, that the distance of the fixed stars is so great, that the diameter of the earth's orbit bears no sensible proportion to it; so that the parallax is not to be discovered by our exactest instruments. Nor is this immense distance of the

fixed stars advanced by the Copernicans merely as an hypothesis for the sake of solving the objection. For there seems great reason to suppose the fixed stars like to our sun, and hence to conclude their distance to be vastly great, since they appear to us of so faint a light, and of no sensible diameter, even in the largest telescopes.

But from the diligence and accuracy of late astronomers, we learn several curious things in confirmation of the motion of the earth about the sun, and serving to solve this only material objection against it. Accordingly, an observer on the surface of the earth has another evident proof of its motion in the phenomenon of the *Aberration*, (see *ABERRATION*) which is a necessary consequence of it, as we shall now explain. About the end of the 17th century, Roemer observed, that the eclipses of the satellites of Jupiter happened sooner about the oppositions of this planet, and later towards the conjunctions. This led him to suspect that light was not transmitted instantaneously from those bodies to the earth, but that it employed a sensible interval of time to traverse the diameter of the orbit of the sun. In fact, Jupiter being in his oppositions nearer to us than in the conjunctions by a quantity equal to this diameter, the eclipses ought to happen sooner to us in the first case, than in the latter, by the time which the light takes to traverse its orbit. The law of retardation, observed in these eclipses, answers so exactly to this hypothesis, that it is impossible to refuse assent to it. It appears that light employs $8' 5''$ in coming from the sun to the earth.

Now, an observer at rest would see the stars according to the directions of their rays, but this will not be the case, on the supposition that he partakes of the motion of the earth. To reduce this case to that of the observer at rest, it is sufficient to assign, in a contrary direction, both to the stars, to the light, and to the observer himself, a motion equal to that by which he is impelled, which would not change the apparent position of the stars: for it is a general law of optics, that if all the bodies of a system are impelled by a common motion, there will result no change in their respective situations. Let us imagine then, that a motion, equal and contrary to that of the observer, be given to the rays of light, and generally to all the other bodies, and let us see what phenomena should result in the apparent position of the stars. We may leave out of the question the diurnal motion of the earth, which is not, even at the equator, $\frac{1}{2}$ th part of that in its orbit round the sun. We may here suppose, also, without sensible error, that all the rays which each point of the disc of a heavenly body transmits to us, are parallel to each other, and to that ray which would come from the centre of the star to the centre of the earth if it were transparent. Thus the phenomena which the stars would present to an observer, placed at the centre of the earth, and which depend on the motion of light combined with that of the earth, are nearly the same for every observer on its surface. Moreover, we may neglect the small eccentricity of the terrestrial orbit.

In the interval of $8' 5''$, which the light employs to traverse the terrestrial orbit, the earth describes a small arc of this orbit, equal to $20''.2$; now it follows, from the law of the composition of motion, that if through the centre of a star, we imagine a small circle parallel to the ecliptic, and whose diameter subtends in the heavens an angle of $40''.5$, the direction of the motion of light, combined with the motion of the earth, and applied in a contrary direction, will meet this circumference in a point where it is intersected by a plane drawn through the centre of the star tangentially to the terrestrial orbit. The star, therefore, should move upon this circumference, and describe

it every year in such a manner, that it should constantly be less advanced by 100 degrees, than the sun in its apparent orbit.

This phenomenon is exactly that which we have explained, after the observations of Bradley, to whom we are indebted both for the discovery and its cause. (See **ABERRATION**.) To reduce these stars to their true position, it is sufficient to place them in the centre of the small circle they appear to us to describe.

Their annual motion, therefore, is only an illusion produced by the combination of the motion of light with that of the earth. The relation of this motion, with the position of the sun, would lead to a suspicion, that it was only apparent, but the foregoing explanation proves it beyond a doubt. It affords a sensible demonstration of the motion of the earth round the sun, in the same manner as the increase of degrees, and of the force of gravity in going from the equator to the poles, proves its revolution on its axis.

The aberration of light affects the positions of the sun, the planets and their satellites, and comets, but in a different manner, according to their particular motions. To divert them of this, and to have the true position of the stars, let us suppose, at every instant, a motion impressed on all these bodies equal and contrary to that of the earth, which thus may be supposed at rest: this, as observed above, neither alters their positions nor appearances. Then it is evident, that a heavenly body, the moment we observe it, is no longer in the direction of the luminous ray which strikes our sight; it has left it in consequence of its real motion combined with that of the earth, which we supposed impressed in a contrary direction. The combination of these two motions, as seen from the earth, forms the apparent, or, as it is termed, the geocentric motion. We shall have then the true position of the object, by adding to the observed geocentric longitude and latitude its geocentric motion in longitude and latitude, for the interval of time which light employs to come from the heavenly body to the earth. Thus, the centre of the sun seems constantly less advanced by $62''.5$ in its orbit, than if its light was transmitted to us instantaneously.

The aberration of light changes the relations of celestial phenomena, both as to space and as to duration. At the moment we see them they no longer exist. We do not see the termination of Jupiter's eclipses till twenty-five or thirty minutes after they have recovered their light, and the variations of light of some of the changeable stars precede by many years the instant of their observations. But the cause of these illusions being well understood, we can always refer the phenomena of the solar system to their true place and epoch.

The consideration of the celestial motions leads us then to displace the earth from the centre of the world where we had placed it, deceived by appearances, and by the natural propensity of man to regard himself as the principal object in nature. The globe, which we inhabit, is a planet in motion on itself and round the sun. In considering it in this point of view, all the phenomena are explained in the most simple manner, all the celestial motions become uniform, and the analogies are preserved. Like Jupiter, Saturn, and Uranus, the earth is accompanied by a satellite, it turns on itself like Venus, Mars, Jupiter, and Saturn, and probably the other planets; it like them borrows its light from the sun, moves round it in the same direction, and according to the same laws. Finally, the hypothesis, of the earth's motion unites in its favour simplicity, analogy, and every thing which characterizes the true system of nature. We

shall see that, following it in its consequences, the celestial phenomena are brought even in their minutest details to one single law, of which they are only the necessary developments. The motion of the earth will thus acquire all the certainty of which physical truths are susceptible. And it may result either from the great number and variety of phenomena which it explains, or from the simplicity of the laws on which it is made to depend. None of the branches of natural knowledge unite these advantages in a higher degree than the theory of the system of the world, founded on the motion of the earth. This motion ennobles our conceptions of the universe, by affording, for a measure of the distances of the heavenly bodies, an immense base, the diameter of the terrestrial orbit. By this we have accurately determined the dimensions of the planetary orbits.

Thus the motion of the earth, after having by illusions, of which it is itself the cause, retarded our knowledge of the planetary motions for a great length of time, at last conducted us to them, and that in a more accurate manner than it had been placed in the centre of their system.

From the point of view in which the comparison of the celestial observations has placed us, let us consider the heavenly bodies, and shew the perfect identity of their appearances with those which we observe. Whether the heavens revolve round the axis of the world, or the earth moves itself in a contrary direction to the heavens, supposed at rest, it is clear that the stars will present themselves to us in the same manner. There will be no other difference, but that in the first case they will come and place themselves successively over the different terrestrial meridians, which, in the second, will place themselves under the stars. The motion of the earth being common to all bodies situated on its surface, and to the fluids which cover it, their relative motions are the same as if the earth was at rest. Thus, in a vessel whose motion is uniform, every thing moves as if the vessel were at rest. A projectile, thrown directly upwards, falls on the same spot from which it was projected; it seems to describe a vertical line to those in the vessel, but seen from the shore, it really describes a parabolic curve. Thus, the rotation of the earth cannot be sensible on its surface, except by the effects of the centrifugal force, which flattens the terrestrial spheroid at the poles, and diminishes the force of gravity at the equator; two phenomena, with which the measure of the degrees at the meridian, and of the pendulum, have made us acquainted.

In the revolution of the earth round the sun, its centre, and all the points of its axis of rotation, being moved with velocities equal and parallel, this axis remains always parallel to itself; on impressing then, at every instant, on all the parts of the earth, a motion equal and contrary to that of its centre, it would rest immovable, like its axis of rotation. This impressed motion does not change at all the appearances of that of the sun; it only transports, in a contrary direction to the sun, the real motion of the earth. The appearances are consequently the same in the hypothesis of the earth at rest, and in that of its motion round the sun. To follow more particularly these appearances, let us imagine a radius drawn from the centre of the sun to that of the earth; this radius will be perpendicular to the plane which separates the hemisphere, which is enlightened from that which is in obscurity. A spectator, at the point where this intersects the terrestrial surface, will see the sun perpendicularly above him, and every point of the terrestrial parallel through which this radius successively passes, in consequence of its diurnal motion, will have, at noon, the sun in its zenith. Thus, whether the sun turns round the earth, or the earth round the sun, and on its own axis, this axis preserving a parallel

parallel position, it is evident that this radius will trace the same curve on the surface of the earth; it will in each case cut the same parallels to the equator, when the sun has the same apparent longitude. This luminary will be equally elevated above the horizon, and the days will be of the same length. Thus the seasons and the days are the same in the hypothesis of the immobility of the sun, or of its motion round the earth; and the explanation of the seasons will be equally intelligible by either hypothesis. The planets all move in the same direction round the sun, but with different velocities: but the length of their revolutions increase in a greater ratio than their distances from the sun. Jupiter, for instance, employs nearly twelve years to perform its revolution; but the radius of his orbit is only five times less than that of the earth: its real velocity is, therefore, less than that of the earth. This diminution of velocity in the planets, as they recede from the sun, applies generally to all the planets, from Mercury, which is the nearest, to Uranus, which is the most remote; and it results from the laws which we shall hereafter demonstrate, that the mean velocities of the planets are reciprocally as the square roots of their mean distances from the sun.

Let us consider a planet, whose orbit is surrounded by that of the earth, and follow it from its superior to its inferior conjunction; its apparent or geocentric motion is the result of its real motion combined with that of the earth, considered as moving in a contrary direction. In the superior conjunction, the real motion of the planet is contrary to that of the earth; its geocentric motion is then the sum of the two motions; and it has then the same direction as the geocentric motion of the sun, which results from the real motion of the earth transferred in a contrary direction to the sun, and thus the apparent motion of the planet is direct.

In the inferior conjunction, the motion of the planet has the same direction as that of the earth, and as it is greater, the geocentric motion preserves the same direction; but it is only the excess of the real motion of the planet above that of the earth: it has, therefore, a motion contrary to that of the sun, and consequently it is retrograde.

It is easy to conceive, that in the interval from the direct to the retrograde motion, the planet should appear without motion, or stationary, and that this will happen between the greatest elongation and the inferior conjunction, when the geocentric motion of the planet, resulting from its real motion, and that of the earth applied in a contrary direction, is directed in the same line as the vernal ray to the planet. These phenomena are entirely conformable to the motions that are observed to take place in the planets Mercury and Venus.

The motion of the planets, whose orbits comprehend those of the earth, has the same direction in their oppositions as the motion of the earth, but it is less; and being combined with this last motion, applied in a contrary direction, it takes a motion contrary to its primitive direction, the geocentric motion of the planet is then retrograde: in the conjunctions it is direct, the same as in the superior conjunctions of Mercury and Venus.

In transferring to the stars (but in a contrary direction) the motion of the earth, they should describe every year a circumference equal and parallel to the terrestrial orbit, and of which the diameter should subtend an angle equal to that which this orbit subtends at the distance of the star. This apparent motion has a great resemblance to that which results from the combination of that of the earth with that of light, and by which the stars seem annually to describe a circle parallel to the ecliptic, the angle of which subtends an arc of 125° ; but it differs in this, that these stars have the

same position as the sun on the first circumference; whereas, in the second, they are less advanced than the sun, by 100° . By this circumstance, the two motions may be distinguished from each other, and it appears that the first is insensible, the immense distance of the stars from us rendering insensible the angle which the terrestrial orb subtends when viewed from them. The axis of the world being nothing more than the prolongation of the earth's axis of rotation, we should refer to this axis the motion of the poles of the celestial equator, indicated by the phenomena of *precession* and *nutation*, which see. Thus, at the same time that the earth moves on its own axis, and round the sun, its axis of rotation moves very slowly round the poles of the ecliptic, but subject to small oscillations, of which the period is the same as that of the motion of the nodes of the lunar orbit.

The figure of the earth is a subject which has never ceased to interest the curiosity of the speculative part of mankind from the earliest dawn of science to the present day.

To its first inhabitants it must have appeared a wide extended plain, on the extremities of which the vast dome of the heavens would appear to rest. The ancients, however, had various opinions with regard to the figure of the earth. Some, as Anaximander, held it to be cylindrical; others, as Leucippus, gave it the form of a drum. But the principal opinion was, that it was flat; and the visible horizon was the boundary of the earth, and the ocean the boundary of the horizon; that the heavens and earth above this ocean were the whole visible universe, and that all beneath the ocean was Hades; and of this opinion were not only several of the ancient poets and philosophers, but also some of the Christian fathers, as Lactantius, St. Augustine, &c.

The progress of the science of astronomy is the continued triumph of the powers of intellect over the first erroneous conceptions of the senses; and its history is so connected with that of the human mind, that we cannot help feeling a strong inclination to know at what time, and by what people, the hypothesis of the spherical figure of the earth was first received.

If, in natural philosophy, the value of an hypothesis may be estimated by the number of difficult phenomena it suddenly explains, few discoveries will be found to have been more important than that which assigned to the earth its true magnitude and figure. But it is in vain that we now attempt to trace its history; it took place in those dark ages of antiquity, when the revolutions of empires were but imperfectly recorded, much less the calm speculations of a few quiet and thoughtful men.

The idea of the earth being a globe is now so familiar to us, that arguments in proof of it are almost unnecessary. We may every day meet with people who have been round it, and the most uninformed seaman can easily comprehend that he is sailing on a globular surface, when he finds that by proceeding forward in any direction, he ultimately arrives at the point from which he departed. Yet, familiar as is this fact to us, many ages must have elapsed before it could have been universally received. So difficult was it to conceive how the inhabitants of the opposite hemisphere could exist with their heads downwards without great inconvenience, that we find St. Augustine, in the 5th century, vehemently contending against the possibility of the existence of antipodes. The earliest astronomical records, which can be received as authentic, do not go back farther than about 800 years before the Christian era, as at that time eclipses seem to have been both observed and registered by more than one of the eastern nations. Astronomy must then have been cultivated as a science at least for some centuries, and therefore, we may conclude with certainty, that the spheri-

real figure of the earth was known above one thousand years before our era, and, probably, by some of the eastern nations many centuries earlier. The observations which led to the discovery were, doubtless, those of the phenomena caused by the diurnal motion of the earth, combined with those produced by change of situation, in removing towards the north or south.

We may suppose the spherical figure of the heavens to have been first established, by observing that those stars, sufficiently elevated towards the North pole, performed their entire revolution round the poles without interruption, from which it might by an easy inference be concluded, that the other stars pursued their course in the same manner when concealed from view.

The arguments for the nearly spherical or globular figure of the earth may be summed up in the following particulars: 1. When you stand upon the shore, the spherical form of the sea is evident to the eye. 2. When a ship leaves the shore, and goes out to sea, you first lose sight of the hull, and then of the mast, gradually from the bottom to the top: and when a ship approaches the shore, you first see the top of the mast, and then the lower parts gradually appear, till at last the whole ship becomes visible. These appearances could not take place if the sea were a plane, for in that case every part of the ship would disappear at once, after quitting the shore, and appear together on its approach to the shore; or rather, the hull, being the largest and most conspicuous part of the ship, would last disappear, and appear first, which is contrary to the well-known fact. But the appearances exactly correspond to the spherical or spheroidal figure of the sea, in which case the convexity of the water would produce the phenomena that are actually observed. 3. From the voyages of the navigators Magellan, sir Francis Drake, lord Anson, captain Cook, and many others, who have sailed round the earth, setting off in one direction, and after continuing their course, returning to the same place in an opposite direction; or sailing towards the east and returning west, or *vice versa*, we may infer that the earth is nearly of a globular figure. 4. These circumnavigators, in the course of their voyage, have observed all the phenomena, both of the heavens and the earth, to correspond to, and to evince this spherical figure. 5. The moon is frequently seen eclipsed by the shadow of the earth; and in all eclipses that shadow appears circular, what way soever it be projected, whether towards the east, west, north, or south, and howsoever its diameter vary, according to the greater or less distance from the earth; hence it follows, that the shadow of the earth, in all situations, is really conical, and consequently, the body that projects it, that is, the earth, is nearly spherical. 6. In travelling towards the south, the northern stars are depressed, and we lose sight of them, and the southern stars are elevated and brought to view, and *vice versa*; and the sun arrives at the meridian of places that are more easterly sooner than to the meridian of those towards the west, in proportion to the distance of the meridians measured upon the equator; which phenomena are owing to the sphericity of the earth. 7. The same globular figure is likewise inferred from the operation of *levelling* (which see); in which it is found necessary to make an allowance for the difference between the apparent and true level. In short, all the appearances, both upon the earth and in the heavens, are such as they should be, upon the supposition that the figure of the earth is globular, but none of them will correspond to that of a plane surface. As for the inequalities on its surface, owing to mountains and vallies, they are of no moment in the estimation of its general figure, being of

no greater account, with respect to relative proportion, than the asperities on the surface of a lemon with regard to the lemon itself; or the smallest grain of sand to a common globe. Indeed the change of figure, arising from the diurnal rotation of the earth, and appearing in an elevation of the equatorial and a flattening of the polar parts, is more sensible; but this does not materially affect the popular phenomena; though the scientific astronomer knows how to make a due allowance for them. See the sequel of this article, and the article DEGREE.

When the spherical hypothesis of the earth was once admitted, a tolerable conception would soon be formed of its magnitude. A person travelling northward, and observing the pole elevated one degree more than at the place of his departure, would easily conclude he had travelled over $\frac{1}{120}$ th part of the whole circumference of the earth. The first approximation that was made by a method of this kind, however inaccurate, must (compared with the state of ignorance that preceded it) have been, at that time, a most important addition to the stock of natural knowledge; and, indeed, except with a view to some very refined scientific investigations, the general idea which the ancients had of the magnitude of the earth, differs but little from that of the moderns: for we are so entirely incapable of forming any accurate idea of number or magnitude, when either exceeds a certain limit, that a traveller who is told that the distance from London to York is about 200 miles, forms, perhaps, in one sense, a more accurate idea of its distance than the philosopher in his closet, who has computed the exact number of inches by trigonometrical calculation.

The magnitude of the earth may be easily estimated by the measure of a meridional degree; but the result will be different, according to the measure that is assumed. According to Cassini, who adopted Picard's measure of a degree, the ambit or circumference of the earth is 123750720 Paris feet, or 134650777 English feet; whence, supposing the earth spherical, its diameter must be 7967 statute miles; and multiplying the square of the diameter by 3.1416, its surface will be 199407056 miles; and multiplying the cube of the diameter by the decimal .5236, we shall have 264779426393 cubic miles for the solid content of the globe of the earth. But if we take 364546 feet for the length of a degree in latitude 45° (see the table under DEGREE), we may consider this as a mean length: hence, 364546×360 (= 131236560 feet) will be the circumference of the earth, considered as a sphere; and since the circumference of every circle is to its radius as 6.28318 to 1, we have 6.28318 : 1 :: 131236560 : 20886964 feet, or 3955 miles, the radius of the earth; and, consequently, its diameter is 7910 miles; its surface 196563942 miles, and its solidity 212600665836 cubic miles.

Dalby makes the earth's equatorial radius 3489932 fathoms, and its semi-axis 3473656 fathoms. (Phil. Transf. vol. for 1791.) Subsequent measurements make the same respectively equal to 3491426 and 3468007 fathoms, or to 7935 and 7882 miles. (Phil. Transf. vol. for 1795.) See the article DEGREE. As an approximation to the best estimation, but without laying much stress upon it, we shall reckon the two axes of the earth respectively equal to 7977 and 7940 English miles. These are commonly called the equatorial and polar diameters of the earth. Hence we may deduce the solid contents of the earth. One of the rules for finding the solid contents of a spheroid, according to the doctrine of mensuration, is to multiply two-thirds of the revolving axis by the area of the generating ellipse, (*viz.* the ellipse, by the revolution of which the spheroid is generated,) and the product will be the content of the spheroid.

spheroid. (See SPHEROID.) The axes, then, being assumed, as above stated, 7940 and 7977 miles respectively, the area of the generating ellipse is $(7940 \times 7977 \times 0.7854 =) 49745178.252$; and its area multiplied by two-thirds of the longer axis, gives the solidity equal to $(49745178.252 \times \frac{2}{3} \times 7977 =) 264544857944.136$ cubic miles. This determination evidently rests upon the supposition that no considerable vacuity exists within the body of the earth. But there are reasons for supposing that the earth is more dense towards the centre than towards the surface. (See De la Lande's *Altron*, vol. ii. art. 3589.) And independently of this, all the mineralogical and geological observations shew, that the earth is not homogeneous. For the method of estimating the mean density of the earth, see the article DENSITY.

It is not exactly known to whom we are indebted for the first suggestion of the oblate figure of the earth.

Picard, in his measure of the earth, published in 1671, speaks of a conjecture proposed to the academy, that supposing the diurnal motion of the earth, heavy bodies should descend with less force at the equator than at the poles, and observes, that for the same reason, there should be a difference in the length of the pendulum vibrating seconds in different latitudes.

It was in this same year that Richer was sent to Cayenne, and among other objects of his voyage, he was charged by the academy to observe the length of the pendulum vibrating seconds. He returned in 1672, and mentions his observation of the pendulum as the most important he had made. The same measure which had been marked at Cayenne on a rod of iron, according to the length which had been found necessary to make the pendulum vibrate seconds, being brought back, and compared with that marked at Paris, the difference was found to be a line and a quarter, that at Cayenne being the shorter. The vibrations of the pendulum on which the experiment was made were very small, and continued sensible for 52 minutes of time, and were compared with an excellent clock which vibrated seconds. Moreover, the clock which Richer took to Cayenne having been adjusted to beat seconds at Paris, retarded two minutes a day at Cayenne, so that no doubt remained of the diminution of the force of gravity at the equator.

This was the first direct proof of the diurnal motion of the earth. Huygens was then led to suspect that the same cause might produce a protuberance of the equatorial parts of the earth, and a corresponding depression of the poles. Cassini had already observed the oblate figure of Jupiter, which analogy strongly favoured the supposition of a similar phenomenon on the earth. The most obvious method of ascertaining the fact being by direct measurement, astronomers were sent to various parts of the world to measure the value of different degrees: of the result of their labours we have given a most ample detail under DEGREE.

Huygens was certainly the first person who attempted to determine the figure of the earth by direct calculation; but he assumed a hypothesis, which, since the discovery of the law of universal gravitation, has been found to be inadmissible: this hypothesis supposes that the whole of the attractive force resides in the centre of the earth, and that its power varies as the square of the distance. Upon this supposition Huygens computes the ellipticity of the earth to be $\frac{1}{177}$, the centrifugal force at the equator being $\frac{1}{285}$ of the force of gravity.

Newton, upon the supposition of the earth's having been an homogeneous fluid, estimates the ellipticity at $\frac{1}{23}$.

But Clairaut was the first mathematician who gave a general solution of this problem, adapted to the hypothesis of a variable density. The result which he obtained from his

investigation was as curious as unexpected; it appeared that if the density of the strata, of which the earth is composed, increases towards the centre, the ellipticity will be less than in the hypothesis of Newton, and greater than in that of Huygens; and moreover, that the fraction expressing the ellipticity being added to the fraction expressing the augmentation of gravity at the poles, will together always make a constant quantity, which is equal to $\frac{2}{3}$ of the fraction which expresses the proportion which the centrifugal force at the equator bears to that of gravity. We shall find that it is by means of this theorem that we are enabled to ascertain the true figure of the earth by experiments on pendulums, in a more accurate manner than can be done by the measurement of degrees.

We shall now subjoin the whole theory of this subject as given by La Place, and for his calculations shall substitute those which are derived from taking into consideration the measurements that have been made in England and Sweden, which bring the result much nearer to the true spheroidal figure than the degrees that had been taken by La Place, in the second volume of *La Mécanique Céleste*.

The force of gravity towards the planets is composed of the attractions of all their particles. If their mass was fluid, and without motion, their strata would be spherical, those nearer the centre being the more dense. The force of gravity at their exterior surface, and at any distance whatever without the sphere, would be exactly the same, as if the whole mass of the planet was compressed into the centre of gravity. It is in consequence of this remarkable property, that the sun, the planets, comets, and satellites, act upon each other, very nearly, as if they were so many material points. At very great distances the attraction of the particles of a body of any figure, which are the most remote, and those which are nearest the particle attracted, compensate each other in nearly the same manner as if they were united in the centre of gravity, and if the ratio of the dimensions of the body be considered as a very small quantity of the first order, this result will be exact to a quantity of the second order. But in a sphere, it is rigorously true, and in a spheroid differing but little from a sphere, it is of the same order as the product of its eccentricity, by the square of the ratio of its radius to the distance of the point attracted. This property of the sphere of attracting, as if its mass was concentrated in its centre, contributes greatly to the simplicity of the motions of the heavenly bodies. It does not belong exclusively to the law of nature; it equally appertains to the law of the attraction varying proportionally to the simple distance, and cannot belong to any other law, but those formed by the addition of these two. And of all the laws which render the force of gravity nothing, at an infinite distance, that of nature is the only one in which the sphere possesses this property.

According to this law, a body placed within a spherical stratum of uniform thickness, is equally attracted by all its parts, so as to remain at rest in the middle of the various attractions which act upon it. The same circumstance takes place in an elliptic stratum, when the exterior and interior surfaces are similar and similarly situated. Supposing, therefore, the planets to be spheres of homogeneous matter, the force of gravity in their interior must diminish as the distance from the centre, for the exterior part relatively to the attracted particle contributes nothing to its gravity, which entirely consists of the attraction of the internal sphere, whose radius is equal to the distance of this point from the centre. But this attraction is equal to the mass of the sphere divided by the square of the radius, and the mass is as the cube of this same radius. The force of gravity on the attracted

attracted particle is therefore equal $\frac{R^3}{R}$, or, simply, to the radius. But if, (as is probably the case,) the strata are more dense as they approach the centre, the force of gravity will diminish in a less ratio than in the case of homogeneity. But the rotatory motion of the planets causes them to differ a little from the spherical figure, the centrifugal force arising from this motion causing the particles situated at the equator to recede from the centre, and produce a flattening of the poles.

Let us consider, first, the effects of this circumstance in the most simple case of the earth's being an homogeneous fluid; and the whole force of gravity residing in its centre, and varying reciprocally as the square of the distance from this point. It will then be easy to prove that the terrestrial spheroid is an ellipsoid of revolution, for if we conceive two columns of fluids communicating with each other at the centre, (*Plate X. A. Iron. fig. 72.*) one terminating at the pole, the other at any point in the surface, these two columns ought to be in equilibrium. The centrifugal force alters nothing of the weight of the column directed to the pole, but diminishes the weight of the other column. This force is nothing at the centre of the earth, and at the surface is proportional to the radius of the terrestrial parallel or very nearly as the cosine of the latitude, but the whole of this force is not entirely employed in diminishing the force of gravity: for these two forces, making an angle with each other equal to the latitude, the centrifugal force decomposed according to the direction of gravity is weakened in the ratio of the cosine of this angle to radius. At the surface of the earth the centrifugal force diminishes the force of the gravity by the product of the centrifugal force at the equator by the square of the cosine of the latitude, thus, the mean value of this denomination in the length of a fluid column is the half of this product, and since the centrifugal force is $\frac{1}{375}$ of the force of gravity at the equator, this value is $\frac{1}{750}$ of the force of the gravity multiplied by the square of the cosine of the latitude. And since it is necessary, for the maintenance of the equilibrium, that the column by its length shall compensate the diminution of its weight, it should surpass the polar column by $\frac{1}{375}$ of its length multiplied by the above cosine. And the augmentation of the radii from the pole to the equator, being proportional to the squares of these cosines, we conclude that the earth would be an ellipsoid of revolution, the equatorial and polar axis of which were in the proportion of 578 to 577.

To determine the law of gravity at the surface of the earth in this case, we should observe that the force of gravity at any point on this surface is less than that at the pole, from its being situated farther from the centre, this diminution is nearly equal to the double of the augmentation of the terrestrial radius; it is equal, therefore, to the product of the $\frac{1}{375}$ th part of the force of gravity by the square of the cosine of the latitude. The centrifugal force diminishes likewise the force of gravity by the same quantity; thus, by the union of these two causes, the diminution of gravity from the pole to the equator is equal $\frac{1}{144\frac{1}{2}} = 0.00694$ multiplied by the square of the cosine of the latitude.

But it is found by experience, both from the measures of various degrees, and determination of the lengths of pendulums, that the ellipticity is greater than $\frac{1}{375}$, and the diminution of the force of gravity less than 0.00694, for we shall find the diminution of the force of gravity experimentally determined to be about 0.005.

We may therefore conclude, that the force of gravity is

not directed to a single point, but is composed of the joint attractions of all particles of the earth.

This being the case, the law of gravity depends on the figure of the terrestrial spheroid, which depends itself on the law of gravity. It is this mutual dependence of the two unknown quantities on each other, that renders the investigation of the figure of the earth very difficult. But, fortunately, the elliptic figure, the most simple next to the sphere, satisfies the condition of equilibrium of a fluid mass, subject to a motion of rotation, and of which all the particles attract each other reciprocally as the squares of the distance.

Newton, upon this hypothesis, and supposing the earth a homogeneous fluid, found the ratio of the equatorial to the polar axis to be 230 to 229.

To determine the law of the variation of the force of gravity upon this hypothesis, we may consider two different points situated on the same radius drawn from the centre to the surface of an homogeneous fluid in equilibrium. It has been before observed, that all the elliptic strata, situated without a point, contribute nothing to its gravity; the resulting force of all the attractions which act on it, is derived entirely from the attraction of the interior spheroid, similar to the entire spheroid, and whose surface passes through the point in question. The similar and similarly situated particles of these two spheroids attract the interior point, and the corresponding point of the exterior surface, proportionally to their masses divided by the squares of their distances. These masses are in the two spheroids as the cubes of their similar dimensions, and the squares of their distances are as the squares of these dimensions. The attractions, then, on similar particles, are proportional therefore to these dimensions. From which it follows, that the entire attraction of the two spheroids are in the same ratio, and the directions parallel. The centrifugal forces of the two points now under consideration are likewise proportional to the same dimensions. Therefore the force of gravity in each of them being the result of these two forces, will likewise be proportionate to their distances from the centre of the fluid mass.

Now, if we conceive two fluid columns directed, as before, to the centre of the spheroid, one from the pole, the other from any point on the surface, it is evident, that if the ellipticity of the spheroid is very small, that is, if it differs but little from a sphere, that the force of gravity decomposed according to the directions of these columns will be nearly the same as the total gravity.

Dividing, therefore, these columns into an equal number of parts infinitely small and proportional to their lengths, the weight of the corresponding parts will be to each other as the products of the lengths of the columns by the force of gravity at the points of their surface where they terminate. The whole weight of these columns will therefore be to each other in this ratio. And as these weights must be equal to be in equilibrium, the force of gravity at their surface must consequently be reciprocally as the length of these columns. Thus the length of the radius of the equator surpassing the radius at the pole a 23rdth part, the force of gravity at the pole should likewise exceed that at the equator a 23rdth part. This supposes the elliptic figure sufficient for the equilibrium of a fluid homogeneous mass. This Mac-laurin has demonstrated in a beautiful manner, from which it results, that the equilibrium is rigorously possible, and that if the ellipsoid differs little from a sphere, the ellipticity will be equal $\frac{1}{375}$ ths of the quantity which expresses the proportion of the centrifugal force to that of gravity under the equator. To the same motion of rotation, there may exist two corresponding figures of equilibrium. But the equilibrium cannot exist with every motion of rotation. The shortest

period of rotation of an homogeneous fluid in equilibrio of the same density as the earth is 0.10089 of a day, and this limit varies reciprocally as the square root of the density.

When the rotation becomes more rapid, the fluid mass becoming more flattened at the poles, its period of rotation becomes less, and ultimately falls within the appropriate limits of a state of equilibrium. After a great many oscillations, the fluid, in consequence of the friction and resistances which it experiences, fixes itself at last in that state which is *unique*, and determined by the primitive motion of rotation.

The preceding results afford us an easy method of verifying the hypothesis of the homogeneity of the earth. The irregularity of the measured degrees may be supposed to leave too much uncertainty, as to the ellipticity, to enable us to decide if it really is such as the above hypothesis requires. But the regular increase of the force of gravity from the equator to the pole, as determined by experiments on the pendulum, is sufficient to throw great light upon the subj. In taking, as unity, the force of gravity at the equator, its increase at the pole, according to the hypothesis of homogeneity, should be equal $\frac{1}{3} = 0.00435$. But by observation (as will hereafter be shown,) this increase is 0.005; the earth, therefore, is not homogeneous. And, indeed, it is natural to suppose, that the density of the strata increase as they approach the centre; it is even necessary for the stability of the equilibrium of the waters of the ocean, that their density should be less than the mean density of the earth; otherwise, when agitated by the winds and other causes, they would overflow their limits, and inundate the adjoining continents. The homogeneity of the earth being thus excluded, by observation, we must, to determine its figure, suppose the sea covering a nucleus composed of different strata, diminishing in density from the centre to the surface. Clairaut has demonstrated, that the equilibrium is still possible, in the supposition of an elliptic figure at the surface, and of the strata of the interior nucleus. In the most probable hypothesis, relative to the law of the densities and ellipticities of these strata, the ellipticity of the earth is less than in the case of homogeneity, and greater than if the force of gravity was directed to a single central point; but the increase of the force is greater than in the first case, and less than in the second. But there exists, between the increase of the force of gravity, taken as unity at the equator and the ellipticity of the earth, this remarkable analogy, that in all the hypotheses relative to the constitution of the internal nucleus which the sea incloses, the ellipticity of the earth is just so much less than that which would take place in the case of homogeneity, as the augmentation of the force of gravity exceeds that which should exist, according to the same supposition, and reciprocally; so that the relations expressing the ellipticity and the augmentation of the force of gravity, always, together, make a constant quantity equal $\frac{2}{3}$ of the fraction $\frac{1}{3}$, which expresses the ratio of the force of gravity to the centrifugal force at the equator. This, on the earth, is equal 0.0086500.

In supposing an elliptic figure to the strata of the terrestrial spheroid, the increase of its radii, the increase of the force of gravity, and the diminution of the degrees from the pole to the equator, will vary as the squares of the cosine of the latitude; and these are connected with the ellipticity of the earth in such a manner, that the total increase of the radii is equal to the ellipticity; and the total diminution of the degree is equal to the ellipticity, multiplied by three times the degree at the equator, (see DEGREE, where this has been demonstrated); and the total increase of the force of gravity is equal to the force of gravity at the equator,

multiplied by the excess of 0.0086500 above the ellipticity. Thus, the ellipticity of the earth may be determined, either by direct measurement of degrees, or by observations on the length of the pendulum.

The observations of the pendulum give 0.005 for the increase of the force of gravity, which, taken from $\frac{1}{3}$, gives $\frac{2}{3}$ for the ellipticity of the earth. If this hypothesis of the ellipse be conformable to nature, it should agree with the various measurements that have been made in different countries to ascertain the value of the meridional degrees. We have seen how discordant many of these measures are, when compared with the above hypothesis; nevertheless, since La Place was occupied with these investigations, the late measurements in England and Sweden appear to give the general result of the earth's figure nearer to a regular ellipse, than could be at that time inferred from the measure of Maupertuis.

To embrace, in the most general manner possible, the theory of the figure of the earth and planets, it is necessary to determine the attraction of spheroids differing little from spheres, and formed of strata variable both in figure and density, according to any law whatever. It will remain, then, to determine the figure which will agree with the equilibrium of a fluid expanded over its surface; for we must imagine the planets covered with a fluid similar to the earth, or their figure would be entirely arbitrary.

A remarkable equation of partial differences, relative to the attraction of spheroids, lead the author, without the aid of integrations, to general expressions for the radii of the spheroids; for the attractions upon any points whatever, either within, on the surface, or without it; for the condition of the equilibrium of the fluids that surround them; for the law of gravity, and for the variation of the degrees at the surface.

All these quantities are connected with each other by analogies extremely simple; from which results an easy method of verifying all the hypotheses that may be formed to represent either the variation of the force of gravity, or that of the values of different degrees of the meridian.

Thus Bouguer, with a view of reconciling the degrees measured at the equator in France and in Lapland, supposed the earth to be a spheroid of revolution, in which the increase of the degrees, from the equator to the pole, was proportional to the fourth power of the sine of the latitude. This hypothesis is shewn to be defective.

The above-mentioned expressions give a direct and general solution of the problem, which consists in determining the figure of a fluid mass in equilibrio, supposing it subjected to a movement of rotation, composed of an infinity of fluids of different densities, whose particles attract each other directly as their mass, and inversely as the squares of their distances. In this general supposition, the fluid necessarily takes the form of an ellipsoid of revolution, of which all the strata are elliptic, whose densities diminish, at the same time that their ellipticities increase from the centre to the surface.

The limits of ellipticity, of the whole ellipsoid, are $\frac{1}{3}$ and $\frac{1}{2}$ of the ratio of the centrifugal force, of the force of gravity at the equator.

The first limit is relative to the hypothesis of homogeneity, and the second to the supposition of the strata, infinitely near the centre being infinitely dense; and, consequently, the whole mass of the spheroid acting as if concentrated in that point. In the latter case, the force of gravity being directed to a single point, and varying inversely as the square of the distance, the figure of the earth would be
such

such as has been above determined; but, in the general hypothesis, the line which determines the direction of the force of gravity, from the centre to the surface of the spheroid, is a curve, every element of which is perpendicular to the stratum through which it passes.

It is remarkable, that the variations observed in the length of the pendulum, follow, pretty correctly, the law of the squares of the cosines of the latitudes; at the same time that the variations in the measured degrees differ very sensibly from this law. The general theory of the attractions of spheroids afford a simple explanation of this phenomenon; it shews us that the terms which, in the value of the terrestrial radius, differ from this law, become more sensible in the expression of the force of gravity, and still more sensible in the expression of degrees, where they may acquire a value sufficiently great to produce the phenomenon under consideration.

This theory likewise shews us, that the limits of the total increase of the force of gravity, taken at the equator as unity, are the products of 2 and $\frac{2}{3}$, the ratio of the centrifugal force, to the force of gravity under the equator; the first limit referring to the case of an infinite density at the centre; and the second to the case of homogeneity. The increase, as derived from observation, being between these limits, indicates that the strata are more dense, as they approach the centre, conformable to the laws of hydrostatics. Thus, the theory seems to accord with observation, as far as could be expected, considering our ignorance of the internal constitution of the earth.

To determine the Figure of the Earth from the following Observations of the Length of the Pendulum.

Place of Observation.	Lat. in decimal Deg.	Length of the Pend. vibrating Centes. Seconds of Mean Time.	Corrected Length.	Error *.
1. Peru	0.00	0.99669	0.99676	+ 0.00007

* The sum of the positive errors will nearly be equal to the sum of the negative, according to the required condition of the problem.

Mr. La Place's method of finding the most probable ellipsis, corresponding to a set of observations similar to the above, or that which shall satisfy the following conditions; namely, that the sum of all the errors shall = 0, and the sum of all the errors taken positively, a minimum.

Let $a^{(1)}, a^{(2)}, a^{(3)}$, be the observed lengths of the pendulum; $l^{(1)}, l^{(2)}, l^{(3)}$, the squares of the sines of the corresponding latitudes.

Suppose these lengths to be expressed by this formula, $z + ky$. And let $x^{(1)}, x^{(2)}, x^{(3)}$ be the errors of observation. Then we shall have the following equations:

$$\left. \begin{aligned} a^{(1)} - z - l^{(1)}y &= x^{(1)} \\ a^{(2)} - z - l^{(2)}y &= x^{(2)} \\ a^{(3)} - z - l^{(3)}y &= x^{(3)} \end{aligned} \right\} A.$$

Add these equations, and divide their sum by n , making the quotient equal to zero; the condition being, that the sum of the errors = 0; then,

$$A - z - ky = 0. B.$$

Subtract this equation from each of the equations A, separately, and new equations will be obtained of the following form:

$$\left. \begin{aligned} l^{(1)} - g^{(1)}y &= x^{(1)} \\ l^{(2)} - g^{(2)}y &= x^{(2)} \\ l^{(3)} - g^{(3)}y &= x^{(3)} \end{aligned} \right\} O.$$

&c. &c.

Compute the quotients $\frac{l^{(1)}}{g^{(1)}}, \frac{l^{(2)}}{g^{(2)}}, \frac{l^{(3)}}{g^{(3)}}$, &c. and arrange them according to their magnitudes, neglecting their signs. Let the quotients thus arranged be denoted thus:

$$h^{(1)}, h^{(2)}, h^{(3)}. P.$$

And observe the order of the first terms of equations O, which correspond to them.

Then to find that value of y , which shall render the sum of all the errors taken positively a minimum; add the quantities $h^{(1)}, h^{(2)}, h^{(3)}$, till their sum begins to surpass half the sum of all these quantities added together; and calling this sum F, a quantity r may be so determined, that

$$\left. \begin{aligned} h^{(1)} + h^{(2)} + h^{(3)} &= + h^{(r)} + 2F \\ h^{(3)} + h^{(2)} + h^{(1)} &= + h^{(r-1)} + \frac{1}{2}F \end{aligned} \right\} Q.$$

Then $y = h^{(r)}$, because, according to the present method, that error is to be supposed zero, which corresponds to that length in the equations O, which gives this value of y . The value of Z may then be obtained by the following equation:

$$Z = A - Ky.$$

Application of this Method to the above Observations.

The observed lengths of the pendulum, with the squares of the sines of the latitude of the places of observation, give the following equations:

$$\left. \begin{aligned} \text{Obs. Length.} & \quad \text{Sin.}^2 \text{ L.} \\ 0.99669 - z - y \cdot 0.00000 &= x^{(1)} \\ .99689 - z - y \cdot 0.02752 &= x^{(2)} \\ .99710 - z - y \cdot 0.04270 &= x^{(3)} \\ .99745 - z - y \cdot 0.09549 &= x^{(4)} \\ .99728 - z - y \cdot 0.10016 &= x^{(5)} \\ .99877 - z - y \cdot 0.31142 &= x^{(6)} \\ .99950 - z - y \cdot 0.47551 &= x^{(7)} \\ .99987 - z - y \cdot 0.55556 &= x^{(8)} \\ 1.00000 - z - y \cdot 0.56672 &= x^{(9)} \\ 1.00006 - z - y \cdot 0.57624 &= x^{(10)} \\ 1.00018 - z - y \cdot 0.61244 &= x^{(11)} \\ 1.00074 - z - y \cdot 0.72307 &= x^{(12)} \\ 1.00101 - z - y \cdot 0.74909 &= x^{(13)} \\ 1.00137 - z - y \cdot 0.84478 &= x^{(14)} \\ 1.00148 - z - y \cdot 0.84829 &= x^{(15)} \end{aligned} \right\} A.$$

These added together, and divided by 15, give
 $0.99293 - z - y 0.43529 = 0$. B.

This equation, taken successively from every one of the equations A, gives O as follows:

$$\left. \begin{aligned} -0.00254 + y 0.43529 &= x^{(1)} \\ -0.00234 + y 0.40777 &= x^{(2)} \\ -0.00213 + y 0.39259 &= x^{(3)} \\ -0.00178 + y 0.33980 &= x^{(4)} \\ -0.00195 + y 0.33513 &= x^{(5)} \\ -0.00046 + y 0.12387 &= x^{(6)} \\ 0.00027 - y 0.04022 &= x^{(7)} \\ 0.00064 - y 0.12067 &= x^{(8)} \\ 0.00077 - y 0.13143 &= x^{(9)} \\ 0.00083 - y 0.14095 &= x^{(10)} \\ 0.00095 - y 0.17715 &= x^{(11)} \\ 0.00151 - y 0.28778 &= x^{(12)} \\ 0.00178 - y 0.31380 &= x^{(13)} \\ 0.00214 - y 0.40949 &= x^{(14)} \\ 0.00225 - y 0.41300 &= x^{(15)} \end{aligned} \right\} O.$$

The quotients $\frac{b^{(1)}}{q^{(1)}}$, $\frac{b^{(2)}}{q^{(2)}}$, arranged as above directed, will stand thus:

- 0.0067131
- 0.0058886
- 0.0058536
- 0.0058352
- 0.0058186
- 0.0057385
- 0.0056724
- 0.0054479
- 0.0054255
- 0.0053627
- 0.0053037
- 0.0052471
- 0.0052384
- 0.0052260
- 0.0037136

The first term of which, $b^{(1)}$, corresponds to $\frac{b^{(1)}}{q^{(1)}}$; the second term, $b^{(2)}$, corresponds to $\frac{b^{(2)}}{q^{(2)}}$. The whole corresponds in the following order:

$$7, 10, 9, 1, 5, 2, 13, 15, 3, 11, 8, 12, 4, 14, 6.$$

The sum of the first six is less than half the sum of all the terms: therefore r , in equation Q, is equal to 7.

Now the 7th term corresponds to the 13th, in the equations O.

The value of y is therefore to be found from this equation, where $x^{(13)} = 0$.

$$\text{Therefore } y = \frac{0.00178}{0.31380} = 0.0056724.$$

And from equation B; $z = 0.99676$ = the length of the pendulum at the equator.

But this value of y is the fraction sought, which, according to the theory of Clairaut, should, with another fraction expressing the ellipticity, make together the constant quantity 0.0086500.

$$\text{Therefore, the ellipticity} = 0.00865 - 0.0056724 = 0.0029776 = \frac{1}{335.7}$$

Such is the determination of La Place; in which it appears to us that a mistake has been committed in employing

y as found by the above equations, instead of its value, found by making the pendulum at the equator equal unity.

The rule of La Place, in his own words, is as follows: Let z be the excess of the length of the pendulum at the pole above that at the equator, divided by the length of the latter; then,

$$\alpha z = \alpha \left(\frac{1}{2} \phi - b \right),$$

$$\text{And } \alpha z + ab = \frac{5}{2} \alpha \phi = .00865.$$

To apply this rule:

$$z = 0.9967600 = \text{pendulum at the equator.}$$

$$\alpha + y \times \sin^2 90^\circ = 1.0024324 = \text{pendulum at the pole.}$$

Excess = .0056724, which, divided by .9967600, gives $\alpha z = 0.0056908$.

$$\text{And the ellipticity } ab = 0.00865 - \alpha z = 0.0089592 = \frac{1}{307.93}$$

Table of the Length of the Pendulum to every 10° of Latitudes, calculated by the above Formula.

0°	1.0000000
10°	1.0001716
20°	1.0006637
30°	1.0014227
40°	1.0023513
50°	1.0033395
60°	1.0044681
70°	1.0057251
80°	1.0071192
90°	1.0086608

In the following calculation, we have introduced the value of the degree measured in England by colonel Mudge, and substituted the northern degree of Swanberg, instead of that of Maupertuis, which was taken by La Place. The reader will see that the result is much more satisfactory.

To determine the most probable Ellipse from actual Measurement of Degrees.

	Latitude.	Toises.	Arc Meas.	Error.
1. Peru	0° 0'	56753	3	+0.5

$$\left. \begin{aligned} 1. 170259 - 3z - y 0.00000^{(1)} \\ 2. 56763 - z - y 0.04709^{(2)} \\ 3. 57037 - z - y 0.30156^{(3)} \\ 4. 56888 - z - y 0.39946^{(4)} \\ 5. 56979 - z - y 0.46541^{(5)} \\ 6. 570185 - 10z - y 5.20930^{(6)} \\ 7. 85611 - 1.5z - y 0.82275^{(7)} \\ 8. 171204 - 3z - y 1.86486^{(8)} \\ 9. 85794 - 1.4z - y 1.25835^{(9)} \end{aligned} \right\} A.$$

1310720 - 23z - y 10.36878, which, divided by 23, gives equation A - z - Py = 0.
 56988 - z - y 0.45081 = 0.

This equation, taken from equations A, gives the equations O, thus:

$$\begin{array}{l} 1. - 235 + y \cdot 0.45081 = x^{(1)} \quad 521 \\ 2. - 225 + y \cdot 0.40372 = x^{(2)} \quad 557 \\ 3. + 49 + y \cdot 0.14925 = x^{(3)} \quad 328 \\ 4. - 100 + y \cdot 0.05135 = x^{(4)} \quad 194 \\ 5. + 9 - y \cdot 0.01460 = x^{(5)} \quad 616 \\ 6. + 30 - y \cdot 0.07012 = x^{(6)} \quad 415 \\ 7. + 86 - y \cdot 0.09769 = x^{(7)} \quad 880 \\ 8. + 80 - y \cdot 0.17081 = x^{(8)} \quad 468 \\ 9. - 208 - y \cdot 0.38809 = x^{(9)} \quad 536 \end{array} \quad O.$$

$$\begin{array}{l} 880 \left[\begin{array}{l} 7 \\ 5 \end{array} \right] y \cdot 0.14653 \\ 616 \left[\begin{array}{l} 5 \\ 2 \end{array} \right] y \cdot 0.01460 \\ 557 \left[\begin{array}{l} 2 \\ 9 \end{array} \right] y \cdot 0.40372 \\ 536 \left[\begin{array}{l} 9 \\ 1 \end{array} \right] y \cdot 0.58213 \\ 521 \left[\begin{array}{l} 1 \\ 8 \end{array} \right] y \cdot 1.35243 \\ 468 \left[\begin{array}{l} 8 \\ 6 \end{array} \right] y \cdot 0.51243 \\ 435 \left[\begin{array}{l} 6 \\ 3 \end{array} \right] y \cdot 0.70120 \\ 328 \left[\begin{array}{l} 3 \\ 4 \end{array} \right] y \cdot 0.14925 \\ 194 \left[\begin{array}{l} 4 \\ 1 \end{array} \right] y \cdot 0.05135 \end{array}$$

The fifth term of the above co-efficients is the first that begins to surpass the half sum of the whole, and it corresponds to N° 1, from which term in equations O, y is to be deduced.

Since $- 235 + y \cdot 0.45081 = 0$,
 $y = 521$.

Substituting this value in equation
 $56988 - z - y \cdot 0.45081$
 $z = 56753$.

And the ellipticity, which is equal to $\frac{521}{3 \times 56753} = \frac{y}{327}$.

The ellipticity obtained by La Place, in his "Mecanique Celeste," is $\frac{1}{312}$.

Calculation repeated with only the five measures that seem most deserving of confidence.

	o	f	n	Toises.	
1. Peru	0	0	0	56753	2
2. India	12	32	0	56763	1
3. France	46	12	0	57018.5	10
4. England	52	2	20	57068	3
5. Sweden	66	20	10	57196	1.5

$$\begin{array}{l} 56753 - z - y \cdot 0.00000 = x^{(1)} \\ 56763 - z - y \cdot 0.04709 = x^{(2)} \\ 57018.5 - z - y \cdot 0.52093 = x^{(3)} \\ 57068 - z - y \cdot 0.62162 = x^{(4)} \\ 57196 - z - y \cdot 0.83890 = x^{(5)} \end{array} \quad A.$$

$$\begin{array}{l} 113506 - 2z - y \cdot 0.00000 \\ 56763 - z - y \cdot 0.4709 \\ 570185 - 10z - y \cdot 5.20930 \\ 171204 - 3z - y \cdot 1.86486 \\ 85794 - 1.5z - y \cdot 1.25835 \end{array}$$

These equations, added together, and divided by the sum of the multipliers, give

$$56997 - z - y \cdot 0.47883$$

This, subtracted from each of the equations A, gives the equations O,

$$\begin{array}{l} 244 - y \cdot 0.47883 = x^{(1)} \\ 234 - y \cdot 0.43174 = x^{(2)} \\ - 21.5 + y \cdot 0.04210 = x^{(3)} \\ - 71 + y \cdot 0.14279 = x^{(4)} \\ - 199 + y \cdot 0.26007 = x^{(5)} \end{array} \quad O.$$

$$\begin{array}{l} 552 \left[\begin{array}{l} 5 \\ 2 \end{array} \right] y \cdot 54010 \\ 542 \left[\begin{array}{l} 2 \\ 3 \end{array} \right] y \cdot 43174 \\ 510.7 \left[\begin{array}{l} 3 \\ 1 \end{array} \right] y \cdot 42100 \\ 510 \left[\begin{array}{l} 1 \\ 4 \end{array} \right] y \cdot 95766 \\ 497 \left[\begin{array}{l} 4 \\ 1 \end{array} \right] y \cdot 42837 \end{array}$$

The third term is the first that surpasses the half sum of the five terms, which answers to N° 3, therefore the value of y is to be deduced from its corresponding equation, and is equal to 510.7, which number expresses the excess in toises of the polar above the equatorial degree; z, the equatorial degree, is deduced from equation $56997 - z - y \cdot 47883$, by substituting the value of $y = 510.7$. Hence $z = 56759.5$.

The ellipticity, which is equal $\frac{510.7}{3 \times 56752.5}$, (see DEGREE,) is thus found equal $\frac{1}{333.4}$.

	Observations.	Observations corrected.	Error.
Peru	56753	56752.5	+ 0.5
India	56763	56776	- 13
France	57018.5	57018.5	0
England	57068	57070	- 2
Sweden	57196	57181.8	+ 14.2

If we take the ellipticity a mean between this last determination, and that given by the pendulum, it will be $\frac{1}{312}$, and nearer than this, it will probably never be known.

Investigation of Clairaut's theorem, on which the above calculations are founded.

Let us suppose a sphere of solid matter, equally dense at equal distances from the centre, and covered with a less dense fluid, and let us suppose that the whole has a form suitable to the velocity of its rotation. It is in this form that we are to find out. With this view, let us suppose, that all the matter by which the solid globe or nucleus is denser than the fluid is collected in the centre. We have seen that this will make no change in the gravitation of any particle of the recumbent fluid.

Thus we have a solid globe covered with a fluid of the same density, and besides the mutual gravitation of the particles of the fluid, we have a force of the same nature, acting on every one of them directed to the central redundant matter.

Now let the globe liquefy or dissolve. This can induce no change of force on any particle of the fluid. Let us then determine the form of the new fluid spheroid, which will maintain itself in rotation. This being determined, let the globe again become solid. The remaining fluid will not change its form, because no change is induced on the force acting on any particle of the fluid. Call this hypothesis A.

In order to determine the state of equilibrium, or the form which insures it, which is the chief difficulty, let us form another hypothesis B, differing from A only in this circumstance, that the matter collected in the centre, instead of attracting the particles of the incumbent fluid, with a force decreasing in the inverse duplicate ratio of their distances, attracts

attracts them with a force increasing in the direct ratio of their distances, keeping the same intensity at the distance of the pole as in hypothesis A. This fictitious hypothesis, similar to Hermann's, is chosen, because a mass for constituted will maintain the form of an accurate elliptical spheroid, by a proper adjustment of the proportion of its axis to the velocity of its rotation. This will easily appear, for we have seen that the mutual gravitation of the particles of the elliptical fluid spheroid produces in each particle a force which may be resolved into two forces, one of them perpendicular to the axis, and proportionate to the distance from it, and the other perpendicular to the equator, and proportional to the distance from its plane. There is now, by hypothesis B, superadded on each particle a force proportional to its distance from the centre, and directed to the centre. This may also be resolved into a force perpendicular to the axis, and another perpendicular to the equator, and proportional to their distances from them. Therefore, the whole combined forces acting on each particle, may be thus resolved into two forces in those directions and those proportions. Therefore, a mass for constituted, will maintain its elliptical form, provided the velocity of its rotation be such that the whole force at the pole and the equator are inversely as the axis of the generating ellipse.

We are to ascertain this form, or this required magnitude, of the centrifugal force. Having done this, we shall restore to the accumulated central matter its natural gravitation, or its action on the fluid in the inverse duplicate ratio of the distances, and then see what change must be made on the form of the spheroid in order to restore the equilibrium.

Let *BAba* (fig. 73.) be the fictitious elliptical spheroid of hypothesis B. Let *BEbe* be the inscribed sphere. Take *EG* perpendicular to *CE*, to represent the force of gravitation of a particle in *E* to the central matter corresponding to the distance *CE* or *CB*. Draw *CG*: draw also *AI* perpendicular to *CA*, meeting *CG* in *I*. Describe the curve *GLR*, whose ordinates *GE*, *LA*, *RM*, &c.

are proportional to $\frac{1}{CE^2}$, $\frac{1}{CA^2}$, $\frac{1}{CM^2}$, &c. These ordinates will express the gravitations of the particles *E*, *A*, *M*, &c. to the central matter by hypothesis A.

In hypothesis A the gravitation of *A* is represented by *AL*; but in hypothesis B it is represented by *AI*. For in hypothesis B, the gravitations to this matter are as the distances. *EG* is the gravitation of *E* in both hypotheses. Now $EG : AL = CA^2 : CE^2$; but $EC : AI = CE : CA$. In hypothesis A the weight of the column *AE* is represented by the space *ALGE*, but by *AIGE* in hypothesis B. If, therefore, the spheroid of hypothesis B was in equilibrio, while turning round its axis, the equilibrium is destroyed by merely changing the force acting on the column *EA*.

There is a loss of pressure or weight sustained by the column *EA*. This may be expressed by the space *LGI*, the difference between the two areas *EGIA* and *EGLA*. But the equilibrium may be restored, by adding a column of fluid *AM*, whose weight *ALRM* shall be equal to *LGI*, which is very nearly equal $\frac{L I \times A E}{2}$.

In order to find the height of this column, produce *GE* on the other side of *E*, and make *EF* to *EG* as the density of the fluid to the density by which the nucleus exceeded it. *EF* will be to *EG* as the gravitation of a particle in *E* to the globe (now of the same density with the fluid) is to its gravitation to the redundant matter collected in the centre. Now, take *DE* to represent the gravitation of *E* to the fluid contained in the concentric spheroid *Eβeβ*, which is func-

tion less than its gravitation to the sphere *Eβeβ*. Draw *CDN*. Then *AN* represents the gravitation of *A* to the whole fluid spheroid. In like manner, *NI* is the united gravitation of *A* to both the fluid and the central matter, in the same hypothesis. But in hypothesis A, this gravitation is represented by *NL*.

Let *NO* represent the centrifugal force affecting the particle *A*, taken in due proportion to *NA* or *NL*, its whole gravitation in hypothesis A. Draw *CKO*. *DK* will be the centrifugal force at *E*. The space *OKGI* will express the whole sensible weight of the fluid in *AE*, according to hypothesis B, and *OKGL* will express the same, according to hypothesis A. *LGI* is the difference, to be compensated by means of a due addition *AM*.

This addition may be defined by the quadrature of the spaces *GEAL* and *GLI*. But it will be abundantly exact to suppose that *GLR* sensibly coincides with a straight line, and then to proceed in this manner. We have, by the nature of the curve *GLR*,

$$\begin{aligned} \text{Also } HA, \text{ or } EG : AI &= EC^2 : AC^2 \\ \text{Therefore } AL : AI &= EC^2 : AC^2. \end{aligned}$$

Now, when a line changes by a very small quantity, the variation of a line proportional to its cube is thrice as great as that of the line proportional to the root. *HI* is the quantity proportional to *EA* the increment of the root *EC*. *IL* is proportional to the variation of the cube, and is therefore very nearly equal to thrice *HI*.

$$\begin{aligned} \text{Therefore since } EG : HI &= EC : AE, \text{ we may} \\ \text{state } EG : LI &= EC : 3AE, \\ \text{or } 3EG : LI &= EC : AE. \end{aligned}$$

Now, *QOLR* may be considered as equal to *QR* × *AM*, or as equal to *KG* × *AM*, and *LGI* may be considered as equal to $L I \times \frac{1}{2} AE$, and $2 KG \times AM = L I \times AE$.

$$\begin{aligned} \text{Therefore } 2KG : AE &= LI : AM \\ \text{but } EC : AE &= 3EG : LI \\ \text{therefore } 2KG \times EC : AE^2 &= 3EG : AM \\ \text{and } 2KG : \frac{AE^2}{EC} &= 3EG : AM \\ \text{and } 2KG : 3EG &= \frac{AE^2}{EC} : AM \end{aligned}$$

That is, twice the sensible gravity at the equator is to thrice the gravitation to the central matter as a third proportional to radius and the elevation of the equator is to the addition necessary for producing the equilibrium required in hypothesis A.

This addition may be more readily conceived by means of a construction. Make *AE : Ec = 2KG : 3EG*. Draw *ea* parallel to *EA*, and draw *Cem*, cutting *AN* in *m*. Then *am* is the addition that must be made to the column *AC*. A similar addition must be made to every diameter *CT*, making $2KG : 3EG = \frac{TV^2}{CV} : Tt$, and the whole will be in equilibrio.

This determination of the ellipticity will equally suit those cases where the fluid is supposed denser than the solid nucleus, or where there is a central hollow. For *EG* may be taken negatively, as if a quantity of matter were placed in the centre acting with a repelling or centrifugal force on the fluid. This is represented on the other side of the axis *Bb*. The space *giI* in this case is negative, and indicates a diminution of the column *ac*, in order to restore the equilibrium.

It is evident that the figure resulting from this construction is not an accurate ellipse. For, in the ellipse, TV would be in a constant ratio to VT , whereas it is as VT^2 by our construction. But it is also evident that in the cases of small deviation from perfect sphericity, the change of figure from the accurate ellipse of hypothesis B is very small. The greatest deviation happens when Ee is a maximum. It can never be sensibly greater in proportion to AE than $\frac{2}{3}$ of AE is in proportion to EC , unless the centrifugal force FD be very great in comparison of the gravity DE . In the case of the earth, where EA is nearly $\frac{1}{20}$ of EC , if we suppose the mean density of the earth to be five times that of sea water, am will not exceed $\frac{1}{113444}$ of EC , or $\frac{1}{11344}$ of EA .

We are not to imagine that, since central matter requires an addition AM to the spheroid, a greater density in the interior parts of this globe requires a greater equatorial protuberancy than if all were homogeneous; for it is just the contrary. The spheroid to which the addition must be made is not the figure suited to a homogeneous mass, but a fictitious figure employed as a step to facilitate investigation. We must therefore define its ellipticity, that we may know the shape resulting from the final adjustment.

Let f be the density of the fluid, and n the density of the nucleus, and let $n - f$ be q , so that q corresponds with $E G$ of our construction, and expresses the redundant central matter (or the central deficiency of matter, when the fluid is denser than the nucleus). Let BC or EC be r , AE be x , and let g be the mean gravity (primitive), and e the centrifugal force at A . Lastly, let π be the circumference when the radius of the circle is 1.

The gravitation of B to the fluid spheroid is $\frac{2}{3} \pi f r$, and its gravitation to the central matter is $\frac{2}{3} \pi q r$. The sum of these, or the whole gravitation of B , is $\frac{2}{3} \pi r r$. This may be taken for the mean gravitation on every point of the spheroidal surface.

But the whole gravitation of B differs considerably from that of A .

CA , or CE , is to $\frac{1}{2} AE$ as the primitive gravity of B to the spheroid is to its excess above the gravitation (primitive) of A to the same. That is, $r : \frac{1}{2} x :: \frac{2}{3} \pi f r : \frac{2}{3} \pi f x$, and $\frac{2}{3} \pi f x$ expresses this excess.

In hypothesis B; we have CE to CA as the gravitation of B or E to the central matter is to the gravitation of A to the same. Therefore CE is to EA as the gravitation of E to this matter is to the excess of A 's gravitation to the same. This excess of A 's gravitation is expressed by $\frac{2}{3} \pi q x$, for $r : x :: \frac{2}{3} \pi q r : \frac{2}{3} \pi q x$.

Without any sensible error, we may state the ratio of g to e as the ratio of the whole gravitation of A to the centrifugal tendency excited in A by the rotation. Therefore $g : e :: \frac{2}{3} \pi n r : \frac{2 \pi n r c}{3g}$, and this centrifugal tendency of

the particle A is $\frac{2 \pi n r c}{3g}$. This is what is expressed by NO in our construction.

The whole difference between the gravitations of B and A is therefore $\frac{2}{3} \pi f x - \frac{2}{3} \pi q x + \frac{2 \pi n r c}{3g}$. The gravitation of B is to this difference as $\frac{2}{3} \pi n r$ to $\frac{2}{3} \pi f x - \frac{2}{3} \pi q x + \frac{2 \pi n r c}{3g}$ or (dividing all by $\frac{2}{3} \pi n$) as r to $\frac{f x}{5n} - \frac{q x}{n} + \frac{c r}{g}$.

Now the equilibrium of rotation requires that the whole polar force be to the sensible gravitation at the equator as the radius of the equator to the semiaxis. Therefore we must make the radius of the equator to its excess above the semiaxis as the polar gravitation to its excess above the

sensible equatorial gravitation. That is, $r : x :: r : \frac{f x}{5n} -$

$\frac{q x}{n} + \frac{c r}{g}$, and therefore $x = \frac{f x}{5n} - \frac{q x}{n} + \frac{c r}{g}$. Hence we

have $\frac{c r}{g} = x \times \frac{q x}{n} - \frac{f x}{5n}$. But $q = n - f$. Therefore

$$\frac{c r}{g} = x + \frac{n x}{n} - \frac{f x}{5n} - \frac{f x}{5n} = x + x - \frac{6 f x}{5n} = 2 x - \frac{6 f x}{5n} = x \times \left(2 - \frac{6 f}{5n} \right)$$

$$\text{Wherefore } x = \frac{c r}{g \times \left(2 - \frac{6 f}{5n} \right)} = \frac{5 n c r}{g \times 10 n - 6 f}$$

is more conveniently expressed in this form $x = \frac{5 c r}{2 g} \times$

$\frac{n}{5 n - 3 f}$. The species, or ellipticity of the spheroid, is

$$\frac{x}{r} = \frac{5 c}{2 g} \times \frac{n}{5 n - 3 f}$$

Such then is the elliptical spheroid of hypothesis B; and we saw that, in respect of form, it is scarcely distinguishable from the figure which the mass will have when the fictitious force of the central matter gives place to the natural force of the dense spherical nucleus. This is true at least in all the cases where the centrifugal force is very small in comparison with the mean gravitation.

We must therefore take some notice of the influence which the variations of density may have on the form of this spheroid. We may learn this by attending to the formula

$$\frac{x}{r} = \frac{5 c}{2 g} \times \frac{n}{5 n - 3 f}$$

The value of this formula depends chiefly on the fraction

$$\frac{n}{5 n - 3 f}$$

If the density of the interior parts be immensely greater than that of the surrounding fluid, the value of this fraction becomes nearly $\frac{1}{3}$, and $\frac{x}{r}$ becomes nearly $\frac{c}{2g}$, and the ellipse nearly the same with what Hermann assigned to a homogeneous fluid spheroid.

If $n = 5 f$; then $\frac{n}{5 n - 3 f} = \frac{5}{22}$; and in the case of the earth, $\frac{x}{r}$ would be nearly $\frac{1}{508.6}$, making an equatorial elevation of nearly seven miles.

If $n = f$, the fraction $\frac{n}{5 n - 3 f}$ becomes $\frac{1}{2}$, and $\frac{x}{r} =$

$\frac{5 c}{4 g}$, which we have already shewn to be suitable to a homogeneous spheroid, with which this is equivalent. The protuberance or ellipticity in this case is to that when the nucleus is incomparably denser than the fluid in the proportion of 5 to 2. This is the greatest ellipticity that can obtain when the fluid is not denser than the nucleus.

Between these two extremes, all other values of the formula

formula are competent to homogeneous spheroids of gravitating fluids, covering a spherical nucleus of greater density, either uniformly dense or consisting of concentric spherical strata, each of which is uniformly dense.

From this view of the extreme cases, we may infer in general, that as the incumbent fluid becomes rarer in proportion to the nucleus, the ellipticity diminishes. M. Bernouilli (Daniel), misled by a gratuitous assumption, says in his theory of the tides, that the ellipticity produced in the aerial fluid which surrounds this globe will be 800 times greater than that of the solid nucleus; but this is a mistake, which a juster assumption of *data* would have prevented. The aerial spheroid will be sensibly less oblate than the nucleus.

It was said that the value of the formula depended chiefly on the fraction $\frac{n}{5n-3f}$. But it depends also on the frac-

tion $\frac{5c}{2g}$, increasing or diminishing as c increases or diminishes, or as g diminishes or increases. It must also be remarked that the theorem $\frac{x}{r} = \frac{5c}{4g}$ for a homogeneous spheroid was deduced from the supposition that the eccentricity is very small. When the rotation is very rapid, there is another form of an elliptical spheroid, which is in that kind of *equilibrium*, which, if it be disturbed, will not be recovered, but the eccentricity will increase with great rapidity, till the whole dissipates in a round flat sheet. But within this limit, there is a kind of stability in the *equilibrium*, by which it is recovered when it is disturbed. If the rotation be too rapid, the spheroid becomes more oblate, and the fluids which accumulate about the equator, having less velocity than that circle, retard the motion. This goes on however some time, till the true shape is overpassed, and then the accumulation relaxes. The motion is now too slow for this accumulation, and the waters flow back again towards the poles. Thus an oscillation is produced by the disturbance, and this is gradually diminished by the mutual adhesion of the waters, and by friction, and things soon terminate in the resumption of the proper form.

When the density of the nucleus is less than that of the fluid, the varieties which result in the form from a variation in the density of the fluid are much greater, and more remarkable. Some of them are even paradoxical. Cases, for example, may be put, (when the ratio of n to f differs but very little from that of 3 to 5,) where a very small centrifugal force, or very slow rotation, shall produce a very great protuberance, and, on the contrary, a very rapid rotation may consist with an oblong form like an egg. But these are very singular cases, and of little use in the explanation of the phenomena actually exhibited in the solar system. The *equilibrium* which obtains in such cases may be called a *tottering equilibrium*, which, when once disturbed, will not be again recovered, but the dissipation of the fluid will immediately follow with accelerated speed. Some cases may be imagined, where there is a deficiency of matter in the centre, or even a hollow.

The chief distinction between the cases of a nucleus covered with an equally dense fluid, and a dense nucleus covered with a rarer fluid, consists in the difference between the polar and equatorial gravities; for we see that the difference in shape is inconsiderable. It has been shewn already that, in the homogeneous spheroid of small eccentricity, the excess of the polar gravity above the sensible equatorial gravity is nearly equal to $\frac{g x}{5r}$ (for $r : \frac{3}{2} x = g :$

$\frac{g x}{5r}$). When, in addition to this, we take into account

the diminution c , produced by rotation, we have $\frac{g x}{5r} + c$ for the whole difference between the polar and the sensible equatorial gravity. But, in a homogeneous spheroid, we have

$$x = \frac{5cr}{4g}. \text{ Therefore the excess of polar gravity in a ho-}$$

monogeneous revolving spheroid is $\frac{c}{4} + c$ or $\frac{5c}{4}$. We may distinguish this excess in the homogeneous spheroid by the symbol E.

But, in hypothesis B, the equilibrium of rotation requires that r be to x as g to $\frac{g x}{r}$, and the excess of polar gravity

in this hypothesis is $\frac{g x}{r}$. But we have also seen that in this

hypothesis $\frac{x}{r} = \frac{5c}{2g} \times \frac{n}{5n-3f}$. Therefore the excess

of polar gravity in this hypothesis is $\frac{5c}{2} \times \frac{n}{5n-3f}$. Let

this excess be distinguished by the symbol e.

The excess of polar gravity must be greater than this in hypothesis A. For, in that hypothesis the equatorial gravity to the fluid part of the spheroid is already smaller. And this smaller gravity is not so much increased by the natural gravitation to the central matter, in the inverse duplicate ratio of the distance, as it was increased by the fictitious gravity to the same matter, in the direct ratio of the distances. The second of the three distinctions, between the

gravitations of B and A, was $-\frac{g x}{n}$. This must now be

changed into $+\frac{2g x}{n}$, where $-\frac{g x}{n}$ is represented by HI

in fig. 72; and the excess, forming the compensation for hypothesis A, is represented by HL, nearly double of HI, and in the opposite direction, diminishing the gravitation of

A. The difference of these two states is $\frac{3g x}{n}$, by which

the tendency of A to the central matter in hypothesis A falls short of what it was in hypothesis B. Therefore, as

$\frac{f x}{5n} - \frac{g x}{n} + \frac{c r}{g}$ is to $\frac{3g x}{n}$, so is the excess ϵ to a quan-

tity ϵ' , which must be added to ϵ , in order to produce the difference of gravities ϵ , conformable to the statement of hypo-

thesis A. Now, in hypothesis B, we had $x = \frac{f x}{5n} - \frac{g x}{n} +$

$\frac{c r}{g}$, and we may, without scruple, suppose x the same in

hypothesis A. Therefore $\epsilon : \epsilon' = x : \frac{3g x}{n} = 1 : \frac{3g}{n}$, and

$\epsilon' = \epsilon \times \frac{3g}{n} = \epsilon \times \frac{3n-3f}{n} = \frac{5c}{2} \times \frac{n}{5n-3f} \times$

$\frac{3n-3f}{n} = \frac{5c}{2} \times \frac{3n-3f}{5n-3f}$. Add to this ϵ , which is

$\frac{5c}{2} \times \frac{n}{5n-3f}$, and we obtain for the excess e of

polar gravity in hypothesis A = $\frac{5c}{2} \times \frac{4n-3f}{5n-3f}$.

Let us now compare this excess of polar gravity above the

the sensible equatorial gravity in the three hypotheses: 1st, A, suited to the fluid surrounding a spherical nucleus of greater density: 2d, B, suited to the same fluid, surrounding a central nucleus which attracts with a force proportional to the distance: and 3d, C, suited to a homogeneous fluid spheroid, or enclosing a spherical nucleus of equal density. These excesses are

$$A \quad \frac{5c}{2} \times \frac{4n-3f}{5n-3f},$$

$$B \quad \frac{5c}{2} \times \frac{n}{5n-3f},$$

$$C \quad \frac{5c}{4}, \text{ or } \frac{5c}{4} \times \frac{5n-3f}{5n-3f}.$$

It is evident that the sum of A and B is $\frac{5c}{2} \times \frac{5n-3f}{5n-3f}$,

which is double of C, or $\frac{5c}{4} \times \frac{5n-3f}{5n-3f}$, and therefore C is the arithmetical mean between them.

Now we have seen that $\frac{5c}{2g} \times \frac{4n-3f}{5n-3f}$ expresses the

ratio of the excess of polar gravity to the mean gravity in the hypothesis A. We have also seen that $\frac{5c}{2g} \times$

$\frac{n}{5n-3f}$ may safely be taken as the value of the ellipticity in the same hypothesis. It is not perfectly exact,

but the deviation is altogether insensible in a case like that of the earth, where the rotation and the eccentricity are so moderate. And lastly, we have seen that the same fraction that expresses the ratio of the excess of polar gravity to mean gravity, in a homogeneous spheroid, also expresses its ellipticity, and that twice this fraction is equal to the sum of the other two.

Hence may be derived a beautiful theorem, first given by M. Clairaut, that "the fraction expressing twice the ellipticity of a homogeneous revolving spheroid is the sum of two fractions, one of which expresses the ratio of the excess of polar gravity to mean gravity, and the other expresses the ellipticity of any spheroid of small eccentricity, which consists of a fluid covering a denser spherical nucleus."

If therefore any other phenomena give us, in the case of a revolving spheroid, the proportion of polar and equatorial gravities, we can find its ellipticity, by subtracting the fraction expressing the ratio of the excess of polar gravity to the mean gravity from twice the ellipticity of a homogeneous spheroid. Thus, in the case of the earth, twice the ellipticity of the homogeneous spheroid is $\frac{1}{75.5}$. A medium of seven comparisons of the rate of pendulums gives the proportion of the excess of polar gravity above the mean gravity $\frac{1}{75.5}$. If this fraction be subtracted from $\frac{1}{75.5}$, it leaves $\frac{1}{75.5}$ or the medium ellipticity of the earth. Of these seven experiments, five are scarcely different in the result. Of the other two, one gives an ellipticity not exceeding $\frac{1}{75.5}$. The agreement in general is incomparably greater than in the cases deduced from the comparisons of degrees of the meridian. All the comparisons that have been published concur in giving a considerably smaller eccentricity to the terraqueous spheroid than suits a homogeneous mass, and which is usually called Newton's determination. It is indeed his determination, on the supposition of homogeneity; but he expressly says, that a different density in the interior parts will induce a different form, and he points out some

supposititious cases, not indeed very probable, where the form will be different. Newton has not conceived this subject with his usual sagacity, and has made some inferences that are certainly inconsistent with his law of gravitation.

That the protuberance of the terrestrial equator is certainly less than $\frac{1}{75.5}$ proves the interior parts to be of a greater mean density than the exterior, and even gives us some means for determining how much they exceed in density. For by making the fraction $\frac{5c}{2g} \times \frac{4n-3f}{5n-3f} = \frac{1}{75.5}$

as indicated by the experiments with pendulums, we can find the value of n .

The length of the seconds pendulum is the measure of the accelerating force of gravity. Therefore let l be this length at the equator, and $l+d$ the length at the pole.

We have $\frac{5c}{2g} \times \frac{4n-3f}{5n-3f} = \frac{d}{l}$, whence $\frac{4n-3f}{5n-3f} = \frac{2gd}{5cl}$.

This equation, when properly treated, gives $\frac{n}{f} = \frac{1.5cl-1}{2.0cl-1}$

$\frac{6g}{1.0gd}$, &c. &c.

We have information very lately of the measurement of a degree, by major Lambton in the Mysore in India, with excellent instruments. It lies in lat. $12^{\circ} 32'$, and its length is 60494 British fathoms. We are also informed by Mr. Melanderhielm of the Swedish academy, that the measure of the degree in Lapland, by Maupertuis, is found to be 208 toises too great. This was suspected.

The same principles may be applied to any other planet as well as to this earth. Thus, we can tell what portion of the equatorial gravity of Jupiter is expended in keeping bodies on his surface, by comparing the time of his rotation with the period of one of his satellites. We find that the centrifugal force at his equator is $\frac{3}{8}$ of the whole gravity,

and from the equation $\frac{5c}{4g} r = n$, we should infer that if

Jupiter be a homogeneous fluid or flexible spheroid, his equatorial diameter will exceed his polar axis nearly 10 parts in 113, which is not very different from what we observe; so much however as to authorize us to conclude that his density is greater near the centre than on his surface.

These observations must suffice as an account of this subject. Many circumstances, of great effect, are omitted, that the consideration might be reduced to such simplicity as to be discussed without the aid of the higher geometry. The student who wishes for more complete information must consult the elaborate performances of Euler, Clairaut, D'Alembert, and La Place. The dissertation of Thomas Simpson on the same subject is excellent. The dissertation of F. Boscovich will be of great service to those who are less versant in the fluxionary calculus, that author having every where endeavoured to reduce things to a geometrical construction. To these we would add the *Cosmographia* of Frisius, as a very masterly performance on this part of the subject.

Under the article DEGREE we gave a very ample extract from the account which Col. Mudge had published in the Philosophical Transactions. This great operation has been since concluded by a continuation of the former arc, as far as Burreleigh-moor, near the mouth of the Tees in the north of Yorkshire. The whole amplitude measured is now $3^{\circ} 57' 13'' .4$. The particulars of this continuation have not yet been laid before the public, but they will soon be published by the Board of Ordnance. But the writer of this

article having, through the politeness of Col. Mudge, been favoured with the most important results relating to it, we have the satisfaction of being able to present them to our readers.

The bearings of the sides of the triangles used in finding the meridional distance from Burleigh-moor to Dunnose, from the several parallels to the meridian of Burleigh-moor, will be as follows :

Greenhoe-moor from Burleigh-moor	9° 7' 2" S.W.
Hemingbrough-spire from Greenhoe-moor	5 35 45 S. E.
Clifton-beacon from Hemingbrough-spire	24 50 42 S.W.
Hatherfedge from Clifton-beacon	62 0 3 S.W.
Orpit from Hatherfedge	5 18 6 S. E.
Bardon-hill from Orpit	21 13 23 S. E.
Arbury-hill from Bardon-hill	71 35 11 S. E.
Brill from Arbury-hill	12 22 34 S. E.
Whitehorse-hill from Brill	50 24 0 S.W.
Higclerc from Whitehorse-hill	27 39 53 S. E.
Butter-hill from Higclerc	34 12 30 S. E.
Dunnose from Butter-hill	21 6 26 S.W.

These bearings give the distances from the meridian of, and perpendicular at Burleigh-moor, as follows :

Greenhoe-moor from the meridian	9658.8 W.	60186.4
Hemingbrough-spire	13145 E.	293464.2
Clifton-beacon	39203.2 W.	406462.9
Hatherfedge-beacon	120635.6 W.	449759.8
Orpit	11242.2 W.	559982.9
Bardon-hill	62048.2 W.	677661.5
Arbury-hill	38228.2 W.	856508.2
Brill	6822.8 W.	999633.1
Whitehorse-hill	119782.4 W.	1093081.4
Higclerc	69376.7 W.	1189233.3
Butter-hill	13847 E.	1311654.3
Dunnose	30778 W.	1442802.9

In the Philosophical Transactions of the Royal Society for the year 1793, the distance of Clifton-beacon (Beacon-hill) from the perpendicular to the meridian of Dunnose, is shewn to be 1036334.4 feet, and its distance from the same meridian is stated in the following page as being 4770 feet. If the calculation there specified be carried from Clifton-beacon to Burleigh-moor, through the same triangles as used in determining the distance from Burleigh-moor to the point where a line from Dunnose parallel to the perpendicular cuts the meridian of that station, we shall have the following bearings for computation, viz.

Clifton-beacon from Hatherfedge	61° 53' 17" N. E.
Hemingbrough-spire from Clifton-beacon	24 42 56 N. E.
Greenhoe-moor from Hemingbrough-spire	5 42 50.5 N.W.
Burleigh-moor from Greenhoe-moor	8 59 15 N. E.

Assuming the distance of Clifton-beacon from the meridian of Dunnose as above-mentioned to be 4470 feet, and from the perpendicular at that station as 1036334.4 feet, we shall get

	Feet.	Feet.
Hemingbrough-spire from the meridian	47323.7 E.	1149511.1 from the Greenhoe-moor from co. 23992.6 E.
Greenhoe-moor from co. 23992.6 E.	1382676.6	perpendr.
And Burleigh-moor	33514.8	1442884.7

Now the latitude of Dunnose is $\frac{7}{10}$ greater than the latitude of the point where the parallel from that station cuts the meridian of Burleigh-moor $\frac{7}{10}$ of a second in the heavens,

corresponds to 42 feet on the surface of the earth. Hence $1442802.9 + 42 = 1442845$ feet may be taken for the distance between the parallels of Burleigh-moor and Dunnose, as derived from the first mode of calculation.

In like manner the latitude of Burleigh-moor being $\frac{3}{10}$ less than the latitude of the point where a line from that station parallel to the perpendicular at Dunnose cuts its meridian, we shall have $1442884.7 - 37.4 = 1442847.3$ feet, for the distance between the parallels as determined by carrying up the calculations with the direction of the meridian observed at Dunnose in the year 1797. These results differ something more than two feet, and at a mean may be taken as 1442846 feet, to which, adding 6.5 feet, the distance of the station from the point where the sector was set up at Dunnose, we get 1442853.8 feet for the true meridional distance.

In the paper presented to the Royal Society, and printed in the Philosophical Transactions for the year 1803, giving an account of the measurement of an arc of the meridian, the difference of latitude between the parallels of Dunnose and Clifton, in Yorkshire, is shewn to be $2^{\circ} 50' 23''.38$; and the terrestrial substance of the arc being 1036337 feet. (See page 487 of the same volume.)

If the former operation as well as the present one be supposed correct, their results must be consistent, unless we suppose the plumb line of the sector at Burleigh-moor to have been affected by attraction, arising from the earth's unequal density, in a greater or less degree than at Clifton-beacon. Setting aside the consideration of elliptical arcs not being proportional to angles formed by the meeting of the verticals or intersections of the radii of curvatures at their extremities, yet, in the present case, the total arc not exceeding two degrees, we may use a statement of simple proportion. Taking, therefore, the terrestrial arc between Dunnose and Clifton as 1036337, and its substance in the heavens as $2^{\circ} 50' 23''.38$; and also the total meridional distance between the parallels of Dunnose and Burleigh-moor as 1442853.8 feet, we shall have 1036337 feet : $2^{\circ} 50' 23''.38$ (10223''.38) :: 1442847.8 feet : $14233''.6 = 3^{\circ} 57' 13''.6$, the substance of that arc, or the difference of latitude between those parallels; but this arc has been found, by observation, to be $3^{\circ} 57' 13''.4$, almost exactly the same as the computed result.

The length of the degree on the meridian at the middle point between Dunnose and Burleigh-moor, of which the latitude is $52^{\circ} 34' 45''$, is 60822.6 fathoms. In the account of the former measurement, the length of the degree in $52^{\circ} 2'$ is stated to be 60820 fathoms, which is nearly the same. Were the earth an ellipsoid, and the diameter of its polar and equatorial axis in the ratio of 229 to 230, the degree in $52^{\circ} 34'$ should be nearly 60850 fathoms, if the length of that in 52° be taken 60820.

From this paragraph commences the account of the measurement between the parallels of Blackdown, in Dorsetshire, and Delamere-forest, in Cheshire, the station on Delamere-forest being nearly 10 miles east from Chester.

When the great circular instrument was placed over the point at Delamere-forest, the direction of the meridian was observed. The bearing of the staff at Kilsare, from the north meridian, was found, as may be seen from the observations made at that station, to be $138^{\circ} 1' 31''$. The angle between Ashley-heath and the same staff was also taken and seen to be $73^{\circ} 24' 7''.5$. These two angles give $31^{\circ} 25' 38''.5$ for the fourth-east bearing of Ashley-heath from the meridian of Delamere-forest with Blackdown, a principal station in Dorsetshire, gives the bearings of the following sides from that meridian, viz.

Ashley-heath from Delamere forest	31° 25' 38".5	S. E.
Brown-clay-hill from Ashley-heath	16 35 10	S. W.
Malvern-hill from Brown-clay-hill	23 25 12	S. E.
Trelect-beacon from Malvern-hill	32 14 58.5	S. W.
Dundry-beacon from Trelect-beacon	6 37 9.75	S. E.
Mendip hill from Dundry-beacon	19 4 46	S. E.
Ash beacon from Mendip-hill	3 23 51.75	S. E.
Mintern from Ash beacon	5 22 58	S. E.
Blackdown from Mintern	10 30 53.5	S. W.

These bearings, with their respective sides, give,

Ashley-heath from the meridian	} 67472.1 E. 110418.2 from the perpendicular
Brownclay-hill from do.	
Malvern-hill from do.	77902.2 E. 407476.5
Trelect-beacon	5975.3 W. 538980.9
Dundry-beacon	9628.2 E. 667692.9
Mendip-hill	32246.2 E. 731085.9
Ash-beacon	368962.2 E. 867525.7
Mintern	42446.6 E. 866431.5
Blackdown.	31546.3 E. 925158.5

The parallel of Blackdown cuts the meridian of Delamere forest 30 feet farther southward than the parallel to the perpendicular, therefore $925158 + 30 = 925188.5$ feet, is the correct distance between the parallels of latitude of the two stations.

The bearings of Mintern, Ash-beacon, Mendip, and Dundry-beacon, from the parallels to the meridian and perpendicular at Blackdown, arc given in the Philosophical Transactions for the year 1800.

If the calculation be carried on from the side of Dundry-beacon and Mendip, through the same series of triangles as before used, we shall have,

Trelect-beacon from Dundry-beacon	6° 1' 26" N. W.
Malvern-hill from Trelect beacon	32 20 43 N. E.
Brownclay-hill from Malvern hill	23 19 27 N. W.
Ashley-heath from Brownclay-hill	16 43 55 N. E.
Delamere-forest from Ashley-heath	31 19 58 N. W.

These bearings, with their respective sides, and the distance from Dundry-beacon to the meridian and perpendicular, viz 21488 feet W. and 259503 feet, give

Trelect-beacon from the meridian.	} 35980.2 W. 386330.2 feet from the perpendicular
Malvern-hill	
Brownclay-hill	47221.4 E. 517612.2
Ashley-heath	11250.8 W. 653225.7
Delamere-forest	37288.9 E. 814689.7
	30000.7 W. 925214.7

From the meridional distance thus found (925214.7 feet) 34 feet must be subtracted, the perpendicular at Dunnose cutting the meridian 34 feet north of the parallel of Delamere forest, therefore, $925214.7 - 34 = 925180.7$ feet for the corrected distance. By calculating with the bearings from Delamere-forest downwards, the distance has been found to be 925188.5 feet, giving a difference of 9 feet nearly, between the two results; the mean, 925184.6 feet, may be taken for the true meridional distance between the two stations.

The distance between the parallels of Blackdown and Dunnose is accurately 25005.3 feet, as proved in the Philosophical Transactions for 1800. Therefore, $925184.6 + 25005.3 = 950189.9$ feet, is the true distance between the parallels of those stations.

Now we have portions of two meridians, springing from the same southern parallel, and running up the extent of $3^{\circ} 57' 13".4$, and the other of $2^{\circ} 36' 12".2$. If the surface

of the earth, in the feat of our operations, be uniform in its meridional figure, the subtense of the arc, between Dunnose and Delamere-forest, should be nearly in the ratio of their amplitudes; this being the case, we shall have 1442853.8 feet (the meridional distance between Dunnose and Burleigh-moor) $3^{\circ} 57' 13".6$, its amplitude : 950189.9 feet (the meridional distance between Dunnose and Delamere-forest) : $2^{\circ} 36' 13".38$ the amplitude of its arc. From the observations made at Delamere-forest, with the zenith sector, in 1806, combined with those at Dunnose in 1802, with the same instrument, it is found that the difference in latitude of those is $2^{\circ} 36' 12".2$, making a difference of $1''$ nearly between the calculated and observed amplitudes, constituting a difference, setting aside the consideration of the spheroidal figure of the earth, of $\frac{1}{5}$ ths of a second in one degree. Perhaps, under the consideration of each meridional line being obtained independently of each other, and admitting that neither of them can be measured with perfect accuracy together with the chance of the amplitudes being, in some small degree, either in excess or defect, we may consider the result as sufficiently consistent and satisfactory, and take 60823 fathoms, in the latitude of $52^{\circ} 34'$ (or the centre of England) as the length of one degree.

Amplitude of the arc comprised by the parallels of latitude of Dunnose and Burleigh-moor, near the mouth of the Tees, in the north of Yorkshire is $3^{\circ} 57' 13".4$.

Amplitude of the arc comprised by the parallels of latitude of Dunnose and Delamere-forest itation= $2^{\circ} 36' 12".2$.

N. B. The observations made with the zenith sector at Burleigh-moor and Delamere-forest were numerous, and when reduced agreed well with each other.

Since writing the article DEGREE, we have been favoured by Mr. Troughton with a rule for placing the repeating circle exactly in the plane of two given objects, and which will be found extremely useful to such of our readers as may have occasion to use that excellent instrument.

Rule.—For placing the reflecting circle in the plane which passes through the eye of the observer, and the two objects whose angular distance is about to be taken.

First, let the tripod of the instrument with one of its feet-screws as near as you can guess in a line with that object, which of the two, you judge to be nearest the horizon; and with the plane of the circle vertical, and the lower telescope horizontal (both to the exactness of two or three minutes), bring the telescope to the object, partly by turning in azimuth, and partly by screwing or propping the foot-screw.

Next, turn the circle round upon the cross-axis of the stand, until it seems by the eye to occupy the proper position; and then, a second time bring the telescope to the object by the foot screw and turning in azimuth.

Lastly, complete the operation, by bringing the upper telescope to the other object, by its own proper motion, in conjunction with that of turning round the cross-axis.

The principle of the above rule is this; the cross-axis of the stand and lower telescope being made parallel, and pointed to the object; the circle may be turned round that axis without changing the angular position of the telescope.

EARTH, *Magnetism of.* All the observations, and all the experiments that have been made, concerning this grand natural agent, tend to prove, that all magnetism is derived from the earth; or, that the earth is the great and original magnet. Iron, which, if not the only one, is at least by far the principal metallic substance with which magnetism is concerned, has been liberally scattered by the hand of nature amongst its works. In all the intermediate states, from its most oxydated to its best metallic form, iron is to be met with

with in greater or less quantity in every part of the earth, from the surface to as great a depth as mankind has been able to penetrate. In great many places, vast masses of iron are found, which are in great measure magnetic; and out of which the natural magnets are obtained.

It can hardly be doubted, that the collected magnetical action of all these masses of iron, and of ferruginous bodies, forms the magnetic power of the earth; and that of course the earth, taking it altogether, must be considered as a complete, though heterogeneous, magnet.

If we compare the phenomena of this grand terrestrial magnet with those which are usually exhibited by such small magnets as are in use amongst philosophers, the similarity will be found to very great and striking, as to leave no farther doubt with respect to their being exactly the same in kind, though vastly different in size. A small magnetic needle, laid pretty near a larger magnet, disposes itself in the direction of the poles of the latter; and alters its inclination, according as it is situated nearer to, or farther from, any one of those poles. The compasses commonly used in navigation, and the dipping needles, which are nothing more than small magnets laid near a large one (*viz.* the earth), shew exactly the same phenomena. The progressive variation of the magnetic needle upon the surface of the earth has been alleged as a peculiar phenomenon, which could not be imitated by laying a small magnetic needle near a common magnet. But the cause of this is, that the small magnets, which are usually employed in philosophical experiments, are not liable to those alterations to which the earth is necessarily subject; and to which alterations the variation of the magnetic needle is most evidently owing. In fact, if a small compass be laid within a moderate distance of a pretty large magnet, be it natural or artificial, and this magnet be subjected to the same alterations as the earth is subject to, the needle of the small compass will be found to alter its direction accordingly. These alterations principally are the action of one magnet upon another, the action of heat and cold, the effects of chemical composition and decomposition, and a local derangement. The approximation of two or more magnets towards each other, or their separation, produces a very considerable alteration in the powers of any one of them: and such separation or approximation may be easily conceived to be produced within the earth by the action of volcanoes, of earthquakes, &c. Mr. Canton shewed, in a most decisive manner, that the action of a magnet is diminished by heat, and increased by cold; upon which facts, Dr. Lorimer established his rational hypothesis of the variation. (See DECLINATION.) Mr. Cavallo's experiments, described in the fourth part of his "Treatise on Magnetism," shew that the action of acids, and particularly of the sulphuric acid, upon iron, produces a remarkable alteration, with respect to its magnetic attraction. See MAGNETISM.

Reasoning then upon these facts, we must naturally conclude, that since the body of the earth contains ferruginous bodies in various states, situations, and sizes; the magnetic needle must be directed by the united actions of all those bodies. But as those bodies are undergoing a continual alteration, arising from the vicissitudes of heat and cold, from chemical action, and other causes, their united effects must act differently upon the needle at different times: whence the variation of its direction is derived. At Naples, the magnetic needle is generally agitated during an eruption of mount Vesuvius. To all these, we may add another cause of alteration in the direction of the magnetic needle, which is the *aurora borealis*; for, though we are as yet ignorant of the cause of that surprising phenomenon, yet it is certain

that the magnetic needle is frequently disturbed during the appearance of the *aurora borealis*.

Following the analogy between the phenomena of the earth and those of small magnets, it is well known, that when a piece of iron is brought within a certain distance of a magnet, the iron itself becomes instantly a magnet. The very same thing takes place when the earth is considered as the magnet. Thus, take a bar of soft iron, about two or three feet in length, and about an inch or two in thickness, (a common kitchen poker is very fit for the experiment,) and place it straight up; or, which is much better, place it in the direction of the magnetical line, which is indicated by the dipping needle. Put a magnetic needle upon a pin, and, holding the pin in your hand, present the needle successively to the various parts of the bar, from top to bottom, and you will find, that, in this island, the lower half of the bar is possessed of the north polarity, capable of repelling the north, and of attracting the south, pole of the needle; and the upper half is possessed of the south polarity, capable of repelling the south, and of attracting the north, pole of the needle. The attraction is strongest at the very extremities of the bar, where, if the bar be pretty long, it will even attract small iron filings. It diminishes from the extremities towards the middle; and it vanishes at about the middle, where no one pole of the needle is attracted in preference to the other. In short, in that situation, the iron bar is as much a magnet as any piece of iron that stands within the influence of a common magnet. If you turn the bar upside down, that extremity of it which was possessed of a south magnetic polarity, when it stood uppermost, will now become possessed of a north polarity; and the other extremity will become possessed of the south polarity. In the southern parts of the world, the lower part of the iron bar shews a south polarity; or, in general, when in any part of the world the iron bar is situated in the magnetic line, each extremity of the bar will acquire the polarity correspondent to the pole of the earth nearest to it. When iron bars remain for a number of years in a situation nearly parallel to the magnetical line, they generally acquire a permanent magnetism; and such is the case with curtain-irons, iron crosses on the tops of churches, steeples, &c.

The only phenomenon, which has not been observed to take place with respect to the earth, and which is the most striking property of a common magnet, is the attraction of a piece of iron. For instance, if a piece of iron be presented to either of the poles of a common magnet, it will be powerfully attracted by it; but if it be presented to the middle of the surface of the magnet, the attraction will be hardly perceptible, or next to nothing. Now, in conformity to this, it might be expected, that a piece of iron would be attracted more powerfully downwards, when near the poles of the earth, than when near the equator; and this attraction, being combined with the attraction of gravitation, ought to be manifested by the difference of the weights of the same piece of iron, when weighed near the poles, and when weighed near the equator: for, if the magnetic attraction of the earth upon it be at all sensible, the piece of iron ought to weigh more in the former case than in the latter. We are inclined to believe, that if this experiment were tried, with all the precautions which may be deemed necessary, it would be found to answer; *viz.* that the same piece of iron would be found to weigh more near the poles, and less near the equator.

The magnetic poles of the earth do not coincide with its astronomical poles, nor are they directly opposite to each other. But this is likewise the case with the common natural

tural magnets, and even with most of the artificial ones; though, in the latter, the uniformity of the substance and of the shape may be carefully attended to. This disposition of the poles evidently arises from the heterogeneous nature of the materials in the small magnets, and especially in the earth. It is owing to the same irregular disposition of materials, that the lines of declination follow several odd and circuitous directions, as is shewn under the article DECLINATION of the *Magnetic Needle*. The hypothesis of an internal magnet, or of two internal magnets, which were supposed to exist, and to move in a peculiar manner, within the body of the earth, and to which the variation of the needle was attributed, cannot possibly demand a formal refutation at the present time, when the concurrence of various facts and observations evidently shew its absurdity.

The great question is, whether the earth has only two magnetic poles, or more than two, as is the case with several irregular small magnets; and, likewise, where are those poles actually situated? But it is much to be regretted, that, in answer to this question, we can offer nothing but guesses and conjectures.

With respect to the number of the poles, we may pretty well judge, (from the remarkable circumstance that the lines of declination do not cross each other,) that the earth has only two; *viz.* that on its northern parts there must be a magnetic polarity, which attracts the north pole of the magnetic needle; and on its southern parts there must be a magnetic polarity, which attracts the south pole of the needle. It is generally supposed, that those magnetic poles lie on the surface of the globe; but if we attentively consider the situation which they may more likely have, it will appear that, in all probability, they are not situated near the surface of this globe, but at some depth below it: at least, this must be the case with the south pole; for, since the water of the sea is incapable of magnetism, and the southern hemisphere, especially about the south pole, contains a great deal more water than land, it is plain that the south magnetic pole must be situated at least near the bottom of the sea: in consequence of which, the variation of the needle in that hemisphere must be different from what it would be, if the magnetic pole were situated on the surface of the terrequeous globe. The same observation may be made with respect to the situation of the north magnetic pole. Besides this, we must also consider the irregularities arising from the unequal and irregular situation of land and sea; it being natural to conceive, that large tracts of land on one side of the magnetic needle will draw it away from the real meridian: whereas, a large ocean cannot produce any such effect. This, however, is subject to a great deal of variety, arising from the nature of the land, the depth of the sea, the nature of the ground at the bottom of the sea, &c.

With respect to the latitudes and longitudes of the magnetic poles of the earth, we are still less satisfactorily informed. Mr. Euler, in the "Memoirs of the Academy of Berlin," places the north magnetic pole in lat. 75° ; Lemoignon, in his "Lois du Magnétisme," places it in lat. 73° ; Buffon places it in lat. 71° ; La Lande places it in lat. $77^{\circ} 4'$; and Churchman of America places it in lat. 60° . The longitude of the above-mentioned pole, La Lande supposes to be $110^{\circ} 35'$ W. of Paris. But from the observations made at Hudson's bay, the longitude of the same from Paris seems to be 86° , (a mean of the two is 98°). Euler makes it 115° ; Buffon makes it 100° ; and Lemoignon makes it only 50° .

The situation of the south magnetic pole is still more

doubtful. Dr. Lorimer says, "It is very remarkable, that when captain Cook, in his second voyage, crossed the line of no declination, which passes through the continent of New Holland, the declination of his compass altered about 14° in two days' run: again, in his last voyage, though not so far south, the alteration of the declination, in proportion to the distance, was greater than usual near to that line. The dipping needle likewise shews a considerable degree of inclination upon this line. In short, from various considerations, it would appear, that if this earth has the common properties of a natural magnet with only two poles, one of them must be situated in this line; and, though not within the 60° of latitude, as Mr. Euler imagined, yet it may possibly be found not far from the 70° . If, therefore, it appears practicable to sail to the 70° of fourth latitude, or beyond it, about the meridian of Botany Bay, keeping in east declination; and then to run westward, till the west declination becomes evident; if, at the same time, they have a dipping needle on board, that without much trouble could give the magnetic inclination at sea with a tolerable degree of accuracy, and about a hundred weight of soft iron, with a good balance, I cannot help thinking that some curious discovery might be made.

"The ingenious Mr. Maupertuis, in his letter to the king of Prussia, on the advancement of the sciences, among other curious articles, having mentioned a northern voyage, adds, "to observe the phenomena of the load-stone, on the very spot from whence it is supposed to draw its original influence." But such voyages were not in the power of Frederick the Great. It is to our present gracious sovereign, George III., that the world will ever be indebted for such noble, extensive, and disinterested undertakings. All access to the north pole having been proved impracticable, by the voyages of lord Mulgrave and captain Cook, it now only remains to be determined, whether it is possible to come at the south magnetic pole; which, for the reasons already mentioned, seems at least more probable, if it be judiciously attempted." Cavallo's Magnetism, p. 262, &c.

The last observations which need be added to this article relate to the various magnetic force in different parts of the earth, and at some height above it.

In these northern parts of the world, it has been observed that, *ceteris paribus*, the north end of a magnet is the strongest; and the contrary is said to be the case in the southern parts of the earth. Thus, in the above-mentioned experiment of the bar of soft iron, which acquires magnetism from the earth, its lower extremity generally shews the strongest power. Mr. Humboldt found, that the intensity of the magnetic force increases from the equator to the poles, excepting trifling local irregularities. He found that the same compass, which at Paris performed 245 oscillations in 10 minutes, performed not more than 211 in Peru; and it constantly varied in the same direction; *viz.* the number of the oscillations always decreased in approaching the equator, and it always increased in advancing towards the north. (Journal de Physique, an. 13.) In an aerostatic voyage of Messrs. Guy Lussac, and Biot, performed in August, 1804, when they ascended to the height of 13,124 English feet, it was observed that the magnetic property shewed no appreciable diminution from the surface of the earth to the above-mentioned height. Its action within those limits was constantly manifested by the same effects, and according to the same laws. This was determined by the oscillation of a magnetic needle.

EARTH, *Theory of the*. Under the article COSMOGONY we have given a concise abstract of the opinions of the ancient

ancient philosophers concerning the universe, the bodies of which it consists, and the time and manner of their formation. These particulars are also detailed, with some variety and amplification, under the biographical articles of the most eminent philosophers of antiquity and the denominations by which their respective systems are distinguished. Under the article CHAOS, we have briefly recited the sentiments of several ancient and modern philosophers, concerning the primitive state of the earth, and under the article CREATION, we have given the scriptural account of its formation into an habitable globe. We proposed in this place to detail the modern theories of the earth, commencing with that of Des Cartes; but we have already, in some degree, anticipated our intention by the statements, which we were under a necessity of introducing under the article DELUGE, for the purpose of illustrating the causes and effects of that memorable catastrophe. It now remains that we should supply what is wanting, in order to render our account of the different theories of the earth as complete as the nature and limits of this work will allow.

In the terraqueous globe some writers have distinguished three parts or regions, *viz.* 1. The external part or crust, which is that from which vegetables arise, and animals are nourished. 2. The middle, or intermediate part, which is possessed by fossils, extending farther than human labour has ever yet penetrated. 3. The internal, or central, part, which is unknown to us, though many authors have supposed it to be of a magnetic nature; by others, it has been conjectured to be a mass, or sphere of fire; by others, an abyss, or collection of waters, surrounded by the strata of earth; and by others, a hollow, empty space, inhabited by animals, who have their sun, moon, planets, and other conveniences within the same. Others divide the body of the globe into two parts, *viz.* the external part, which they call the cortex, including the whole depth or mass of the strata of the earth; and the internal, which they call the nucleus, being of a different nature from the former, and possessed of fire, water, or the like; but it is needless to dwell on these fanciful conjectures.

The figure of the earth has been already ascertained, and described under a preceding article (see EARTH, in *Astronomy*); and here it will be sufficient to observe, that the natural cause of this figure is, according to Sir Isaac Newton, the great principle of attraction, which the Creator has assigned to all the matter of the universe; and by which, whatever be its precise origin or the intermediate instruments of its operation in subordination to the energy of the Deity, all bodies, and all the parts of bodies, mutually attract one another. In conformity to the operation of this principle of gravity combined with the diurnal rotation of the earth on its axis, our globe, like other planetary bodies, similarly circumstanced, is higher under the equator than at the poles; so that its figure is nearly that of an oblate spheroid, swelling out towards the equatorial parts, and flattened, or contracted, towards the poles. If the earth was originally in a fluid state, or composed of yielding materials, its revolution round its axis would necessarily make it assume such a figure; because the centrifugal force being greatest towards the equator, the parallels of diurnal rotation increasing towards this limit, the fluid, or yielding matter, would there rise and swell most: and that its figure really should be so now, seems necessary, in order to keep the sea in the equinoctial regions, from overflowing the earth about these parts.

The external part of the globe either exhibits inequalities, as mountains or vallies; or it is plain and level; or dug in channels, fissures, beds, &c. for rivers, lakes, seas, &c.

These inequalities in the face of the earth are supposed, by most naturalists, to have arisen from a rupture or subversion of the earth by the force either of the subterraneous fires or waters. The earth, in its natural and original state, Des Cartes, and after him Burnet, &c. (see the sequel of this article) suppose to have been perfectly round, smooth, and equable; and they account for its present rude and irregular form principally from the great deluge. In the external, or cortical part of the earth, we discover various strata, which are supposed by some to have existed in the primitive earth, and which others have ascribed to the sediments of various floods; the waters of which being replete with materials of different kinds, as they dried up or oozed through, deposited these various matters, which in time hardened into strata of stone, sand, coal, clay, &c.

The Aristotelian philosophy, with regard to the universe (for an account of which, see ARISTOTLE, *PERIPATETICS*, and also *COSMOGONY*) was superseded by that of Des Cartes, which was, in fact, a revival of the Atomic (see *ATOMIC*), or that of DEMOCRITUS and EPICURUS, with some corrections and emendations. (See *CARTES* and *CARTESIAN*.) This of course was supplanted by the NEWTONIAN system. (See *NEWTON* and *NEWTONIAN*.) It is hardly necessary to observe, that the Cartesian cosmogony was somewhat modified by Mr. Hutchinso, who attempted to graft his on the authority of revelation, literally interpreted. The subordinate agents in his cosmogony were fire, light, and air; the operations of which he and his followers have unsuccessfully endeavoured to explain and to accommodate to the system of nature.

Some of the principal difficulties that occur in forming a satisfactory theory of the earth are those that relate to its figure, the distribution of its water, the origin and permanence of its mountains, the disposition of its internal strata, and the introduction of vegetable and marine productions, such as leaves, &c. and shells into the most solid rocks of marble and limestone.

The first theory we shall mention, is that of Mr. Thomas Burnet, who was a man of genius and taste, and who was the first who treated of this subject in a systematic manner, in his "Telluris Theoria sacra, &c." published at London in the year 1680. Under the splendour of his conceptions and the elegance of his style, he has had the art to conceal feeble arguments, and erroneous principles of philosophy. His work, though it acquired great reputation, was criticised by many of the learned, and particularly by Keill, in a treatise, entitled "An Examination of the Theory of the Earth." Burnet supposes that the primeval earth was a fluid mass, composed of heterogeneous materials, the heaviest of which descended to the centre, and there formed a hard and solid body. The water was collected round this body, and all lighter fluids, particularly the air, ascended above the water or encompassed the whole. Between the orbs of water and air was interposed an oily matter, upon which the impure earthy particles, blended with the air, descended, and formed with it a crust of earth and oil. This crust was the first habitable part of the earth, and the abode of men and other animals. The earth in this state had no variety of seasons, because its equator was supposed to be coincident with the plane of the ecliptic. The soil, formed in the manner above stated, was light and rich, and adapted to the various purposes of vegetation. The surface of the earth was level and uniform, without mountains, seas, or other inequalities. In this state it remained about 16 centuries; till by degrees the heat of the sun dried the forementioned crust, and produced at first superficial and afterwards deeper fissures, so as thoroughly to penetrate it. The earth at length

length was rent in pieces, and the waters gushed out, with such force and in such abundance, as to overwhelm the dry land and occasion the universal deluge. After a certain period the water subsided into the cavities that were left between the solid masses of earth; and as these cavities were filled with water, the earth appeared in the most elevated parts, and the lower parts or valleys were occupied by the water, which formed the ocean. See DELUGE.

This theory, announced in England by Burnet, is said to have been first communicated by Francesco Patrizio, a professor at Ferrara and Rome, above a century before, in a dialogue, entitled "Il Lamberto." M. Buffon has not ungenerously styled this theory an elegant romance; the product of mere imagination, and unsupported by any observed phenomena.

About the same time the celebrated Leibnitz published, in the Leipzig Transactions, a sketch of an opposite system, under the title of "Protogæa." According to this writer, the earth, and also the other planets, were originally fixed and luminous stars, which, after burning for many ages, were extinguished from a deficiency of combustible matter, and became opaque bodies. The fire, by fusion of the matter composing the earth, produced a vitrified crust; so that the basis of all terrestrial bodies is glass, of which sand and gravel are the fragments. The other species of earth resulted from a mixture of sand with water and fixed salts; and, when the crust had cooled, the moist particles, which had been elevated in the form of vapour, fell down and formed the ocean. These waters at first covered the whole surface, and even overtopped the highest mountains; and the author alleges that the shells and other spoils of the ocean, which every where abound, are indelible proofs of the sea's having formerly covered the earth. This theory, though ingenious, is altogether hypothetical, and inapplicable to the present state of the earth.

The signal changes that have taken place on the surface of the earth were long ago ascribed by Xanthus, the Lydian, to earthquakes and subterranean fires, which have from time to time elevated and depressed the bed of the sea, which is thus rendered very unequal; and thus he accounted for the immense quantities of shells and fossils, found on the summits of the highest mountains. Our countryman, Ray, revived this opinion, in his "Physico-Theological Discourses," published in the year 1692. This author supposes that the waters, which originally overflowed the earth, gradually subsided, that dry land first appeared in the territories that are adjacent to the spots inhabited by the progenitors of our race immediately after their creation: and that, as it extended itself by degrees, a considerable time elapsed before the waters had retired to their proper beds. During this interval, the shell-fish having multiplied, were universally distributed by the agitation of the waters; and when the bottom of the sea was raised by the earthquakes which accompanied the deluge, and formed the mountains, beds of marine productions were thrown up along with it.

For an account of Dr. Woodward's theory, we refer to the article DELUGE.

Mr. Whiston, who published his "New Theory of the Earth," at London, in 1708, begins with an account of the creation of the world; and he alleges, probably not without reason, (see CREATION,) that the description of Moses, in the first chapter of Genesis, is not an exact, or philosophical account of the creation and origin of the universe; but only an historical narrative of the formation of the terrestrial globe. The earth, in his estimation, formerly existed in a chaotic state; and at the time mentioned by Moses, it merely received a form, situation,

and confidence, suitable to the habitation of mankind. Accordingly, he says, that the primitive earth was an uninhabitable comet, subject to such alternations of heat and cold, that its constituent matter, being sometimes liquefied and sometimes frozen, was in the form of a chaos, or an abyss, surrounded with utter darkness; so that as the sacred writer says, *darkness covered the face of the deep*. This chaos (see CHAOS) was the atmosphere of the comet, a body composed of heterogeneous materials, in the centre of which was a globular, solid, hot nucleus, about 2000 leagues in diameter. This was an extensive mass of a dense fluid, the various materials of which were agitated and blended in the utmost confusion. Such he conceives to have been the condition of the earth at the era of the creation. But in proportion as the eccentricity of the comet's orbit decreased, and it became more nearly circular, the materials of the circumambient fluid arranged themselves according to their specific gravities, and formed the earth, the water, and the air. Thus the immense volume of chaos was reduced to a sphere of moderate magnitude, including the unchanged central nucleus, which retained its primeval heat, which the author calculates may continue 6000 years. An earthy substance, consisting of the heavier parts of the chaotic atmosphere, mixed with aqueous particles, encompassed the central globe of fire, and was enclosed by a body of water, round which was formed the crust of earth destined to be the habitation of mankind. On this crufted surface there were irregularities, composed of the heaviest parts of the earth, which sunk deeply into the subjacent fluid, and formed plains and valleys; while those of less weight remained at a greater elevation, and constituted mountains. We shall here observe, that, according to Mr. Whiston, the annual motion of the earth commenced when it received its new form; but that its diurnal motion was not given to it till the fall of Adam: that the ecliptic intersected the tropic of Cancer in a point precisely opposite to the situation of Paradise, which lay on the N.W. frontier of Assyria; that, before the deluge, the year began at the autumnal equinox, and that the orbits of the earth and planets were then perfect circles; that the deluge commenced in the manner related under that article, on the 18th of November, in the year of the Julian period 2365, or 2349 B. C., and that before the deluge, the solar and lunar year were the same, and consisted of exactly 360 days, but that the figure of the earth was changed from that of a sphere into a spheroid. This latter effect was produced by the centrifugal force resulting from the diurnal motion of the earth, and by the attraction of the comet; for the earth, when passing through the tail of the comet, was so situated, that its equatorial parts were nearest to it; and, of course, the comet's attraction, concurring with the earth's centrifugal force, elevated the equatorial regions with the greater facility; because the crust was broken in an infinite number of places, and because the flux and reflux of the abyss pushed more violently against the equator than any where else. In accounting for the changes, which the earth has undergone in consequence of the deluge, Mr. Whiston adopts Woodward's theory, and coincides with him in his remarks on the present state of the earth.

In 1729, M. Bourguet projected a theory of the earth, but did not live to execute the system which he had planned. The fundamental propositions of his theory were the following:—that the earth was formed at once, and not successively;—that its figure and disposition demonstrate, that it was formerly in a fluid state;—that the present condition of the earth is very different from what it was for some ages after its first formation;—that the matter of the globe was originally

originally softer than after its surface was changed;—that the condensation of its solid parts diminished gradually with its velocity; so that after a certain number of revolutions round its axis, and round the sun, its original structure was suddenly dissolved;—that this happened at the vernal equinox;—that the sea-shells insinuated themselves into the dissolved matters;—that the earth, after this dissolution, assumed its present form;—and that, as soon as the fire, or heat, operated upon it, its consumption gradually began, and, at some future period, it will be blown up with a dreadful explosion, accompanied with a general conflagration, which will augment the atmosphere, and diminish the diameter of the globe;—and then the earth, instead of strata of sand, or clay, will consist only of beds of calcined materials, and mountains composed of amalgams of different metals.

In 1740, Lazaro Moro, an Italian geologist, published a work at Venice, in which he partially adopts the hypothesis of Ray. His professed design was to account for the remains of marine animals found in mountains at a distance from the sea. With this view, he conjectured, that the earth, in general, and its mountains in particular, were elevated from the bottom of the sea by the force of subterraneous fires, which began to burn soon after the creation. At first a portion of land was raised up, in which no shells are found, as the ocean had not then been stocked with fish. Afterwards, large quantities of shells and other marine substances were thrown up with the soil, and disposed in strata, according to their specific gravity. But how the strata were consolidated, and the shells were found in the strata mineralized, he has not informed us. Mr. Raspe, in his “*Specimen Historiæ Naturalis Globi Terraquei*,” published at Leipzig, A. D. 1763, inclines to the hypothesis of Moro.

For other theories by Schenbzer, Steno, Hooke, De La Pyrie, &c. &c. we refer to the article DELUGE.

The theory of M. Buffon next claims our particular notice. The author has embellished it with the beauties of language, and rendered it plausible and interesting, by an elaborate discussion of the arguments, which he alleges in support of it, and of the objections which he conceived might be urged against it. We can only present to view some of its most prominent features, and refer those, who wish for further satisfaction and amusement, to his own account of it. The earth, and also the other planets, were, according to the hypothesis of M. Buffon, portions of the body of the sun, which were detached from it by the oblique stroke of a comet. These masses of igneous particles, issuing from the sun in the form of torrents and not of globes, and afterwards assuming a globular figure by the mutual attraction of their parts, receded from it with an accelerated motion to such a distance, as to admit of their acquiring a circular, or elliptical movement round the sun. Their revolutions on their axes he ascribes to the obliquity of the original stroke impressed by the comet. By means of the rotatory motion of the earth, on its axis, and of the fluidity of the matter, of which it consisted at its first formation, it acquired the figure of an oblate spheroid. The earth, being removed to a considerable distance from the sun, gradually cooled; and the vapours, which in their expanded state resembled the tail of a comet, condensed by degrees, and fell down in the form of water upon the surface. The water deposited a slimy substance, mixed with sulphur and salts, part of which was carried, by the motion of the waters, into the perpendicular fissures of the strata, and produced metals, and the rest remaining on the surface gave rise to the vegetable mould, which abounds in different places, with more or less of animal or vegetable particles, the organization of

which is not obvious to the senses. The interior parts of the globe were originally composed of vitrified matter, which the author apprehends to be their present state. Above this vitrified matter were placed those bodies, which the fire had reduced to the smallest particles, as sands, which are merely portions of glass; and above these pumice stones and the scoria of melted matter, which produced the different clays. The whole was covered with water to the depth of 500 or 600 feet, which originated from the condensation of the vapours, when the earth began to cool. This water deposited a stratum of mud, mixed with all those matters, which are capable of being sublimed, or exhaled by fire; and the air was formed of the most subtle vapours, which, from their levity, rose above the water. “Such,” says our author, “was the condition of the earth, when the tides, the winds, and the heat of the sun, began to introduce changes on its surface. The diurnal motion of the earth, and that of the tides, elevated the waters in the equatorial regions, and necessarily transported thither great quantities of slime, clay, and sand; and, by thus elevating those parts of the earth, they, perhaps, sunk those under the poles about two leagues, or the 23rd part of the whole: for the waters would easily reduce into powder pumice stones, and other spongy parts of the vitrified matter upon the surface; and thus excavate some places and elevate others, which, in time, would produce islands and continents, and all these inequalities on the surface, which are more considerable towards the equator, than towards the poles. Indeed, both the land and sea have most inequalities between the tropics, as is evident from the incredible number of islands peculiar to those regions.”

In order to accommodate his theory to the present state of the globe, he surveys and recounts the phenomena which it exhibits, and the parts of which it consists, in their various dispositions and arrangements, as far as our observation is capable of being extended.

The surface of this immense globe exhibits to our observation, heights, depths, plains, seas, marshes, rivers, caverns, gulfs, and volcanoes, “without any apparent order in the disposition of them.” Upon penetrating into the bowels of the earth, we discover metals, minerals, stones, bitumens, sands, earth, waters, and every kind of matter, placed, as it were, by accident, and without any obvious design. After a more accurate inspection, we find sunk mountains, caverns filled up, shattered rocks, whole countries swallowed up, new islands emerged from the ocean, heavy substances placed above light ones, and hard bodies inclosed in soft ones; all of them blended in confusion, and forming a chaos, that resembles the ruins of a world.

In examining the bottom of the sea, this author says, we perceive it to be equally irregular with the surface of the dry land, presenting to our notice hills and valleys, plains and hollows, rocks and earths of every kind. Islands are observed to be the summits of vast mountains; and other mountains have their tops nearly on a level with the surface of the ocean. In the sea are likewise discovered currents, which flow rapidly in various directions. We likewise perceive numerous agitations and convulsions in the ocean, which are owing to volcanoes, whose mouths, though situated many fathoms below the surface, vomit forth torrents of fire. In other parts we discern smooth and calm regions, which, nevertheless, are equally dangerous to the mariner. The bottom of the ocean, and the shelving sides of rocks, produce many species of plants in great abundance as well as variety. Its soil consists of sand, gravel, rocks, and shells; in some places a fine clay, in others a compact earth. Upon the whole, the bottom of the sea exactly resembles the dry land which we inhabit.

In a survey of the dry land our author finds, that the great chains of mountains lie nearer to the equator than to the poles; that those of the old continent tend more to the east, to west than from south to north, and in the new world that they have a contrary direction. He observes, that the prominent angles of one mountain are constantly opposite to the concave angles of the neighbouring mountains, and that they are of equal dimensions; whether they be separated by an extensive plain or a small valley. Opposite hills, he observes, are nearly of the same height; and mountains generally occupy the middle of continents, islands and promontories dividing them by their greatest length. The direction of the principal rivers is nearly perpendicular to the coasts of the seas, into which they discharge themselves; and during the greater part of their course they follow the direction of the mountains from which they spring. The sea-coasts are generally bordered with rocks of marble and other hard stones; or, rather, with earth and sand accumulated by the waters of the sea, or deposited by rivers. On opposite coasts, separated by small intervals of sea the different strata or beds of earth are composed of the same materials. Volcanoes, says our author, never exist but in very high mountains; some are extinguished; and some are connected with others by subterraneous passages, and their eruptions frequently happen at the same time. Lakes and seas communicate with one another in a similar manner. Mediterranean or inland seas receive large supplies of water from many large rivers without any augmentation of their bounds; and, therefore, probably discharge part of their supply by subterraneous passages.

In the prosecution of his inquiry and examination, our author finds that the upper stratum of the earth is universally the same substance; that this substance, from which all animal and vegetable substances derive their nourishment, is merely a composition of the decayed parts of animal and vegetable bodies, reduced into particles so small, that their former organic state is not distinguishable. Upon a deeper penetration he finds the real earth, beds of sand, brimstone, clay, shells, marble, gravel, chalk, &c. These beds are parallel to one another, and of the same thickness. In neighbouring hills, beds or strata of the same materials are uniformly found at the same levels, however the hills may be separated. Strata of every kind, even of the most solid rocks, are uniformly divided by perpendicular fissures. Shells, skeletons of fishes, marine plants, &c. are often found in the bowels of the earth, and on the tops of mountains, even at the greatest distance from the sea; and these shells, fishes, and plants, are exactly similar to those which exist in the ocean. Petrified shells are found every where in great quantities, not only included in rocks of marble and lime-stone, as well as in earths and clays, but actually incorporated and filled with the substances in which they are inclosed. Upon the whole he concludes, from repeated observations, that marbles, lime-stones, chalks, marls, clays, and sands, and almost all terrestrial substances, wherever situated, are full of shells and other spoils of the ocean.

From this survey, all the particulars of which we cannot enumerate, Mr. Buffon deduces the following conclusions, *viz.*

The changes which the earth has undergone during the last two or three thousand years are inconsiderable, when compared with the great revolutions which must have happened in those ages that immediately succeeded the creation. For, as terrestrial substances could only acquire solidity by the continued action of gravity, it is easy to demonstrate, that the surface of the earth was at first much softer than it is now; and, consequently, that the same causes, which at

present produce but slight and almost imperceptible alterations during the course of many centuries, were then capable of producing very great revolutions in a few years. It appears indeed, to be an incontrovertible fact, that the dry land which we now inhabit, and even the summits of the highest mountains, were formerly covered with the waters of the sea; for shells, and other marine bodies, are still found upon the very tops of mountains. It likewise appears, that the waters of the sea have remained for a long series of years upon the surface of the earth; because, in many places, such immense banks of shells have been discovered, that it is impossible for great a multitude of animals could exist at the same time. This circumstance seems likewise to prove, that, although the materials on the surface of the earth were then soft, and, of course, easily dissolved, moved, and transported, by the waters; yet these transportations could not be suddenly effected. They must have been gradual and successive, as sea-bodies are sometimes found more than 1000 feet below the surface. Such a thickness of earth or of stone could not be accumulated in a short period. Although it should be supposed, that, at the deluge, all the shells were transported from the bottom of the ocean, and deposited upon the dry land; yet, beside the difficulty of establishing this supposition, it is clear, that, as shells are found incorporated in marble and in the rocks of the highest mountains, we must likewise suppose, that all these marbles and rocks were formed at the same time, and at the very instant when the deluge took place; and that, before this grand revolution, there were neither mountains, nor marbles, nor rocks, nor clays, nor matter of any kind, similar to what we are now acquainted with, as they all, with few exceptions, contain shells, and other productions of the ocean. Besides, at the time of the universal deluge, the earth must have acquired a considerable degree of solidity, by the action of gravity for more than sixteen centuries. During the short time the deluge lasted, therefore, it is impossible that the waters should have overturned and dissolved the whole surface of the earth, to the greatest depths that mankind have been able to penetrate.

It is certain, that the waters of the sea have, at some period or other, remained for a succession of ages upon what we now know to be dry land; and, consequently, that the vast continents of Asia, Europe, Africa, and America, were then the bottom of an immense ocean, replete with every thing which the present ocean produces. It is likewise certain, that the different strata of the earth are horizontal and parallel to each other. This parallel situation must, therefore, be owing to the operation of the waters, which have gradually accumulated the different materials, and given them the same position that water itself invariably assumes. The horizontal position of strata is almost universal: in plains, the strata are exactly horizontal. It is only in the mountains that they are inclined to the horizon; because they have originally been formed by sediments deposited upon an inclined base. These strata must have been gradually formed, and they are not the effect of any sudden revolution; because nothing is more frequent than strata composed of heavy materials placed above light ones, which never could have happened, if, according to some authors, the whole had been blended and dissolved by the deluge, and afterwards precipitated. On this supposition every thing should have had a different aspect from what now appears. The heaviest bodies should have descended first, and every stratum should have had a situation corresponding to its specific gravity. In this case, we should not have seen solid rocks or metals placed above light sand, nor clay under coal.

Another circumstance demands our attention. No cause

but the motion and sediments of water could possibly produce the regular position of the various strata of which the superficial part of this earth is composed. The highest mountains consist of parallel strata, as well as; the lowest valleys. Of course, the formation of mountains cannot be imputed to the shocks of earthquakes, or to the eruptions of volcanoes. Such small eminences, as have been raised by volcanoes or convulsions of the earth, instead of being composed of parallel strata, are mere masses of weighty materials blended together in the utmost confusion. But this parallel and horizontal position of strata must necessarily be the operation of a uniform and constant cause.

We are, therefore, authorized to conclude, says our author, from repeated and incontrovertible facts and observations, that the dry and habitable part of the earth has for a long time remained under the waters of the sea, and must have undergone the same changes which are at present going on at the bottom of the ocean.

The ocean, from the creation of the solar system, has been constantly subject to a regular flux and reflux. These motions, which happen twice in twenty-four hours, are principally occasioned by the action of the moon, and are greater in the equatorial regions than in other climates. The earth likewise performs a rapid motion round its axis, and, consequently, has a centrifugal force, which is also greatest at the equator. This last circumstance, independent of actual observations, proves, that the earth is not a perfect sphere, but that it must be more elevated under the equator than at the poles. From these two combined causes, the tides, and the motion of the earth, it may be fairly concluded, that although this globe had been originally a perfect sphere, its diurnal motion, and the ebbing and flowing of the tides, must necessarily, in a succession of time, have elevated the equatorial parts, by gradually carrying mud, earth, sand, shells, &c. from other climates, and depositing them at the equator. On this supposition, the greatest inequalities on the surface of the earth ought to be, and, in fact, are found in the neighbourhood of the equator. Besides, as the alternate motion of the tides has been constant and regular since the existence of the world, is it not evident, that, at each tide, the water carries from one place to another a small quantity of matter which falls to the bottom as a sediment, and forms those horizontal and parallel strata that every where appear? The motion of the waters, in the flux and reflux, being always horizontal, the matter transported by them must necessarily take the same parallel direction after it is deposited.

To this reasoning, it may be objected, that, as the flux is equal to, and regularly succeeded by, the reflux, the two motions will balance each other; or, that the matter brought by the flux will be carried back by the reflux; and, consequently, that this cause of the formation of strata must be chimerical, as the bottom of the ocean can never be affected by a uniform alternate motion of the waters; far less could this motion change its original structure, by creating heights, and other inequalities.

But, in the first place, as the author replies, the alternate motion of the waters is by no means equal; for the sea has a continual motion from east to west: besides, the agitations occasioned by the winds produce great inequalities in the tides. It will likewise be acknowledged, that, by every motion in the sea, particles of earth, and other materials, must be carried from one place, and deposited in another; and that these collections of matter must assume the form of parallel and horizontal strata. Farther, a well-known fact will entirely obviate this objection. On all coasts, where the ebbing and flowing are discernible, numberless materials

are brought in by the flux, which are not carried back by the reflux. The sea gradually increases on some places, and recedes from others, narrowing its limits, by depositing earth, sand, shells, &c. which naturally take a horizontal position. These materials, when accumulated and elevated to a certain degree, gradually shut out the water, and remain for ever in the form of dry land.

But, to remove every doubt concerning this important point, let us examine more closely the practicability of a mountain's being formed at the bottom of the sea, by the motion and sediments of the water. On a high coast which the sea washes with violence during the flow, some part of the earth must be carried off by every stroke of the waves. Even where the sea is bounded by rock, it is a known fact, that the stone is gradually walled by the water; and, consequently, that small particles are carried off by the retreat of every wave. These particles of earth or stone are necessarily transported to some distance. Whenever the agitation of the water is abated, the particles are precipitated in the form of a sediment, and lay the foundation of a first stratum, which is either horizontal, or inclined, according to the situation of the surface upon which they fall. This stratum will soon be succeeded by a similar one, produced by the same cause; and thus a considerable quantity of matter will be gradually amassed, and disposed in parallel beds. In process of time, this gradually accumulating mass will become a mountain in the bottom of the sea, exactly resembling, both in external and internal structure, those mountains which we see on the dry land. If there happened to be shells in that part of the bottom of the sea where we have supposed the sediments to be deposited, they would be covered, filled, and incorporated, with the deposited matter, and form a part of the general mass. These shells would be lodged in different parts of the mountains, corresponding to the times they were deposited. Those which lay at the bottom, before the first stratum was formed, would occupy the lowest station; and those which were afterwards deposited, would be found in the more elevated parts.

It has been conceived, that the agitation produced by the winds and tides is only superficial, and affects not the bottom, especially when it is very deep. But it ought to be remembered, that, whatever be the depth, the whole mass is put in motion by the tides at the same time; and that, in a fluid globe, this motion would be communicated even to the centre. The power which occasions the flux and reflux is penetrating; it acts equally upon every particle of the mass. Hence the quantity of its force, at different depths, may be determined by calculation. Indeed, this point is so certain, that it admits not of dispute.

We cannot, therefore, hesitate in pronouncing, that the tides, the winds, and every other cause of motion in the sea, must produce heights and inequalities in its bottom; and that these eminences must uniformly be composed of regular strata, either horizontal or inclined. These heights will gradually augment; like the waves which formed them, they will mutually respect each other; and if the extent of the base be great, in a series of years they will form a vast chain of mountains. Whenever eminences are formed, they interrupt the uniform motion of the waters, and produce new motions, known by the name of currents. Between two neighbouring heights in the bottom of the ocean, there must be a current, which will follow their common direction, and, like a river, cut a channel, the angles of which will be alternately opposite through the whole extent of its course. These heights must continually increase; for, during the flow, the water will deposit its ordinary sediment upon their ridges, and the waters which are impelled by the current will force along,

from great distances, quantities of matter, which will subside between the hills, and, at the same time, scoop out a valley with corresponding angles at their foundation. Now, by means of these different motions and sediments, the bottom of the ocean, though formerly smooth, must soon be furrowed and interperforated with hills and chains of mountains, as we actually find it at present. The soft materials of which the eminences were originally composed, would gradually harden by their own gravity. Such of them as consisted of sandy and crystalline particles, would produce those enormous masses of rock and flint in which we find crystals and other precious stones. Others, composed of stony particles mixed with shells, give rise to those beds of lime-stone and marble, in which vast quantities of sea shells are still found incorporated. Lastly, all our beds of marble and chalk have derived their origin from particles of shells mixed with a pure earth, collected and deposited at particular places in the bottom of the sea. All these substances are disposed in regular strata; they all contain heterogeneous matter, and vast quantities of sea-bodies situated nearly in proportion to their specific gravities. The lighter shells are found in chalk; the heavier in clay and lime-stone. These shells are uniformly filed with the matter in which they are found, whether it be stone or earth. This is an incontestible proof, that they have been transported along with the matter that fills and furrows them, and that this matter was then in the form of an impalpable powder. In a word, all those substances, the horizontal situation of which has arisen from the waters of the sea, invariably preserve their original position.

If we investigate more minutely the situation of those materials which compose the superficial part of the globe, we shall find that the different strata of stones in quarries are almost all horizontal, or regularly inclined. Those founded upon hard clay, or other solid matter, are evidently horizontal, especially in plains. The disposition of quarries, where flint or brownish free-stone is found in detached portions, is indeed less regular. But even here the uniformity of nature is not interrupted; for the horizontal or regularly inclining position of the strata is apparent in granite and brown free-stone, wherever they exist in large connected masses. This position is universal, except in flint and brown free-stone in small detached portions, substances the formation of which was posterior to those just now mentioned. The strata of granite, vitrifiable sand, clays, marbles, calcareous stones, chalk, and marles, are always parallel or equally inclined. In these the original formation is easily discoverable; for the strata are exactly horizontal, and very thin, being placed above each other like the leaves of a book. Beds of sand, of soft and hard clay, of chalk, and of shells, are likewise either horizontal or uniformly inclined. Strata of every kind preserve the same thickness through their whole extent, which is often many leagues, and might, by proper observations, be traced still farther. In a word, the disposition of strata, as deep as mankind have hitherto penetrated, is the same.

Those beds of sand and gravel which are washed down from mountains, must, in some measure, be excepted from the general rule. The strata formed by rivers are not very ancient; they are easily distinguished by their frequent interruptions, and the inequality of their thickness. But the ancient strata uniformly preserve the same dimensions through their whole extent. Besides, these modern strata may be distinguished, with certainty, by the form of the stones and gravel they contain, which bear evident marks of having been rolled, smoothed, and rounded, by the motion of water. The same observation may be made with regard to those beds of turf, and corrupted vegetables, which are found in

marshy grounds, immediately below the soil: they have no claim to antiquity, but have derived their existence from successive accumulations of decayed trees and other plants. The strata of slime, or mud, which occur in many places, are also recent productions, formed by stagnating waters, or the inundations of rivers. They are not so exactly horizontal, nor so uniformly inclined, as the more ancient strata, produced by the regular motions of the sea. In strata formed by rivers, we meet with river, but seldom with sea-shells; and the few which occur are broken, detached, and placed without order. But, in the ancient strata, there are no river-shells; the sea-shells are numerous, well preserved, and all placed in the same manner, having been transported and deposited at the same time, and by the same cause. From whence could this beautiful regularity proceed? Instead of regular strata, why do we not find the matters composing the earth huddled together without order? Why are not rocks, marbles, clays, marles, &c. scattered promiscuously, or joined by irregular or vertical strata? Why are not heavy bodies uniformly found in a lower situation than light ones? It is easy to perceive, that this uniformity of nature, this species of organization, this union of different materials by parallel strata, without regard to their weights, could only proceed from a cause equally powerful and uniform as the motions of the sea, produced by regular winds, by the tides, &c.

These causes act with superior force under the equator than in other climates; for there the tides are higher, and the winds more uniform. The most extensive chains of mountains are likewise in the neighbourhood of the equator. The mountains of Africa and Peru are the highest in the world, often extending through whole continents, and stretching to great distances under the waters of the ocean. The mountains of Europe and Asia, which extend from Spain to China, are not so elevated as those of Africa and South America. According to the relations of voyagers, the mountains of the north are but small hills, when compared with the mountains of the equatorial regions. Besides, in the northern seas, there are few islands; but, in the torrid zone, they are innumerable. Now, as islands are only the summits of mountains, it is apparent, that there are more inequalities on the surface of the earth near the equator, than in northerly climates.

Those prodigious chains of mountains which run from west to east in the Old Continent, and from north to south in the New, must have been formed by the general motion of the tides. But the origin of the less considerable mountains and hills must be ascribed to particular motions, occasioned by winds, currents, and other irregular agitations of the sea.

Our author next proceeds to answer some questions, which require solution, in consequence of the theory which he has advanced. How, *e. g.* is that earth, which has been inhabited by us and our ancestors for ages, become an immense continent, dry, compact, and removed from the reach of the water, and exalted to such a height above the waters, if it was formerly the bottom of an ocean? In reply to this, and similar enquiries, the author says, we daily observe the sea gaining ground on certain coasts, and losing it on others. We know, that the ocean has a general and uniform motion from east to west; that it makes violent efforts against the rocks and the low grounds which encircle it; that there are whole provinces which human industry can hardly defend from the fury of the waves; and that there are instances of islands which have but lately emerged from the waters, and of regular inundations. History informs us of inundations and deluges of a more extensive nature. Should not all these

These circumstances convince us, that the surface of the earth has experienced very great revolutions, and that the sea may have actually given up possession of the greatest part of the ground which it formerly occupied? For example, let us suppose, that the Old and New Worlds were formerly but one continent, and that by a violent earthquake, the ancient Atlantis of Plato was sunk. What would be the consequence of such a mighty revolution? The sea would necessarily rush in from all quarters, and form what is now called the Atlantic ocean; and vast continents, perhaps those which we now inhabit, would, of course, be left dry. This great revolution might be effected by the sudden failure of some immense cavern in the interior part of the globe, and an universal deluge would infallibly succeed. Such a revolution, however, has happened, and in the opinion of the author, happened naturally; for, if a judgment of the future is to be formed from the past, we have only to attend carefully to what daily passes before our eyes. It is a fact, established by the repeated observation of voyagers, that the ocean has a constant motion from east to west. This motion, like the trade-winds, is not only perceived between the tropics, but through the whole temperate climates, and as near the poles as navigators have been able to approach. As a necessary consequence of this motion, the Pacific ocean must make continual efforts against the coasts of Tartary, China, and India; the Indian ocean must act against the east coast of Africa; and the Atlantic must act in a similar manner against all the eastern coasts of America. Hence the sea must have gained, and will always continue to gain, on the east, and to lose on the west. This circumstance alone would be sufficient to prove the possibility of the change of sea into land, and of land into sea. If such is the natural effect of the sea's motion from east to west, may it not reasonably be supposed, that Asia, and all the eastern continent, is the most ancient country in the world? and that Europe, and part of Africa, especially the west parts of these continents, as Britain, France, Spain, &c. are countries of a more recent date?

But, besides the constant motion of the sea from east to west, other causes concur in producing the effect just mentioned. There are many lands lower than the level of the sea, and are defended by a narrow isthmus of rock only, or by banks of still weaker materials. The action of the waters must gradually destroy these barriers; and, consequently, such lands must then become part of the ocean. Besides, the mountains are daily diminishing, part of them being constantly carried down to the valleys by rains. It is likewise well known, that every little brook carries earth, and other matters, from the high grounds into the rivers, by which they are at last transported to the ocean. By these means the bottom of the sea is gradually filling up, the surface of the earth is approaching to a level, and nothing but time is wanting for the sea's successively changing places with the land.

We shall give, says our author, some certain and recent examples of the changes of sea into land, and of land into sea. At Venice, the bottom of the sea is constantly rising: if the canals had not been carefully kept clean, the moats and city would, long ere now, have formed a part of the continent. The same thing may be said of most harbours, bays, and mouths of rivers. In Holland the bottom of the sea is elevated in many places; the gulf of Zuderzee and the straits of the Texel cannot receive such large vessels as formerly. At the mouth of almost every river, we find small islands, and banks of earth and sand brought down from the higher grounds; and it is incontrovertible, that the sea is constantly dammed up, wherever great rivers empty themselves. The

Rhine is lost in the sands which itself has accumulated. The Danube, the Nile, and all large rivers, after having transported great quantities of slime, sand, &c. never more arrive at the sea by a single channel; they split into branches, the intervals of which consist of the materials which they themselves have transported. Marshes are daily drained; lands, abandoned by the sea, are now plowed and sown; we navigate whole countries now covered by the waters; in a word we see so many instances of land changed into water, and water into land, that we must be convinced of the continual, though slow, progress of such changes in all places. Hence the gulfs of the ocean will in time become continents; the isthmuses will be changed into straits; and the tops of the mountains will be metamorphosed into shoaly rocks in the sea.

The waters, therefore, have covered, and may still cover, every part of the earth which is now dry. In the investigation of the causes of those perpendicular fissures with which the earth abounds, our author's reasoning is as follows.

As the various materials which constitute the different strata were transported by the waters, and deposited in the form of sediments, they would at first be in a very diluted state, and would gradually harden and part with the superfluous quantity of water they contained. In the process of drying, they would naturally contract, and of course split at irregular distances. These fissures necessarily assumed a perpendicular direction; because, in this direction, the action of gravity of one particle upon another is equal to nothing; but it acts directly opposite in a horizontal situation: the diminution in bulk could have no sensible effect but in a vertical line. The contraction of the parts in drying, not the contained water forcing an issue, as has been alleged, is the cause of perpendicular fissures; for it has often been remarked, that the sides of these fissures, through their whole extent, correspond as exactly as the two sides of a split piece of wood. Their surfaces are rude and irregular. But, if they had taken their rise from the motion of water, they would have been smooth and polished.

Perpendicular fissures vary greatly as to the extent of their openings. Some are about half an inch, or an inch, others a foot or two feet; some extend several fathoms, and give rise to those vast precipices which so frequently occur between opposite parts of the same rocks in the Alps and other high mountains. It is plain, that the fissures, the openings of which are small, have been occasioned solely by drying. But those which extend several feet are partly owing to another cause; namely, the sinking of the foundation upon one side, while that of the other remained firm. If the base sinks but a line or two, when the height of the rock is considerable, an opening of several feet, or even fathoms, will be the consequence. When rocks are founded on clay or sand, they sometimes slip a little to a side; and the fissures are of course augmented by this motion. Those large openings, those prodigious cuts, which are to be met with in rocks and mountains, could not be produced by any other means than the sinking of immense subterraneous caverns which were unable longer to sustain their incumbent load. But these cuts or intervals in mountains are not of the same nature with perpendicular fissures: they appear to have been ports opened by the hand of nature for the communication of nations. This seems to be the intention of all large openings in chains of mountains, and of those straits by which different parts of the ocean are connected; as the straits of Thermopylæ, of Gibraltar, &c.; the gaps or ports in Mount Caucasus, the Cordeliers, &c. A simple separation, by the drying of the matter, could not produce this effect: large portions of earth must have been sunk,

swallowed up, or thrown down. See EARTHQUAKE and VOLCANO.

The greatest changes upon the surface of the earth are occasioned by rains, rivers, and torrents from the mountains. These derive their origin from vapours raised by the sun from the surface of the ocean, and are transported by the winds through every climate. The progress of these vapours, which are supported by the air, and transported at the pleasure of the winds, is interrupted by the tops of the mountains, where they accumulate into clouds, and fall down in the form of rain, dew, or snow. At first, these waters descended into the plains without any fixed course; but they gradually hollowed out proper channels for themselves. By the power of gravity, they ran to the bottom of the mountains, and, penetrating or dissolving the lower grounds, they carried along with them sand and gravel, cut deep furrows in the plains, and thus opened passages to the sea, which always receives as much water by rivers as it loses by evaporation. The windings in the channels of rivers have uniformly corresponding angles on their opposite banks; and as mountains and hills, which may be regarded as the banks of the valleys by which they are separated, have likewise sinuities with corresponding angles, this circumstance seems to demonstrate, that the valleys have been gradually formed by currents of the ocean, in the same manner as the channels of rivers have been produced.

Our author concludes from previous reasoning, that the flux and reflux of the ocean have produced all the mountains, valleys, and other inequalities on the surface of the earth; that currents of the sea have scooped out the valleys, elevated the hills, and bellowed on them their corresponding directions; that the same waters of the ocean, by transporting and depositing earth, &c. have given rise to the parallel strata; that the waters from the heavens gradually destroy the effects of the sea, by continually diminishing the height of the mountains, filling up the valleys, and choking the mouths of rivers; and, by reducing every thing to its former level, they will, in time, restore the earth to the sea, which, by its natural operations, will again create new continents, interspersed with mountains and valleys, every way similar to those which we now inhabit. See Buffon's Nat. Hist. vol. i. Eng. Transl. by Smellie.

To this theory, however elegantly displayed and plausibly supported by its ingenious author, several objections have been suggested by those who are conversant with subjects of this nature. The original formation of the earth has been thought hypothetical by all, and by many fanciful. That a torrent of igneous particles should recede from the sun with an accelerated motion, acquire at a certain distance a globular figure, an elliptic motion, and a rotation round its axis, is very improbable, not to say unphilosophical. The formation of mountains by winds and tides, the previous dissolution of terrestrial substances after vitrification by the sun's heat, the analogy between mountains on dry land and islands in the sea, and the confused disposition of the earth's strata, are circumstances pertaining to our author's theory, which, with all his ingenuity, he has not been able satisfactorily to explain and to establish. Indeed, it is altogether incredible that the cavities of the earth should contain a body of water equal in height to the most elevated mountains; nor is it conceivable, how the caverns of the sea, after having raised up a quantity of sand, earth, and shells, should deposit them again in parallel and horizontal beds; nor how torrents should have existed at the bottom of the ocean capable of producing these effects, and of penetrating the strata of mountains, and of dividing them into hills and valleys. Of this theory it has been justly observed, that the

author introduces the action of water to destroy mineral bodies, and afterwards to give them a new arrangement into strata; but that he makes no provision for the consolidation of these strata, nor for their angular elevation; nor has he any adequate means for explaining the unstratified rocks, and the irregularities of the surface of the earth.

Professor Pallas, in a "Dissertation on the Origin and Structure of Mountains," published A.D. 1779, refutes the opinion that they were formed in the ocean. From undoubted facts he attempts to prove, that the great chain of primitive mountains, that binds together the various parts of the globe, could not have been the production of waters. This chain is granite, with a basis of quartz, mixed with spars, mica, and small portions of basalt, scattered without order, and in irregular fragments. This rocky substance, and the sand produced by its decomposition, form the basis of all the continents. Granite, says this author, is never found in strata, or beds, but in blocks, or masses, which exhibit no vestige of organic impression. The secondary and tertiary mountains he supposes to be of a more recent origin:—the former having been produced by the decomposition of granite; and the latter having arisen from the wrecks of the sea, elevated and transported by volcanic eruptions and consequent inundations. See MOUNTAIN.

Of the theory of Mr. Whitehurst, as far as it concerns the deluge, we have already given some account under that article. We shall here introduce some further particulars. This author agrees with many others, in supposing that the earth was originally in a state of fluidity; and hence he concludes, that it has not existed from eternity, as some persons have imagined. Its fluidity he infers from its oblate spheroidal form. In this fluid state, its component parts were uniformly blended together, without any difference of weight, and formed a mass of uniform consistency from the surface to the centre; so that the globe, at its first formation, was unfit for the support of animal or vegetable life. The component parts of this chaos, being heterogeneous, or endued with peculiar laws of elective attraction, similar bodies were disposed to unite and to form select substances of various denominations, as air, water, earth, &c.; and then the chaos was progressively formed into a habitable world. As soon as the oblate spheroidal figure of the earth was completed, the component parts began to act more freely, according to their affinities; that is, the particles of air united to those of air, those of water to water, and those of earth to earth; and from this union resulted their specific gravities. Accordingly, those parts that were the most dense approached towards the centre of gravity, and those of the greatest levity ascended towards the surface; and as air is about 800 times specifically lighter than water, the former was sooner freed from the general mass than the latter, and formed a kind of muddy impure atmosphere, which surrounded the newly formed globe. Water succeeded the air, and encompassed the earth in one immense ocean. In process of time, these elements were purified, and became fit for animal life. From this separation of the component parts, and their aggregation into solid bodies, the following consequences ensued: as the sun and moon were coeval with the chaos, the solids could not uniformly subside from every part of the surface, and become equally covered by water; for as the separation of the solids and fluids proceeded, the tides increased, and removed the former from one place to another without any precise order. Hence the sea became unequally deep; and whilst these inequalities were gradually advanced, dry land at length appeared, and separated the waters which had universally covered the earth. The primitive islands, being thus formed,

formed, became firm and dry, and fit for the reception of animals and vegetables. In this progression of things, several days and nights must have preceded the sun's first appearance in the heavens, or its becoming visible on the fourth day, agreeably to the account of scripture. Previously to the formation of the primitive islands, the ocean was purified and stocked with marine animals; which became enveloped and buried in the mud, by the continual action of the tides: and this was more especially the case with shell-fish, which were least able to disentangle themselves. These marine animals, being thus imbedded in the earth at various depths, bear sufficient testimony, that they were interred at successive periods of time; and that they were created before the formation of the primitive islands and terrestrial animals. The beds occupied by marine shells, the remains of those animals that perished on the spot where they were deposited, were originally the bottom of the ocean. As to the mountains and continents, Mr. Whitehurst apprehends, that they are the effects of subterraneous fire, and produced at a period of time very distant from that of the creation of the world, when the frata had acquired firmness and cohesion, and the tefaceous matter had assumed a stony hardness. For further particulars, see DELUGE.

Mr. Kirwan (Irish Transf. vol. vi.) agrees with many other writers, in supposing that the primæval earth, at least as far as respects its superficial parts, to a certain depth, was in a soft or liquid state. This he infers from its present spheroidal shape, and also from some geological observations, which he has adduced. Its interior and more central parts, he conceives, contained, at the time of its creation, and for many subsequent centuries, immense empty caverns, which consisted of materials of sufficient solidity to resist the pressure of the enormous mass of liquid substance that rested upon them. The liquidity of the superficial parts must have proceeded either from igneous fusion or solution in water. The former cause he rejects, and adopts the latter, which he endeavours to establish. The aqueous fluid, which served as a menstruum for this solution, was heated, as he imagines, to at least 33 degrees, and possibly much higher; and it contained the eight generic earths, all the metallic and semi-metallic substances now known, the various simple saline substances, and the whole tribe of inflammables, solid and liquid, variously distributed. Hence he concludes, that elementary fire, or the principle of heat, must have been coeval with the creation of matter; and that the general properties of gravitation and elective attraction may be supposed of equal date. The proportion, as he supposes, of the different materials contained in the chaotic fluid, to each other, was nearly the same as that which they at present bear to each other; the siliceous earth being by far the most copious, next to that the ferruginous, then the argillaceous and calcareous, and, lastly, the magnesian, barytic, Scottish, and Jargonian, in the order now named, the metallic substances (except iron) most sparingly. M. Buffon and Dr. Hutton, however, have excluded calcareous earth from the number of the primæval, asserting that the masses of it which we now observe proceed from shell-fish. Mr. Kirwan replies, that the supposition of shell-fish, or any animals, possessing the power of producing any simple earth is unfounded; and that before the existence of any fish, the stony masses that enclose the bafon of the sea must have existed, and among these there is not any one in which calcareous earth is not found. In a fluid constituted like that just mentioned, it is evident, says our author, from the laws of elective attraction, that the various solids diffused through it must soon have coalesced in various proportions, according to the laws of this attraction, and the presence or proximity

of the ingredients, and thus have crystallized into different groups, which descended to and were deposited upon the inferior solid kernel of the globe. In those tracts, in which the siliceous, and next to it the argillaceous, earth most abounded (such tracts being the most extensive,) granite and gneiss seem to have been first formed, in the manner which the author has explained. The high degree of heat, arising from different concurring causes which existed in the earth, disengaged all the oxygen contained in the contiguous chaotic fluid; and this uniting partly with more metallic iron, partly with the sulphurated and partly with the carbonic and bituminous substances, must have occasioned a stupendous conflagration, the effects of which may well be supposed to have extended even to the solid basis on which the chaotic fluid rested, and to have split it to an unknown extent. These volcanic eruptions were attended with important consequences: the first must have been the diffusion of a considerable heat through the whole mass of the chaotic fluid, by which means the oxygen and nephitic acids dispersed through it must have been extricated, and thus gradually formed the atmosphere. The second production was that of fixed air from the union of oxygen with the ignited carbon; and this at first rose into and diffused itself through the atmosphere; but in proportion as the chaotic fluid cooled, it was gradually absorbed by it. This absorption occasioned the precipitation, and more or less regular crystallization of the calcareous earth; the greater part of which, being much more soluble than the other earths, still remained in solution, after the others had been for the most part deposited.

The immense masses concreted and deposited on the interior nucleus of the earth formed the "primitive mountains." The formation of "plains" is easily understood: for in the wide intervals of distant mountains, after the first crystallized masses had been deposited, the solid particles still contained in the chaotic fluid, but too distant from each other's sphere of attraction to concrete into crystals, and particularly those that are known to be least disposed to crystallize, and also to have least affinity to water, were gradually and uniformly deposited. Of this nature argillaceous particles are known to be, intermixed, as we may well imagine, with a large proportion of siliceous and ferruginous particles, of all the most abundant, and some particles of the other earths: and by these compound and slightly concreted earths, the surface of plains was originally covered. In process of time, these earths received an increase from the decomposition of primitive mountains, which was an event of much posterior date.

The next important event, necessary to fit the globe for the reception of land animals, was the diminution and recess of the chaotic fluid, in the bosom of which the mountains were formed, and the consequent disclosure of the dry land. By the operation of the preceding volcanoes, the bed of the ocean was scooped, most probably in the southern hemisphere: but no change or transposition of the solid materials deposited from the chaotic fluid could lower its level, unless the inferior nucleus of the globe could receive it within its hollow and empty caverns. This admittance it gained through the numerous rifts occasioned by the antecedent fires: at first rapidly, afterwards more slowly, in proportion as the perpendicular height of the fluid was diminished; and thus the emerged continent, consisting of mountains and plains, was gradually laid bare and dried, and, by drying, consolidated. The disclosure of the actual continents appears to have been gradual. The tracts at first uncovered were those whose height over the present seas amounts to 8500 or 9000 feet, or more. This height comprehends most of the eastern summits of Siberia, between latitude 49°

and 55°, and of the extensive regions of Great Tartary, Tibet, the desert of Coby or Chamo, and China, reaching in some places to latitude 35°, and extending in the northern parts from the sources of the Irisk, long. 95°, and in the more southern from the heads of the Ganges and Burram-pooter, long. 86°, Hoanho and Porentho to long. 190° at the east, and perhaps still farther into the unknown parts of Eastern America. In Europe, only the summits of the Alps, Pyrenées, and of a few other mountains, were uncovered; but in America, the narrow but long chain of the Cordeliers must have raised its summits far above the ocean.

When the level of the ancient ocean was lowered to the height of 8500 or 9000 feet, and not before, it began to be flocked with fish. That the creation of the fish, says Mr. Kirwan, was subsequent to the emergence of the tracts just mentioned, and to the reduction of the waters to the height now stated, is proved by the observations of all who have visited those countries. In these elevated tracts, no marine shells or petrifications are found in the body of any mountain, nor in any stone, not even in lime-stone, though it abounds particularly about the sources of the Amour. Hence our author concludes, that these tracts, which, like all others, were formed in the bosom of the primitive ocean, were uncovered before the creation of fish; and since they contain lime-stone, that this stone does not necessarily and universally originate from comminuted shells, as Buffon and others have advanced. No petrifications or shells are incorporated in the rocks or strata, that form several other lofty mountains. This is attested by De la Perouse with respect to the Pyrenées, which, nevertheless, are mostly calcareous. Nor are any found in Santo Velino, the highest of the Appenines, the height of which is 8300 feet; whereas they abound in those that are lower. In the Savoyan Alps, Salenche, Saleve Mole, the Dole, all of which are calcareous, but below the height of 7000 feet, contain petrifications; but the Buet, which is also for the greater part calcareous, but whose height exceeds 10,000 feet, contains none. (Sausure, *passim*.) After this elevated tract of the globe had been uncovered, there is no reason to suppose that it long remained divested of vegetables or unstocked with animals, as it was fitted to receive them. The author proceeds to adduce several reasons, which, in his opinion, prove, that the retreat of the sea from the lower parts of our present continents was gradual, and not fully effected till after the lapse of several centuries. (See CONTINENT and MOUNTAIN.) This retreat of the sea continued, as our author imagines, until a few centuries before the deluge. Its cessation, long before this catastrophe took place, he infers from the hardness which the mountains must have acquired, to withstand the shocks they must then have undergone. To acquire this hardness a long period of time was necessary, both for their desiccation and the infiltration of those particles, to which the strata of secondary mountains owe their solidity. Our author closes his theory of the primitive earth with an attempt to accommodate it to the Mosaic account of the creation. For his application of it to the deluge, we refer to that article.

We now proceed to give an account of two other theories of the earth, which have superseded most of the others already recounted, and each of which has had its learned and zealous advocates. The first of these is that of Dr. James Hutton, the detail of which occupies a considerable part of the first volume of the Edinburgh Transactions. The author begins an elaborate development and explanation of his theory by observing, that in order to acquire a comprehensive view of the mechanism of the globe, by

which it is adapted to the purpose of being a habitable world, it is necessary to distinguish three different bodies, which compose the whole, *viz.* a solid body of earth, an aqueous body of sea, and an elastic fluid of air. The central body of the globe is supposed, without sufficient reason, as our author imagines, to be solid and inert; the fluid body of water, which by gravitation is reduced to a spherical form, and by the centrifugal force of the earth's rotation to an oblate figure, is essential to the constitution of the world, as it affords the means of life and motion to animals of various kinds, as it is the source of growth and circulation to the organized bodies of the earth, and as it is the receptacle of our rivers, and the fountain of our vapours; the irregular body of land raised above the level of the ocean, although it be the smallest part of our globe, is the most interesting, as plants grow on its surface, and animal life, and also vegetation, are sustained by it. The surrounding body of atmosphere is no less necessary than the other parts, in a variety of respects sufficiently obvious, and which it is needless for us to recite. Having thus described the mechanism of the globe, our author proceeds to enumerate some of those powers by which motion is produced and activity imparted to the mere machine.

These are the projectile or progressive power, that of gravitation, whence it derives its rotatory motions; the influence of light and heat, of cold and condensation; and the powers of electricity and magnetism. Moreover, a solid body of land, our author observes, could not have answered the purpose of a habitable world, without a soil adapted to the growth of plants; and this soil consists merely of the materials that are collected from the destruction of the solid land. The surface of this land, inhabited by man, and covered with plants and animals, is made by nature to decay, in dissolving from that hard and compact state in which it is found below the soil; and the soil itself is necessarily washed away by the continual circulation of the water running from the summits of the mountains towards the general receptacle of that fluid; thus the heights of our land are levelled with the shores; our fertile plains are formed from the ruins of the mountains; and the moveable materials, after previous migration, are carried forwards to the unfathomable regions of the ocean. As the vegetable soil is thus constantly removed from the surface of the land, whatever may be the supply which it receives from the dissolution of the solid earth, the land gradually tends to destruction, which, in a course of ages, is inevitable. In order to counteract this destructibility, our author suggests, that in the constitution of this world there may be a reproductive operation, by which a ruined constitution may be again repaired, and a duration and stability procured to the machine, considered as a world sustaining plants and animals. Although, according to Dr. Hutton, the Mosaic account places the commencement of the existence of man upon the earth at no great distance; and we have no document in natural history which attributes a high antiquity to the human race; yet this is not the case with regard to the inferior species of animals, particularly those which inhabit the ocean and its shores. Accordingly we find also in the relics of sea animals that are discovered in the solid body of our earth evidences of an earlier existence than that to which the Mosaic history seems to trace the origin of our earth. We are thus led to represent our author's sentiments, with regard to the formation of the terrestrial globe. The solid parts of the globe, he says, are, in general, composed of sand, of gravel, of argillaceous and calcareous strata; or of the various compositions of these, with other substances. Sand is separated and sized by streams and currents; gravel is formed

By the mutual attrition of stones agitated in water; and marley or argillaceous strata have been collected, by subsiding in water with those watery substances had been floated. Hence he is led to infer, that so far as the earth is formed of these materials, the solid body would appear to have been the production of water, winds, and tides. But that which renders the original of our land clear and certain, in his opinion, is the immense quantity of calcareous bodies, which had belonged to animals, and the intimate connection of these masses of animal production with the other strata of the land. Accordingly he proceeds to prove, that all those calcareous bodies, from the collection of which the strata were formed, have belonged to the sea, and were produced by it. For which purpose he alleges, that we find the traces of marine animals in the most solid parts of the earth; and, therefore, these solid parts must have been formed after the ocean was inhabited by those animals, which belong to that fluid medium. Before he investigates the natural history of these solid parts, and the manner in which they were formed, he undertakes to shew that all the masses of marble and limestone are composed of the calcareous matter of marine bodies. To this purpose, he observes, that there are few masses of marble or limestone in which we may not find some of those objects, which indicate the marine origin of the mass. Besides, in these calcareous strata, which are evidently of marine origin, there are many parts that are of a sparry structure, or, in other words, the original texture of these beds, in such places, has been dissolved, and a new structure has been assumed, which is peculiar to a certain state of the calcareous earth. This change is produced by crystallization, in consequence of a previous state of fluidity, which has so dispersed the concreting parts, as to allow them to assume a regular shape and structure proper to that substance. Moreover, in all the regions of the earth there are huge masses of calcareous matter, in that crystalline form or sparry state, in which, perhaps, no refuge can be formed of any organized body, nor any indication that such calcareous matter had belonged to animals: but, as in other masses, this sparry structure, or crystalline state, is evidently assumed by the marine calcareous substances, in operations which are natural to the globe, and which are necessary to the consolidation of the strata, it does not appear that the sparry masses, in which no figured body is formed, have been originally different from other masses, which being only crystallized in part, and in part still retaining their original form, bear ample evidence of their marine origin. From this kind of reasoning he concludes, that all the strata of the earth, both those consisting of hard calcareous masses, and others superincumbent upon these, have had their origin at the bottom of the sea, by the collection of sand and gravel, of shells, of coralline and crustaceous bodies, and of earths and clays, variously mixed, or separated and accumulated. There is, however, a part of the solid earth which is excluded from the result of this reasoning, and this part consists of certain mountains and masses of granite, which are thought to be older in their formation, and are very rarely found superincumbent on strata, which must be acknowledged as the productions of the sea. We thus obtain solid land, the greater part of which, if not the whole, was originally composed at the bottom of the sea; but this, our author says, is not the world which we inhabit; and therefore the question is, how such continents as we have upon the globe could be elevated above the level of the sea. This question he proceeds to resolve, by shewing, first, how this change could not be effected, and then, by stating the mode in which he conceives the strata of the globe formed at the bottom of the sea were consolidated.

In this operation the general agents are fire and water. Rejecting, after a minute examination of its effect on various substances, and in different circumstances, the agency of water, he adopts that of fusion by heat, and examines its effect on the siliceous and calcareous strata, which are the prevailing substances on the globe, all the rest being, in comparison of these, as nothing; or unless they be the bituminous or coal strata, there is hardly any other which does not necessarily contain more or less of one or other of these two substances. If, therefore, it can be shewn, that both of these two general strata have been consolidated by the simple fusion of their substance, no doubt will remain with regard to the nature of that operation, which has been carried on at great depths of the earth, inaccessible to human observation. Our author, therefore, proceeds to prove, that these strata have been consolidated by simple fusion, and that this operation is universal, in relation to the strata of the earth, as having produced the various degrees of solidity or hardness in these bodies. Having adduced arguments and facts in proof of the first position, Dr. Hutton exemplifies the second, in the case of chalk, which is naturally a soft calcareous earth, but which may be also found consolidated in every different degree. Through the middle of the isle of Wight there runs a ridge of hills of indurated chalk. This ridge runs from the isle of Wight directly west into Dorsetshire, and passes by Corfe-castle towards Dorchester, or beyond that place. The sea has broken through this ridge at the west end of the isle of Wight, where columns of the indurated chalk remain, called the Needles: the same appearance being found upon the opposite shore in Dorsetshire. In this field of chalk, we find every gradation of that soft earthy substance to the most consolidated body of this indurated ridge, which is not solid marble, but which has lost its chalky property, and has acquired a kind of itony hardness. This cretaceous substance may be found in its most indurated and consolidated state in the north of Ireland, not far from the Giants' Causeway. This body, which was once a mass of chalk, is now a solid marble. Then, if it be by means of fusion that the strata of the earth have been, in many places, consolidated, we must conclude, that all the degrees of consolidation, which are indefinite, have been brought about by the same means. The author afterwards shews, that granite, which forms a part of the structure of the earth, is consolidated by means of fusion, and in no other mode. The author proceeds to argue, that if strata have been consolidated by means of heat, acting in such a manner as to soften their substance, then, in cooling, they must have formed rents or separations of their substance, by the unequal degrees of contraction, which the contiguous strata may have suffered. There is no appearance more distinct, than that of the perpendicular fissures in strata. They are generally known to workmen by the terms of veins, or backs and cutters; and there is no considerable stratum without them. If it be by means of heat and fusion that strata have been consolidated, then, in proportion to the degree of consolidation they have undergone from their original state, they should, *ceteris paribus*, abound more with separations in their mass; and this conclusion is fully justified by appearances.

The author concludes upon the whole, from chemical principles, capable of demonstration, that all the solid strata of the globe have been condensed by means of heat, and hardened from a state of fusion. The proposition also admits, he says, of proof upon principles which are purely mechanical.

Our author's next object is to shew by what operation masses of loose materials, collected at the bottom of the sea,

were raised above its surface, and transformed into solid land. The power of heat for the expansion of bodies is, so far as we know, unlimited; but by the expansion of bodies placed under the strata at the bottom of the sea, the elevation of these strata may be effected; and therefore the question to be resolved is, how far have we reason to conclude, that this power of expansion has been employed in the production of this earth above the level of the sea? The examination of natural appearances will serve to evince the elevation of strata by the power of heat above the level of the sea. The strata formed at the bottom of the ocean are necessarily horizontal, or nearly so, and continuous in their horizontal direction or extent: If, therefore, these strata are cemented by the heat of fusion, and elevated by an expansive power acting from below, we may expect to find every species of fracture, dislocation, and contortion, in these bodies, and every degree of departure from a horizontal towards a vertical position. The strata of the globe are, accordingly, found in every possible position: from horizontal, they are often found vertical: from continuous, broken and separated in every possible direction: and from a plane, bent and doubled. They could not have been thus originally formed; and the power that has produced this change cannot have been inferior to that which might have been required for their elevation from the place in which they had been formed. Natural appearances confirm this reasoning; and the inference is, that the land on which we dwell has been elevated from a lower situation by the same agent, which had been employed in consolidating the strata, in giving them stability, and preparing them for the purpose of the living world. This agent is matter actuated by extreme heat, and expanded with amazing force. It is also a power of the same nature that has been employed in forming, by fracture and dislocation, mineral veins. By tracing the effects of volcanoes, and by a variety of other investigations, which we cannot pursue, our author deduces this general conclusion, that all the continents and islands of this globe have been raised by means of fire above the surface of the ocean; and, therefore, that almost the whole of what we see on this earth, was originally formed at the bottom of the sea. From the consideration of the materials which compose the present land, Dr. Hutton thinks there is reason to conclude, that during the time this land was forming, by the collection of its materials at the bottom of the sea, there had been a former land containing materials similar to those which we find at present in examining the earth. We may also conclude, he says, that there had been operations similar to those which we now find natural to the globe, and necessarily exerted in the actual formation of gravel, sand, and clay: and, moreover, that there had been in the ocean a system of animated beings, which propagated their species, and which have thus continued their respective race to this day. In order to be convinced of this truth, we have merely to examine the strata of our earth, in which we find the remains of animals; of every genus now existing in the sea, and probably every species, and perhaps some species with which we are not now acquainted. There had been also, our author supposes, a world of plants as well as an ocean replenished with living animals.

Having ascertained the state of a former earth, in which plants and animals had lived, as well as the gradual production of the present earth composed from the materials of a former world, it must be evident, as Dr. Hutton supposes, that here are two operations, which are necessarily consecutive. The formation of the present earth necessarily involves the destruction of continents in the ancient world; and by pursuing in our minds the natural operations of a

former earth, we clearly see the origin of that land, by the fertility of which, we, and all the animated bodies of the sea, are fed. It is, in like manner, that, contemplating the present operations of the globe, we may perceive the actual existence of those productive causes, which are now laying the foundation of land in the unfathomable regions of the sea, and which will, in time, give birth to future continents.

Upon our author's principles of decay and renovation, there may have been an indefinite succession of worlds in past time, and there may be a similar succession in future time. The same process, or series of operations, may be repeated without end, and may have taken place for ages past. He observes, indeed, that our earth is composed of the materials, not of the earth which immediately preceded the present, but of the earth, which we may consider as the third in ascending backwards, and which had existed before the land that was above the surface of the sea, while our present land was beneath the water of the ocean; so that we have three distinct successive periods of existence, and each of these, in our measurement of time, having an indefinite duration. The result of our author's inquiry, as he expressly says, is that, in the succession of worlds, "we find no vestige of a beginning,—no prospect of an end." The principles of this theory have been clearly explained, and elegantly illustrated by professor Playfair, who has also successfully combated the charge of impiety, which Dr. Hutton's opponents endeavoured to attach to his opinions. In connection with this system, we should have introduced some remarks on volcanoes from sir William Hamilton, and others; but having extended this article far beyond our customary limits, we must refer to VOLCANO.

Another theory, which is now held by many in high estimation, is called the "Neptunian," or "Wernerian," from professor Werner of Freybourg, one of the most distinguished mineralogists of the present day, and a zealous supporter of this theory. He professes to banish every thing hypothetical, and to deduce, from accurate observation, such conclusions as seem to be unavoidable. He sets out, however, in conformity to most other theorists, with conjecture, and states, that the earth, to a considerable depth, has been once in a state of fluidity, produced, not by fire, as the Huttonians suppose, but by aqueous solution. The outlines of the system, founded on this principle, are as follow: 1. The superficial parts of the earth, to a certain depth, must have been originally in a soft or liquid state, which may be inferred from its present spheroidal shape, and from a variety of geological observations. 2. That, at the time of the creation, and for many centuries after, the interior and more central parts contained immense empty caverns; and, consequently, consisted of materials sufficiently solid to resist the pressure of the enormous mass of superincumbent liquid substance. 3. The materials of which the strata of the earth are composed, were at one period dissolved, or suspended in water; and from this fluid they had successively consolidated in various combinations, partly by crystallization, and partly by mechanical deposition:—granite, as the basis on which the greatest number of strata rest, having been first formed, and the other primitive strata in due order, by precipitations chiefly chemical. 4. From the period of the formation of these strata, the water, which covered the earth, began to decrease in height, by retiring gradually into cavities in the internal parts of the earth; and, during this process, other precipitations were effected, and the intermediate strata, or strata of transition, were formed, of which siliceous schist and transition are the principal. 5. When the water was still abating, the mechanical action of its mass on the strata already formed, occasioned in them a partial disintegration;

dilintegration; the materials from this source, together with the remaining part of the matter originally dissolved, by their precipitation and consolidation, formed the secondary strata, which are generally arranged in horizontal beds, and abundant in organic remains. 6 During the gradual consolidation of these strata, rents and cavities opened, into which the water, holding various substances in solution, retired; hence, the formation of mineral veins. 7. Volcanic fires and eruptions have produced some inconsiderable and partial changes on the surface of the earth. See PAYFAIR'S *System of Geography*, vol. i. See DELUGE, FOSSILS, SHELLS, STRATA, and VOLCANO.

EARTH, in *Agriculture and Gardening*. See SOIL, LAND, &c.

EARTH, *Untried*, the soil, or earth, which is six or seven inches deep, where neither spade nor plough has reached. This is greatly recommended by Mr. Lawrence, for amendments and improvements, both in the fruit and kitchen garden. He assures us, from his own experience, that no kind of compost, made with art, exceeds it; and adds, that if the choicest fruit-trees be planted herein, they presently discover an uncommon healthfulness and vigour; and that, if any tender sort of annuals be discreetly sown in this earth, made fine by sifting, their looks, colour, &c. soon discover that they like the soil. Melons and cucumbers need no other compost but this untried earth; and asparagus itself will prosper, at least, as well in this untried earth, if laid a foot and a half deep, as with all the usual expence of dung; though for the tenderer flowers, and exotics, this earth is not found to have any extraordinary excellencies. For annual plants, produced from seed, a coat of this untried earth, two inches deep, may suffice: on other occasions, a greater depth is required.

EARTH, in *Chemistry and Philosophy*. The ancient naturalists imagined, that all material substances were ultimately resolvable into four simple bodies, air, fire, water, and earth, which on this account were called the four elements. The empyreum, or external sphere of the visible world, in which the sun and the other stars perform their revolutions, was supposed to be the peculiar seat of fire: the region, interposed between the earth and the empyreum, was called the atmosphere, the superior part of which, (or the æther,) was considered as the peculiar residence of the element of air, while the lower portion, in which the clouds float, was regarded as the natural situation of the element of water. The earth, the lowest and innermost of these spheres, was supposed to be the great reservoir of elementary earth. The natural characters of the supposed elements were imagined to be analogous to the above hypothetical distribution of them. Thus fire was considered as the active principle of the universe, the source of animal and vegetable life, the great cause of change and renovation. Earth, on the contrary, was regarded as the principle of fixity, hardness, and solidity; as that to which the persifery of the various forms of animated and inanimate beings was owing. The opinions of the ancient naturalists were received with respect and submission by the early chemists, whose researches they directed, and from whom they derived, in return, the support of experimental arguments. In proof of the first it may be stated, that the universal method of analysis adopted by the old chemists was, the exposure of the substance operated on to different degrees of heat, from which circumstance, indeed, they were familiarly known by the appellation of *Philosophers by fire*. Of the nature of the experiments by which the above-mentioned properties of earth were supposed to be demonstrated, the following may serve as a specimen. If a vegetable or animal is exposed to

the action of an open fire, those of its component parts that are volatilizable or combustible, are resolved into flame and vapour, and air, and there remains behind a white, dry, fixed, pulverulent, earthy matter, to which, as the only permanent part of the subject of experiment, its form was attributed.

As chemical processes came to be multiplied, it was found convenient to classify the earths; whence arose the distinction of metallic earths, or calces, (which were thought to be ultimately resolvable into one general metallic or *mercurial* earth,) alkaline earths, and earths proper, that is, such as were neither alkaline nor metalizable. The metallic earths were found to differ remarkably from the rest by their superior specific gravity, till the discovery of barytes took place; the high specific gravity of which occasioned many attempts, but wholly without success, to reduce it to the metallic state. This, however, was not considered as absolutely conclusive of the non-metallic nature of barytes, and in the opinion of many, was fully counterbalanced by the positive argument of its great weight. When Lavoisier published his theory, he stated, as an analogical inference, the probability that the earths would one day be proved to be metallic oxyds; and soon after, the actual metalization of barytes and some of the other earths was announced by M. M. Ruprecht and Tondi. On the repetition, however, of their experiments by Klaproth and Savarese, the supposed discovery was clearly proved to be an entire mistake; the metallic globules which were produced in the experiments alluded to being only phosphuret of iron, and derived from the crucible in which the fusions were performed.

Of late years the hypothesis of the metallic nature of the earths was entirely abandoned, and the only innovation on the old arrangement was, the detaching of the alkaline earths, barytes, strontian, lime, and magnesia, and placing them with the other alkalies; and leaving flint, zircon, alumine, glucine, and yttria, to form the class of earths proper, characterized by infusibility in fire, infusibility in water, the absence of acid or alkaline properties, and irreducibility to the metallic state.

The recent splendid discoveries of professor Davy on electro-chemical agency, have, however, disclosed a multitude of highly important facts, of which one of the most interesting is, that not only the earths, but the alkalies themselves, are compounds of peculiar metallic bases with oxygen, in consequence of which the class of earths, heretofore distinguished by negative properties, is done away. See ELECTRICITY and METALS.

EARTH, *Animal*, is phosphet of lime, of which the hard parts of the warm blooded animals are principally composed, and which remains behind after the dissipation by combustion of the other ingredients.

EARTH of *Dew*, an earth much valued by many former chemical experimenters, and prepared in the following manner: a large quantity of dew is to be collected, and set in a wooden vessel, in a cool shady place, covered with a canvas, to keep out dust and flies, there will in three weeks, and sometimes longer, come out a putrefaction in the liquor. During the time of this putrefaction, certain films are daily formed on the surface of the liquor, and these falling down to the bottom, one after the other, form, by degrees, a sediment of a sort of mud. This is to be thrown away, and the dew, when separated from it, is to be filtered clear, and evaporated to a dryness, the remainder is a greyish earth, which is the true earth of dew: this is very light and friable, and is of a foliated fracture in the mass, looking like so many leaves of brown paper, spread very thin and even over one another. Phil. Trans. N^o 3.

This earth, exposed to a smart fire, loses its foliated texture, and runs into a mass, resembling a mixture of salt and brimstone melted together, but it is not at all inflammable. This, ground on a levigating stone, tinges the water to a purplish colour. A pound of this earth, properly treated by calcination and elixivation, will yield an ounce of a pure and white salt, somewhat resembling nitre. The chemists have been at great pains to procure this earth, but they do not seem yet to have made any very important use of it; and in all probability it is no other than that common spar which we know to be contained in all water, and which encrusts the sides of our tea-kettles, and other vessels, in which water is often boiled. We know, by manifold instances, that spar is rarifiable into vapour with water, and therefore it would be a greater wonder if the dew were found not to contain it, than that it does.

EARTH, in *Geography*, denotes the terraqueous globe, which we inhabit, consisting of land and water; the surface of which is diversified by countries and seas of various boundaries and dimensions. On the earth, in this view of it, are described several circles, which either properly belong to the earth itself, or which are transferred to it from the visible heavens. These circles are the *Equator*, *Ecliptic*, *Tropics*, *Polar circles*, *Meridians*, *Horizon*, *Parallels*, &c. which see respectively. See also *GLOBE*. In order to estimate the proportion of the land to the water on the surface of the earth, so far as discoveries had been extended in his time, Dr Long took off the paper from a terrestrial globe, and, separating the land from the sea, weighed the parts respectively; and in this way he found the proportion of the land to the sea to be as 124 to 349. This conclusion, which after all must be very vague and unsatisfactory, would have been more accurate, if the land were separated from the sea before the paper was palled on the globe. The paper of modern globes, including all the modern discoveries, would afford a more just inference. The seas and unknown parts of the earth, independent of some late discovered islands and countries, are said, in consequence of a measurement of some of the best maps, to contain 160,522,026 square miles; the inhabited parts, 38,990,569; Europe, 4,456,065; Asia, 10,768,823; Africa, 9,654,807; America, 14,110,874; in all, 199,512,595, being the number of square miles on the whole surface of our globe. In consequence of recent discoveries, it has been concluded that more than two-thirds of the surface of the terrestrial globe are covered with water. (See *OCEAN and SEA*.) EARTHS of *Mineral Waters*. All mineral waters contain earth of some kind, though very different in quantity and in nature. There are found, in different waters, of very different colours and appearances, some white, some grey, some yellowish, some reddish, and some brown. They are also as different in their qualities as in their form; some of them are soluble in acids, others are not so; some fusible in the fire; others not; and some retain their natural colour, after burning; others change it in the fire. By this we learn, that some are marley, others argillaceous, others ochreous, and some sandy; others there are which are produced by the

concretion of certain juices, saline or sulphureous, and others not so. Some are simply mineral, others are metallic. And as many of these are very different from any of the known earths, even in their pure and separate state, they are yet much less distinguishable when mixed one with another, as they very frequently are in the waters of even our common springs, much more so in the mineral medicinal ones.

The simple infusions of certain sulphureous mineral earths may remarkably alter the waters of wells and fountains, without having any thing of these earths remaining, after their distillation; in the same manner as nothing is separable, by art, from certain liquors, rendered emetic by antimony. The hot mineral waters may contract some alteration from the sulphureous and bituminous matters which they meet with in their course; for these substances all contain subtle salts, which hot water may take up, and carry away with it. EARTH-Bags, *Sacks à Terre*, in *Fortification*. See *SACKS of Earth*, and *SAND-Bags*.

EARTH-Banks, in *Husbandry*, &c. are a very common fence about London, and in several other parts of England. Where stones are not to be had cheap, these are to be preferred to all other fences, both for soundness and duration.

The best manner of making them is this: dig up some turf in a grassy place, a spit deep, or nearly to the breadth of the spade, and about four or five inches thick; lay these turfs with the grass outward, even by a line on one side, and on the backside of these lay another row of turf, leaving a foot space of solid ground on the outside, to prevent the bank from slipping in, if it should be any way faulty. On the outside of this make a ditch, or else let the sides be lowered both ways with a slope two feet deep, and there will be no pasture lost by the fence, because it will bear grass on both sides.

The earth that is dug out of the ditches, or from the slopes, must be thrown in between the two rows of turf, till the middle is made level with the rest. Then lay on two more rows of turf in the same manner, and with more of the earth fill up, and make level as before. Let this method be continued till the bank is raised four feet high, or more if necessary, only observing, that the higher it is to be carried, the wider the foundation must be made. As the bank is carried up, the sides must not be raised perpendicular, but sloping inward both ways, so that at the top it may be about two feet and a half wide. This sort of fence, when made with less care, and faced with clay, is left naked, and serves very well in some places; but when it is thus managed with the turf, the joinings of the several pieces are hid in a little time, by the growth of the grassy part of the turf on each side; and it makes a beautiful fence, of as green and pleasant a colour as the rest of the field.

The great improvement upon this plan, is the planting quicksets, or young white-thorn plants, in the middle of the top of the bank. The earth on each side of these may be raised up with a sort of wall, and the rain that falls wholly preferred for the plants. This plenty of water, and depth of fine earth, make the young plants grow quicker and more vigorously than in any other way; and the most beautiful of all hedges is formed in this manner. When this sort of hedge is young, there must be placed on each side of it a short dry hedge, of about a foot high, to keep the sheep from

from cropping the young plants, but this may be taken away after a little time.

There is one caution necessary in regard to the making of these banks, which is, that they must never be made in a very dry season, because if much rain should follow, the earth of the bank would swell and burst out, or spoil the shape of the bank; but if this should happen, it is easily enough repaired. This is beautiful fence may be made at a smaller price than those unaccustomed to these things may imagine. In good digging ground, where men work for fourteen pence a day, it may be made and planted with quick for two shillings a pole. It may be made proper for the keeping in of deer, only by the small addition of planting, at every eight or ten feet distance, a post a little slanting, with a mortise in it: let this stand about two feet above the bank, and into the mortise all along, put a rail made of a bough of any tree, no deer will ever go over this, nor can they creep under it, as they often do when a pale tumbles down. The quick, on the top of this bank, may be kept clipped, and will grow very thick, and afford the best shelter for cattle of any fence in use with us. Mortimer's Husbandry.

EARTH-Pitch. See *BITUMEN*.

EARTH-Pucerons, in *Natural History*, a name given by authors to a species of puceron very singular in its place of abode. In the month of March, if the turf be raised in several places in any dry pasture, there will be found, under some parts of it, clusters of ants, and, on a further search, it will be usually found, that these animals are gathered about some pucerons of a peculiar species. These are large, and of a greyish colour, and are usually found in the middle of the clusters of ants. See *PUCERON*.

The common abode of the several other species of pucerons is on the young branches or leaves of trees; as their only food is the sap or juice of vegetables, probably these earth kinds draw out those juices from the roots of the grasses and other plants, in the same manner that the others do from the other parts. The ants that conduct us to these, are also our guides where to find the greater part of the others; and the reason of this is, that as these creatures feed on the saccharine juices of plants, they are evacuated from their bodies in a liquid form, very little altered from their original state; and the ants, who love such food, find it ready prepared for them, in the excrements which these little animals are continually voiding. EARTHING, in the general sense. See *INTERMENT*.

EARTHING, in *Agriculture and Gardening*, denotes the covering of vines, clemery, and other shrubs and plants with earth.

EARTHQUAKE, in *Natural History*, is a sudden concussion of some part or other of the earth, generally accompanied with unusual noises, and productive of various effects, such as the emission of flames, water, vapours, &c.; and agitating the ground in various degrees, from the slightest shocks to the most tremendous convulsions, and the overthrow of buildings, towns, rocks, mountains, and very extensive tracts of land.

It has been justly observed, that of all the phenomena of nature, none is so apt to impress the human mind with terror

as an earthquake. Its unlimited, its sudden, its dreadful effects have no certain remedy, or no refuge to the terrified individuals. Seneca, speaking of it, says, "A tempestate ros vindictat portus: nimborum vim diffusam, et sine fine cadentes aqua; tectis propellunt: fugientes non sequitur incedendum: aetheris tonitrua et minas cæli, subterranea: damus, et de-fecti in altum specus remedia fuit. Nullum malum sine effugio est. Hoc malum latissimè patet, inevitabile avdum, publicè noxium. Non enim domos solum, aut familias, aut urbes singulas haurit, sed gentes totas, regionesque subvertit; et modo ruinis operit, modo in altam voraginem condit." *Quæst. Nat. lib. vi.*

There is no country upon this globe, whether continent or island, which is not more or less subject to earth quakes. Even the sea is affected by them. And the histories of all times record an immense series of earthquakes, which has hardly left a month, a week, or perhaps a single day, unmarked by their devastations in the annals of the world. But though history speaks of the frequency, of the variety, and of the destruction, of earthquakes; yet no certain information respecting their origin has been transmitted to us from the experience of our predecessors, whose knowledge of the subject seems not to have amounted merely to conjectures and vague hypotheses. In short, we know nothing certain respecting the cause or causes which produce the earthquakes; neither are we acquainted with any certain indications of their going to take place, nor with any mode of averting them. Yet these are the objects to which the industry of philosophers must be attentively directed; and for the attainment of which, all the facts that have been more authentically recorded should be carefully collected, compared, and reflected upon. In conformity to this, we shall, in the first place, state such accounts of particular earthquakes as are more likely to convey a competent idea of their variety, their powers, their extent, &c.; principally dwelling upon those, which, in consequence of their being of a more recent date, have been more circumstantially described by eye-witnesses, some of whom are still living. We shall afterwards examine the hypotheses that have been offered in explanation of the phenomena; and shall endeavour to place the philosophical part of the subject under a concise and comprehensive form.

Several ancient authors, as Seneca, Strabo, Callisthenes, Pausanias, Pliny, Thucydides, &c. mention a variety of stupendous effects produced by earthquakes, either preceding or during their life-time; such as the separation of mountains, the appearance and disappearance of islands, the destruction of a great many cities, some of which were swallowed up, together with their inhabitants, so effectually as not to leave even a vestige of their former existence.

In the 17th year of the Christian era, under the reign of the emperor Tiberius, twelve cities of Asia Minor were destroyed in one night:—a dreadful disaster, the memory of which, or rather of the towns that were raised in lieu of those that were destroyed, is attested by a medal, still extant, of the above-mentioned emperor, on the legend of which we find, "Civitatibus Asiæ Relictis." (Strabo. lib. xii. Tacitus Ann. lib. ii.) Eusebius adds Ephesus also to the above-mentioned twelve cities, which raises their number to thirteen. A remarkable circumstance attending the destruction of these towns is particularly noticed by Dr. Stukeley, as peculiarly favourable to his hypothesis, of which we shall speak hereafter. The circumstance is, that these thirteen cities must have occupied a circuit of about 300 miles in diameter; and though the cities themselves were completely destroyed, yet neither the mountains were reversed, nor the springs and fountains broken, nor was the course of the

EARTHQUAKE.

rivers altered. In short, there was no kind of alteration produced in the surface of the country, which indeed remains the same to this day.

In the 63d year of the Christian era, another violent earthquake took place in the neighbourhood of the mount Vesuvius, which was attended with extensive destruction. And about 16 years after this, various other earthquakes were felt near the same place, which preceded that famous eruption of Vesuvius, in which the elder Pliny lost his life.

Under the reign of the emperor Gallienus, the greatest part of the country which forms the present Italy was shaken by earthquakes during several days. They were preceded and accompanied by horrid sounds beneath the surface of the earth, and with reports like thunder. Various fissures of the earth, which were repeatedly opened and closed in a great many places, swallowed up a vast number of human beings.

In the second year of the reign of Valentinian and Valens, on the morning of the 21st of July, A. D. 365, (Gibbon says, from the account of Ammianus,) the greatest part of the Roman world was shaken by a violent earthquake. The impression was communicated to the waters. The shores of the Mediterranean were left dry, by the sudden retreat of the sea; great quantities of fish were caught with the hand, and large vessels were stranded on the mud. But the tide soon returned, with the weight of an immense and irresistible deluge, which was severely felt on the coasts of Sicily, of Dalmatia, of Greece, and of Egypt. Large boats were transported, and lodged on the roofs of houses, or at the distance of two miles from the shore; the people, with their habitations, were swept away by the waters; and the city of Alexandria annually commemorated the fatal day, on which 50,000 persons lost their lives in the inundation.

In the sixth century, during the reign of Justinian in the East, which lasted 38 years, earthquakes (as it appears from the histories of Procopius, Agathias, John Malala, and Theophanes) were peculiarly frequent, and remarkably destructive. Gibbon, in his account of those times, accompanies his concise narrative with several observations of a moral or philosophical nature, which render the passage peculiarly interesting. "Without," he says, "assigning the cause, history will distinguish the periods in which these calamitous events have been rare or frequent, and will observe, that this fever of the earth raged with uncommon violence during the reign of Justinian. Each year is marked by the repetition of earthquakes, of such duration, that Constantinople has been shaken above forty days; of such extent, that the shock has been communicated to the whole surface of the globe, or at least of the Roman empire. An impulsive or vibratory motion was felt; enormous chasms were opened; huge and heavy bodies were discharged into the air; the sea alternately advanced and retreated beyond its ordinary bounds; and a mountain was torn from Libanus, and cast into the waves, where it protected as a mole the new harbour of Botrys, in Phœnicia. Two hundred and fifty thousand persons are said to have perished in the earthquake of Antioch, on the 20th of May, 526, whose domestic multitudes were swelled by the conflux of strangers to the festival of the Ascension. The loss of Berytus, on the 9th of July, 551, was of smaller account, but of much greater value. That city, on the coast of Phœnicia, was illustrated by the study of the civil law, which opened the fount of wealth and dignity: the schools of Berytus were filled with the rising spirits of the age; and many a youth was lost in the earthquake, who might have lived to be the scourge or the guardian of his country. In these disasters, the architect becomes the enemy of mankind. The

hut of a savage, or the tent of an Arab, may be thrown down without injury to the inhabitant; and the Peruvians had reason to deride the folly of their Spanish conquerors, who with so much cost and labour erected their own sepulchres. The rich marbles of a patrician are dashed upon his own head; a whole people is buried under the ruins of public and private edifices; and the conflagration is kindled and propagated by the innumerable fires, which are necessary for the subsistence and manufactures of a great city. Instead of the mutual sympathy, which might comfort and assist the distressed, they dreadfully experience the vices and passions which are released from the fear of punishment: the tottering houses are pillaged by intrepid avarice; revenge embraces the moment, and selects the victim; and the earth often swallows the assassin or the ravisher, in the consummation of their crimes."

One of the most remarkable events in the history of earthquakes occurred in the year 1538, on the coast of Puzzuoli, (the ancient Puteoli) in the kingdom of Naples, and is particularly recorded by many historians, some of whom were eye-witnesses of the phenomenon. Simon Porzio, Capaccio, Da Toledo, Summonte, in his "History of the Kingdom of Naples," and others, relate that from the year 1537, until the month of September, 1538, shocks of earthquake were frequently felt along the coast of Puzzuoli; but, during the 27th and the 28th of that month, the shocks became much more violent, and followed each other so closely, as hardly to admit an interval of a few minutes. The sea retired several yards from the accustomed shore. But on the 29th of the above-mentioned month, at about two hours after the setting of the sun, a most tremendous shock took place, which at once annihilated the lake Lucrinus; a town, with its inhabitants, was swallowed up by the earth, which opened itself in various places, and emitted flames, with sand and red-hot stones. That extent of ground, which lay between the Avernian lake and a hill called mount Barbaro, began to rise, and, with the accession of the ignited matter, formed, in a single night, a new hill, which is actually existing under the name of Monte Nuovo; and its perpendicular height from the level of the sea is, according to a late measurement, equal to 1127 English feet. The habitations of the neighbourhood were completely demolished, so that, 24 hours after, no vestige of their existence could be perceived.

Meaco, in Japan, experienced a destructive earthquake in 1595. It was again destroyed by a like calamity, which continued three hours, in September, 1596; and it was also destroyed in 1738.

In the year 1638, a terrible earthquake happened in Calabria, the spot which seems to be particularly devoted to such dreadful calamities; and is described in the following manner by Kircher, who was an eye witness of it. "On the 24th of March, he says, "we launched in a small boat from the harbour of Messina, in Sicily, and arrived the same day at the promontory of Pelorus. Our destination was for the city of Euphemia, in Calabria, but on account of the weather, we were obliged to remain three days at Pelorus. At length, wearied with the delay, we resolved to prosecute our voyage; and although the sea seemed more than usually agitated, yet we ventured forward. The gulf of Charybdis, which we approached, seemed whirled round in such a manner as to form a vast hollow, verging to a point in the centre. Proceeding onward, and turning my eyes to mount Etna, I saw it cast forth large volumes of smoke, of mountainous size, which entirely covered the island, and blotted out even the shores from my view. This, together with the dreadful noise, and the sulphureous stench, which

EARTHQUAKE.

which was strongly perceived, filled me with apprehensions that some more dreadful calamity was impending. The sea itself seemed to wear a very unusual appearance; those who have seen a lake in a violent shower of rain all covered over with bubbles, will have some idea of its agitations. My surprisè was still increased by the calmness and serenity of the weather; not a breeze, not a cloud appeared, which might be supposed to put all nature thus into motion. I therefore warned my companion, that an earthquake was approaching; and, after some time, making for the shore with all possible diligence, we landed at Tropea. But we had scarce arrived at the Jesuits' college in that city, when our ears were stunned with an horrid sound, resembling that of an infinite number of chariots driven fiercely forward, the wheels rattling and the thongs cracking. Soon after this, a most dreadful earthquake ensued; so that the whole track upon which we stood seemed to vibrate, as if we were in the scale of a balance that continued waving. This motion, however, soon grew more violent; and being no longer able to keep my legs, I was thrown prostrate upon the ground. After some time, finding that I remained unhurt amidst the general concussion, I resolved to venture for safety, and running as fast as I could, reached the shore. I did not search long here before I found the boat from which I had landed, and my companion also. Leaving this seat of desolation, we prosecuted our voyage along the coast; and the next day, came to Rochetta, where we landed, although the earth still continued in violent agitations. But we were scarcely arrived at our inn, when we were once more obliged to return to our boat; and in about half an hour we saw the greatest part of the town, and the inn at which we had set up, dashed to the ground, and hurrying all its inhabitants beneath its ruins. Proceeding onward in our little vessel, we at length landed at Lopizium, a castle midway between Tropea and Euphemia, the city to which we were bound. Here, wherever I turned my eyes, nothing but scenes of ruin and horror appeared: towns and castles levelled to the ground; from both, though at sixty miles distance, belching forth flames in an unusual manner, and with a noise which I could distinctly hear. But my attention was quickly turned from more remote to contiguous danger. The rumbling sound of an approaching earthquake, which, by this time we were grown acquainted with, alarmed us for the consequences. It seemed every moment to grow louder, and to come nearer. The place on which we stood now began to shake most dreadfully; so that, being unable to stand, my companion and I caught hold of whatever shrub grew nearest to us, and supported ourselves in that manner. After some time, the violent paroxysm ceasing, we again stood up, in order to prosecute our voyage to Euphemia, which lay within sight. In the mean time, while we were preparing for this purpose, I turned my eyes towards the city; but could only see a frightful dark cloud, that seemed to rest upon the place. This the more surprisèd us, as the weather was so very serene. We waited, therefore, till the cloud was passed away: then turning to look for the city, it was totally sunk; and nothing but a dismal and putrid lake was to be seen where it stood."

The island of Jamaica is so very subject to earthquakes, that, as Dr. Sloane relates, its inhabitants expect one at least every year. Among these earthquakes, Dr. Sloane describes one of so destructive a nature, as perhaps to equal the severest of such calamities. This earthquake took place in the year 1692. In two minutes time the shock destroyed and drowned nine-tenths of the town of Port Royal, at that time the capital of the island. (Phil. Trans. n. 259.) The houses sunk 30 or 40 fathoms deep. The earth open-

ing, swallowed no people; and they rose in other streets; some in the middle of the harbour; and yet many were saved, though there were 2000 people lost, and 1000 acres of land sunk. All the houses were thrown down throughout the island. One Hopkins had his plantation removed half a mile from its place. Of all the wells, from one fathom to six or seven, the water flew out at top with a vehement motion. While the houses on one side of the street were swallowed up, on the other they were thrown on heaps; and the sand in the street rose like waves in the sea, lifting up every body that stood on it, and immediately dropping down into pits; and at the same instant a flood of water breaking in, rolled them over and over; some catching hold of beams, rafters, &c. Ships and sloops in the harbour were overset and lost; the Swan frigate, particularly, was thrown over by the motion of the sea, and the sinking of the wharf, and was driven over the tops of many houses. It was attended with a hollow rumbling noise, like that of thunder. In less than a minute, three quarters of the houses, and the ground they stood on, with the inhabitants, were all sunk quite under water; and the little part left behind was no better than a heap of rubbish. The shake was so violent, that it threw people down on their knees or their faces as they were running about for shelter. The ground heaved and swelled like a rolling sea; and several houses, still standing, were shuffled and moved some yards out of their places. A whole street is said to be twice as broad now as before; and in many places, the earth would crack, and open and shut, quick and fall: of which openings, two or three hundred might be seen at a time; in some whereof, the people were swallowed up; others the earth closing, were caught by the middle, and pressed to death; as to others, the heads only appeared. The larger openings swallowed up houses; and out of some would issue whole rivers of water, spouted up a great height into the air, and threatening a deluge to that part the earthquake spared. The whole was attended with stench and offensive smells, the noise of falling mountains at a distance, &c. and the sky in a minute's time was turned dull and reddish like a glowing oven. Yet, as great a sulcer as Port Royal was, more houses were left standing therein than on the whole island beside. Scarce a planting-house or sugar-work was left standing in all Jamaica. A great part of them was swallowed up, houses, people, trees, and all at once; in lieu of which, afterwards, appeared great pools of water, which, when dried up, left nothing but sand, without any mark that ever tree or plant had been thereon. Above twelve miles from the sea, the earth gaped, and spouted out with a prodigious force vast quantities of water into the air; yet the greatest violences were among the mountains and rocks; and it is a general opinion, that the nearer the mountains the greater was the shake, and that the cause thereof lay there. Most of the rivers were stopped up for 24 hours, by the falling of the mountains, till swelling up, they made themselves new tracks and channels, tearing up in their passage trees, &c. After the great shake, many of those people who escaped got on board ships in the harbour, where many continued above two months; the shakes all that time being so violent, and coming so thick, sometimes two or three in an hour, accompanied with frightful noises, like a rustling wind, or a hollow rumbling thunder, with brimstone blasts, that they durst not come ashore. The consequence of the earthquake was a general sickness, from the noisome vapours belched forth, which swept away above 3000 persons of those who were left.

In the year 1692, the island of Sicily experienced a most tremendous earthquake, whose shocks were severely felt as

EARTHQUAKE.

far as Naples on one side, and Malta on the other. The destruction occasioned by this earthquake was immense; fifty four cities and towns, together with an immense number of villages, were either totally destroyed or in great measure damaged; and among them was counted the famous Catania, once the residence of monarchs, and adorned by elegant buildings, a university, &c. Father Serroviato, who was riding in sight of it, observed from the distance of a few miles, that a dense black cloud hung over that city. *Ætna* at the same time issued vast volumes of flame; the sea was wonderfully agitated, and a roaring noise proceeded from it; the birds were terrified, the animals in the fields roared and trembled; the ground shook violently; all seemed to threaten destruction. In the middle of this horrid scene, an explosion, with a shock of enormous magnitude took place, which levelled Catania with the ground, and a cloud of dust, which rose in the air, indicated the fatal spot. Out of 18,900 inhabitants of that once famous city, 900 are said to have survived that lamentable event. But Sicily and the kingdom of Naples have experienced so many earthquakes, that their dates alone would form a considerable list. Among these, the earthquakes of the year 1783 are remarkable, not only for their duration, and for the variety of their destructive effects, but likewise for their having been carefully examined and particularly described by competent observers. Of those, however, we shall speak hereafter.

In the years 1737 and 1738, violent earthquakes happened at Kamtschacka, which ruined the habitations of the natives. And about the same time, the volcanoes of the neighbourhood made formidable eruptions; for that country abounds in volcanoes, some of which are extinct, whilst others are still burning. Peking suffered a terrible earthquake in the year 1739.

In South America, and especially in the vicinity of volcanoes, the earthquakes are frequent and generally violent. In 1746 Callao and Lima were almost totally destroyed. But the last mentioned town is so very subject to earthquakes, that since the establishment of the Spaniards in that country, various such disasters have taken place. In 1746 at Quito, in Peru, not less than 200 shocks of earthquake were counted in 24 hours; and within about one year 451 such shocks were felt. In July 1773 San Jago of Guatimala was so effectually destroyed by a terrible earthquake, that not a single building was left standing in it.

Great Britain, and France, though upon the whole no very great sufferers, have not, however, been exempt from earthquakes. In France, indeed, the various extinct volcanoes it contains indicate, that in a remote period that country must have frequently experienced such calamities; and, in fact, several occurrences of the kind are actually recorded.

The last shocks of earthquake felt in London took place on the 8th of February, and on the 8th of March, 1749. But they only affrighted the inhabitants. In the year following, on the 30th of September, an earthquake affected various parts of England. The centre of the shock seems to have been about Daventry, in Northamptonshire. A few other slight shocks have also been felt in various parts of England and Wales since that time.

Mr. Henry, in the Phil. Transf. for 1778, describes the earthquake which was felt at Manchester in 1777. It extended 140 miles; the bells tolled twice: it was observed that most noise was heard in the neighbourhood of conductors of electricity; and some shocks were felt.

The year 1755 was rendered memorable by the dreadful earthquake of Lisbon, the effects of which were more or less

severely felt by almost the whole of Europe. Of this also we shall take particular notice hereafter.

In 1759, during the months of October and November, several violent earthquakes happened in Syria. Damascus, and another large city of Syria, were entirely demolished; and it was reckoned that 6000 human beings in the former, and nearly all the inhabitants of the latter, were buried under the ruins. Tripoli of Syria, together with several other towns, villages, &c. also suffered considerably at the same time.

During the year 1767, frequent earthquakes were felt in Germany, in Switzerland, and other circumjacent places. In 1769, Bagdad was almost totally destroyed by an earthquake. In June, 1770, the island of St. Domingo suffered a tremendous earthquake, which was attended with the opening of a volcano. In September, 1774, at Altdorf, in Switzerland, a great number of edifices were destroyed by several strong shocks of earthquake. In 1775, Ternate, among the Molucca islands, and Iceland, suffered violent earthquakes, which were accompanied with eruptions of their volcanoes. In 1778, Manheim, and Smyrna, the former in April, and the latter in July, suffered greatly in consequence of earthquakes. In short, there is no part of the habitable world, which is not more or less subject to the destructive action of earthquakes. Nor are the islands more exempt from such disasters. On the contrary, it appears, upon the whole, that earthquakes are more frequent and more destructive among them than upon continents. In fact, the Caribbee islands, the Azores, the Moluccas, the Philippine islands, &c. are peculiarly subject to earthquakes.

A full history of earthquakes, as far as may be collected from the annals of the various countries of the earth, would prove a disgusting monotony, alike destitute of amusement and of instruction; unless, indeed, every particular account contained an accurate description of some singular phenomenon, which might be likely to throw light upon a subject which is equally obscure and important. But the accounts of such events, especially during a remote period, are mostly contaminated by exaggerations and uncertainties, so that they can afford but little assistance to the mind of a speculative philosopher. The foregoing accounts have been selected as the most striking instances of the kind, and as being sufficient to convey an adequate idea of the force, the extent, the variety, and the duration of earthquakes. But we have reserved the account of two remarkable cases for our particular examination, *viz.* the earthquake of Lisbon in 1755, and those of Calabria in 1783. The wonderful effects produced by these earthquakes are, perhaps, not exceeded by those of any other convulsion of the kind. They were also particularly noticed by a variety of intelligent and creditable persons, who have recorded, with sufficient concurrence of testimony, all the principal phenomena that preceded, accompanied, and followed them, so as to afford ample scope for conjecture and for hypotheses, respecting the origin, the nature, and the proper method of averting, so great a scourge of the human species.

The great earthquake of Lisbon, the capital of Portugal, took place on the 1st of November, 1755, but its effects were felt at an immense distance from Lisbon. Previous to it several peculiarities of the weather were remarked, which are as follows. In the year 1750 Lisbon experienced a slight, but sensible tremor of the earth, and similar very slight tremors were frequently perceived in the course of the four following years, which proved so very dry, that several springs and fountains, usually abundant, failed entirely. The wind mostly blew from the north, or the north-east. The next year, *viz.* the year 1755, was very wet and rainy; the

EARTHQUAKE.

the summer was unusually cool; and during the 40 days which immediately preceded the earthquake, the weather was clear, but not remarkably so. On the day immediately preceding that of the earthquake, a remarkable gloominess prevailed in the atmosphere, and the sun was obscured. At last, on the morning of the fatal day, November the 1st, a thick fog arose early in the morning, but this was soon dissipated by the heat of the sun. There was no wind, nor the least agitation of the sea; the weather was remarkably warm. In the midst of this universal stillness, at 35 minutes after nine in the morning, a subterranean rumbling noise was heard, and soon after a tremendous earthquake shook the whole city, throwing several of its buildings to the ground. The shocks were at first short and quick; but they soon changed into another kind of vibration, which tossed the houses from side to side with so much violence, as to destroy by far the greatest part of the city, killing, at the same time, a multitude of its inhabitants. The whole destructive scene lasted about six minutes, and not less than 60,000 persons are said to have perished in it. The effects in the river Tagus were equally remarkable. At the commencement of the earthquake, those who were in boats at about a mile from the city perceived a noise, as if their boats were running aground, though they were in deep water, and at the same time they saw the houses fall on both sides of the river. The vessels of all sizes were driven from their moorings, and were violently tossed about, repeatedly appearing to strike, or actually striking the ground; for in many places the bed of the river rose above its surface. It is remarkable that a new quay, with several hundreds of persons upon it, sunk to an unfathomable depth, and not one of the dead bodies ever floated to the surface. At first, the bar was laid dry from shore to shore; but soon after the sea rolling in like a mountain, instantly rose to the height of about 50 feet near Belem castle. Another shock happened at about noon of the same day, and during this the walls of the few houses that remained standing were seen to open, about a foot from top to bottom, and then to close again, without hardly leaving a mark of the fissure. Such were the disasters of Lisbon on that memorable day; we shall now gradually proceed to relate the effects of the same earthquake at other places.

At Colares, about 20 miles from Lisbon, and two miles from the sea, on the last day of October, the weather was clear, and uncommonly warm. About four o'clock in the afternoon there arose a fog, unusual at that time of the year, which came from the sea, and spread itself over the vallies. Soon after the wind changing to the east, the fog returned to the sea, collecting itself and becoming very thick. As the fog retired, the sea rose with a prodigious roaring. The 1st of November the day broke with a serene sky, the wind continued at east; but about nine o'clock the sun began to grow dim, and about half an hour after was heard a rumbling noise, like that of chariots, which increased to such a degree, that it became equal to the explosion of the largest cannon. Immediately a shock of an earthquake was felt, which was quickly succeeded by a second, and a third; and at the same time several light flames of fire issued from the mountains, resembling the kindling of charcoal. In these three shocks the walls of the buildings moved from east to west. In another situation, from whence the sea coast could be discovered, there issued from one of the hills, called the Fojo, a great quantity of smoke, very thick, but not very black. This still increased with the fourth shock, and afterwards continued to issue in a greater or less degree. Just as the subterranean rumblings were heard, the smoke was observed to burst forth at the Fojo; and the quantity of smoke was always proportioned to the noise. On visiting

the place from whence the smoke was seen to arise, no signs of fire could be perceived near it.

At Oporto, near the mouth of the river Douro, the earthquake began about 40 minutes past nine. The sky was very serene, when a dreadful hollow noise, like thunder, or the rattling of coaches at a distance, was heard, and almost at the same instant the earth began to shake. In about a minute or two the river rose and fell five or six feet, and continued to do so for four hours. It ran up at first with so much violence, that it broke a ship's hawser. In some parts the river opened, and seemed to discharge vast quantities of air; and the agitation in the sea was so great about a league beyond the bar, that air was supposed to have been discharged there also.

St. Ubes, a sea-port town about 20 miles south of Lisbon, was entirely swallowed up by the repeated shocks and the vast surf of the sea. Huge pieces of rock were detached at the same time from the promontory at the west end of the town, which consists of a chain of mountains containing fine Jasper of different colours.

The same earthquake was felt all over Spain, except in Catalonia, Arragon, and Valencia. At Ayamonte, near where the Guadiana falls into the bay of Cadiz, a little before ten o'clock on the 1st of November, the earthquake was felt, having been immediately preceded by a hollow rushing noise. Here the shocks continued for fourteen or fifteen minutes, damaged almost all the buildings, throwing down some, and leaving others irreparably shattered. In little more than half an hour after, the sea and river, with all the canals, overflowed their banks with great violence, laying under water all the coasts of the islands adjacent to the city and its neighbourhood, and flowing into the very streets. The water came on in tall black mountains, white with foam at the top, and demolished more than one half of a tower at the bar named De Canala. In the adjacent strands every thing was irrevocably lost; for all that was overflowed sunk, and the beach became a sea, without the least resemblance of what it was before. Many persons perished; for although they got aboard some vessels, yet part of these foundered; and others being forced out to sea, the unhappy passengers were so terrified, that they threw themselves overboard. The day was serene, and not a breath of wind stirring.

At Cadiz, some minutes after nine in the morning, the earthquake began, and lasted about five minutes. The water of the cisterns under ground washed backwards and forwards, so that a great froth arose. At ten minutes after eleven a wave was seen coming from the sea, at eight miles distance, at least 60 feet higher than usual. It dashed against the west part of the town, which is very rocky. Though these rocks broke a good deal of its force, it came at last upon the city walls, beat in the breast work, and carried pieces of the building, of eight or ten ton weight, to the distance of 40 or 50 yards. When the wave was gone, some parts that are deep at low water were left quite dry; for the water returned with the same violence with which it came. At half an hour after eleven came a second wave, and after that four other remarkable ones; the first at ten minutes before twelve; the second half an hour before one; the third ten minutes after one; and the fourth ten minutes before two. Similar waves, but smaller, and gradually lessening, continued with uncertain intervals till the evening.

At Gibraltar, the earthquake was not felt till after ten. It began with a tremulous motion of the earth, which lasted about half a minute. Then followed a violent shock; after that, a trembling of the earth for five or six seconds; then another shock, not so violent as the first, which went off gradually.

EARTHQUAKE.

gradually as it began. The whole lasted about two minutes. Some of the guns on the battery were seen to rife, others to sink, the earth having an undulating motion. Most people were seized with giddiness and sickness, and some fell down; others were stupified, and many that were walking or riding, felt no motion in the earth, but turned fish. The sea rose six feet every fifteen minutes; and then fell so low, that boats and all the small craft near the shore were left aground, as were also numbers of small fish. The flux and reflux lasted till next morning, having decreased gradually from two in the afternoon.

At Madrid the earthquake came on at the same time as at Gibraltar, and lasted about six minutes. At first every body thought they were seized with a swimming in their heads; and afterwards, that the houses were falling. It was not felt in coaches, nor by those who walked on foot, except very slightly; and no accident happened, except that two lads were killed by the fall of a stone-cross from the porch of a church.

Malaga felt a violent shock; the bells rung in the steeples, the water of a well overflowed, and as suddenly retired.

Saint Lucar, at the mouth of the Guadalquivir, was violently shocked, and the sea broke in and did a great deal of mischief.

At Seville several houses were shaken down; the famous tower of the cathedral, called "La Giralda," opened in the four sides; and the waters were so violently agitated, that all the vessels in the river were driven ashore.

In Africa the earthquake was felt almost as severely as it had been in Europe. Great part of the town of Algiers was destroyed. At Arzilla, in the kingdom of Fez, about ten in the morning, the sea suddenly rose with such impetuosity, that it lifted up a vessel in the bay, and dropped it with such force on the land, that it was broken to pieces; and a boat was found two musket-shot within land from the sea. At Fez and Mequinez, a great many houses fell, and a multitude of people were buried in the ruins.

At Morocco, many people lost their lives by the falling down of a great number of houses: and about eight leagues from the city, the earth opened and swallowed up a village with all the inhabitants, who were known by the name of the "Sons of Besumba," to the number of about 8000 or 10,000 persons, together with all their cattle, &c. and soon after, the earth closed again in the same manner as before.

At Salle, a great deal of damage was done. Near a third part of the houses was overthrown; the waters rushed into the city with great rapidity, and left behind them great quantities of fish.

At Tangier, the earthquake began at ten in the morning, and lasted 10 or 12 minutes. The sea came up to the walls, which was not known to have ever happened before; and went down immediately with the same rapidity with which it arose, leaving a great quantity of fish behind it. These commotions were repeated 18 times, and lasted till six in the evening.

At Tetuan, the earthquake began at the same time it did at Tangier, but lasted only seven or eight minutes. There were three shocks, so extremely violent, that it was feared the whole city would be destroyed.

In the city of Funchal, in the island of Madeira, a shock of the earthquake was first perceived at 38 minutes past nine in the morning. It was preceded by a rumbling noise in the air, like that of empty carriages passing hastily over a stone pavement. The observer felt the floor immediately to move with a tremulous motion, vibrating very quickly. The shock continued more than a minute; during which time the vibrations, though continual, were weakened and increased

in force twice very sensibly. The increase, after the first remission of the shock, was the most intense. The noise in the air accompanied the shock during the whole of its continuance, and lasted some seconds after the motion of the earth had ceased; dying away like a peal of distant thunder rolling through the air. At three quarters past eleven, the sea, which was quite calm, (it being a fine day, and no wind stirring,) retired suddenly some paces; then rising with a great swell without the least noise, and as suddenly advancing, overflowed the shore, and entered the city. It rose 15 feet perpendicular above the high-water mark, although the tide, which flows there seven feet, was then at half ebb.

The water immediately receded, and after having fluctuated four or five times between high and low water mark, it subsided, and the sea remained calm as before. In the northern part of the island the inundation was more violent, the sea there retiring above 100 paces at first, and, suddenly returning, overflowed the shore, forcing open doors, breaking down the walls of several magazines and store-houses, leaving great quantities of fish ashore, and in the streets of the village of Machico. All this was the effect of one rising of the sea, for it never afterwards flowed high enough to reach the high-water mark. It continued, however, to fluctuate here much longer before it subsided than at Funchal; and in some places farther to the westward, it was hardly, if at all, perceptible.

The shocks of this earthquake were also felt in a great many other places, much more distant from Portugal, but in general very slightly. They were felt in several provinces of Sweden, in Italy, and especially at Milan; in England at Early Court, Berks; at Eyam-bridge, Derbyshire, where the shocks were pretty smart; in France, as at Bayonne, Bourdeaux, and Lyons, &c. But the effects of this earthquake in distant places, were observed to affect the waters of seas, lakes, rivers, springs, wells, &c. in a most extraordinary manner; and such phenomena took place principally in Norway, Sweden, Germany, Holland, Corsica, Switzerland, Antigua, Barbadoes, Great Britain, Ireland, &c.

In some of those places the waters turned muddy, and were strangely agitated, in others, they overflowed the banks with violence and then retired; unusual tides came on at different places, a bubbling hissing or roaring was perceived in some lakes, and so forth: but we must be more particular in describing some of those effects, which were observed in England, Scotland, and Ireland.

At Bailborough in Derbyshire, between 11 and 12 in the morning, a surprising and frightful noise was heard near a large body of water called "Pibley Dam," a large swell of water came in a current from the south, and rose two feet on the north side of the lake. It then subsided, returned again, and so on, gradually decreasing in its motion until it ceased entirely. A similar noise, with agitation, and overflowing of the water of a canal, was observed at about half an hour after ten in the morning, at Busbridge in Surrey; a similar agitation was observed in a pond at Cobham in Surrey. At Dunstall in Suffolk, the water of a pond rose gradually for several minutes in the form of a pyramid, and fell down like a water-spout. Other ponds in the neighbourhood had a smooth flux and reflux from one end to the other. Near Durham, about half an hour after ten, a rushing noise was heard to issue from a pond, and its water was seen to rise and to descend alternately, without any fluctuating motion, and continued this rising and falling during six or seven minutes, making four or five such vibrations in a minute. At Early Court, Berks, about 11 o'clock, after a violent trembling of the earth, a motion of the water of a fish-pond was observed from the south to the north end of

EARTHQUAKE.

the pond, leaving the bottom at the south end altogether dry for about six feet. It then returned, and flowed at the fourth end, rising three feet up the slope bank; and immediately after returned to the north bank, rising there also about three feet. In the time between the flux and reflux, the water swelled up in the middle of the pond, collected in a ridge about 20 inches higher than the level on each side, and hoiled like a pot. This agitation from south to north lasted about four minutes. At Eaton bridge, Kent, the water of a pond was seen to open in the middle, so that a pot could be seen a good way down, almost to the bottom. The water in the mean time dashed over a bank two feet high, and perpendicular to the pond. This was repeated several times with a great noise. At Shireburn castle, Oxfordshire, at a little after ten in the morning, a strange motion was observed in the water of a moat which surrounds the house. Though there was not the least wind, the water was observed to flow at one corner, and to retire again successively and regularly. Every flood began gently; its velocity increased by degrees, and at last it rushed in with great impetuosity, till it had attained its full height. After a little time it ebbed in a similar manner, &c. At every flux, the whole body of water seemed to be violently thrown against the bank, but neither during the time of the flux nor that of the reflux, did there appear the least wringle of a wave on the other parts of the moat.

The like movement was observed at the opposite corner of the moat; but it was remarked with surprise, that the water flowed at both corners, which stood diagonally opposite to each other, at the same time, and also ebbed at the same time in both places.

At White Rock, Glamorganshire, at about two hours ebb of the tide, and near three quarters after six in the evening, a vast quantity of water rushed up with a prodigious noise; floated two large vessels, broke their moorings, drove them across the river, and had like to have overlet them.

The whole rise and fall of this extraordinary body of water did not last above 10 minutes, nor was it felt in any other part of the river, so that it seemed to have gushed out of the earth at that place.

At Loch Lomond in Scotland, at about half an hour after nine in the morning, the water, without the least apparent cause, rose against its banks with great rapidity, then subsided far below the usual level. It rose again, and so forth.

The greatest perpendicular height of this swell was two feet, and four inches. A remarkable phenomenon attended the earthquake in this lake, which was, that a large stone, lying at some distance from shore, but in such shallow water that it could easily be seen, was forced out of its place in the lake upon dry land, leaving a deep furrow in the ground, all along the way in which it had moved. At Loch Ness, at about half an hour after nine, a great agitation was observed in the water of the river Oich.

At Kinsale, in Ireland, between two and three in the afternoon, the weather being calm, and the tide near full, a large body of water suddenly rushed into the harbour with such rapidity, that it broke the cables of two floops, and it whirled round several vessels. At one place it overflowed, and poured into the market place. It then subsided, and again rose, continuing this motion for about 10 minutes. But between six and seven in the evening, the water rose again, though not with so great violence as before, and it continued to ebb and flow alternately till three in the morning.

At sea, the shocks of this earthquake were felt most violently. Off St. Lucar, the captain of the Nancy frigate felt his ship so violently shaken, that he thought he had

struck the ground; but on heaving the lead, found he was in a great depth of water. Captain Clark from Denia, in N. lat. $36^{\circ} 24'$, between nine and ten in the morning, had his ship shaken and strained as if she had struck upon a rock, so that the seams of the deck opened, and the compass was overturned in the binacle. The master of a vessel bound to the American islands, being in N. lat. 25° . W. long. 40° , and writing in his cabin, heard a violent noise, as he imagined, in the steerage, and while he was asking the cause of it, the ship was put into a strange agitation, and seemed as if she had been suddenly jerked up and suspended by a rope fastened to the mast-head. He immediately started up with great terror and astonishment; and looking out at the cabin-window, saw land, as he took it to be, at the distance of about a mile. But coming upon the deck the land was no more to be seen, but he perceived a violent current cross the ship's way to the leeward. In about a minute, this current returned with great impetuosity, and at a league's distance he saw three craggy pointed rocks throwing up water of various colours resembling fire. This phenomenon, in about two minutes, ended in a black cloud, which ascended very heavily. After it had risen above the horizon, no rocks were to be seen; though the cloud, still ascending, was long visible, the weather being extremely clear. Between nine and ten in the morning, another ship, 40 leagues west of St. Vincent, was so strongly agitated, that the anchors, which were lashed, bounced up, and the men were thrown a foot and a half perpendicularly up from the deck. Immediately after this, the ship sunk in the water as low as the main chains. The lead shewed a great depth of water, and the line was tinged of a yellow colour, and smelled of sulphur. The shock lasted about ten minutes, but smaller ones were felt during about 24 hours after the first.

Thus we have stated the most material particulars which were observed on the first of November 1755, during an earthquake remarkable for its destructive effects, for its extent, and for the singularity of the phenomena with which it was accompanied. Many other particulars might have been added which were observed in some of the above-mentioned places as well as in others; but we have thought proper to omit them, considering that they are neither of much consequence, nor essentially different from some of those which have been already mentioned. See Phil. Transf. vol. xlv. and xlix.

The earthquakes of Calabria are of a more recent date, but of a duration vastly greater than the preceding. In fact, it was a repetition of shocks more or less violent and destructive, which continued to afflict that country from the beginning of the year 1783 to the end of the year 1786. The most violent shocks, however, and the greatest destruction, took place during February and March of the first of those years. The most authentic account of these earthquakes was written by the chevalier Vivenzio, physician to their Sicilian majesties. This intelligent gentleman published his first account in the year 1783, immediately after the most destructive shocks; and his documents were derived from the accounts which were regularly transmitted to the court of Naples, from the various parts of Calabria and Sicily, which places were the actual sufferers of the misfortunes. But in the year 1788, when the shocks had entirely ceased, and when the former accounts had received due corrections and enlargements, the same gentleman published a second edition, much amended and improved, with the addition of elegant plates. The title of the book is "Istoria de Tremuoti Avenuti nella provincia della Calabria Ulteriore, e nella Città di Messina, nell' anno 1783, &c. Di Giovanni Vivenzio, Cavaliere," &c. Amongst other improvements,

improvements, this second edition contains a most singular and accurate journal of the earthquakes, kept by a learned physician of Monteleone, in Calabria, named Dr. Domenico Pignataro, who resided upon that devoted spot all the time. This journal expresses the time, the strength, the direction, and the effects of each shock, and is accompanied with an accurate statement of the concomitant phenomena of the atmosphere, such as the strength and direction of the wind, rain, temperature, &c.

Besides the above, several other partial accounts were also published about that time; and Sir William Hamilton, then English minister at the court of Naples, also transmitted his accounts, which contain several curious observations. From all these documents we have extracted the following account, which, considering the variety and the importance of the facts, we have endeavoured to render as concise as it was in our power.

The southern part of the kingdom of Naples consists of two provinces of the same name, *viz.* the Hither Calabria, and the Further Calabria, or Calabria Citra, and Calabria Ultra, the latter of which is separated from the island of Sicily by the channel of straits of Messina. This province extends from latitude 37° 45' 30" 12' N., it is separated from the other Calabria provinces by the mountains called Sile, and by the mountains of Nicastro; and is itself divided nearly from north to south by a ridge of mountains called the Appennines, among which there are Monte Dijo, Monte Sacro, and Monte Caulone, extending westward to the Tyrrhene sea. It was in the vicinity of these mountains that the earthquake in general exerted its greatest force. Catanzaro is the principal city or capital of the province.

With respect to weather, temperature, &c. of the year 1783, preceding that of the earthquake, it was observed in that province, that the summer proved remarkably hot and dry, the autumn was peculiarly rainy and cold; but the beginning of the winter was rather mild. The winds mostly predominant were, the S. E., the S., and the S. W. On the 28th of October a violent hurricane arose, and blew along the coast of Catanzaro, the heights of Thiolo, and as far as the plains of Crisafolo, rooting up trees, cutting and destroying whatever happened to be in its way. The violent rains of October and November filled the cisterns, wells, ponds, and rivers, to an unusual degree, which occasioned a great deal of damage throughout the province, and on the 10th of December upwards of a hundred persons lost their lives in consequence of the violent overflow of a torrent.

In the course of the night of the 1st of January, 1783, a slight shock of an earthquake was felt; and it was said by some, that two other slight shocks were also felt during two other nights of the same month. This, however, is uncertain. During the first two days of February, the weather was either clear, though not perfectly so, or covered with broken clouds: the wind blew either from the south-east, or from the west. The sun appeared somewhat inflamed. The morning of the 5th commenced with nearly the same appearances, but a haziness came on gradually. On the shores of Bovino and Pizzo the fishermen were obliged to relinquish their occupations, and to land, for though there was no wind, yet the sea at some distance appeared to be in an extraordinary state of ferment and ebullition. On the eastern coast, near cape Rizzuto, the sea being unusually agitated, overflowed the shores, and at that time some assert that they felt a slight tremor of the earth. From about ten until very near twelve o'clock at noon, some rain fell in different parts of the province; but at Monteleone it rained abundantly. The wind was S. S. E. In this state of the atmosphere, at about a quarter before one in the afternoon,

a rumbling subterranean noise, like a succession of thunders was in about two seconds succeeded by a dreadful earthquake. At first the soil began to shake gently, but the vibrations soon became violent in the direction of S. S. W. and N. N. E. some of them, however, were extremely strong and irregular, then they decreased nearly in the same manner as they had commenced, and the whole lasted about two minutes. The water of the sea was instantly put in agitation; at first it retired from the shore, and it flowed soon after, and this was repeated three times successively. This earthquake shook, fractured, or entirely demolished, several buildings on the northern part of the island of Sicily, as well as all over the province of Calabria. The ground was thrown up or sunk in several places, changing the face of the country, and interrupting the course of rivers, the overflowing of which occasioned incredible damage. At the same time the fires, which were naturally kindled among the houses and villages that were destroyed, contributed to the distress of the natives. Some of these fires continued to burn two or three days, and even longer. The inhabitants of Monteleone saw a dense fog rise from the sea, and those who happened to be involved in it, perceived a disagreeable strong smell, as if it came from the rubbish of the buildings that were destroyed. Water was seen to spring out of the ground in a great many places, and these, as well as the waters of rivers, &c. became muddy, and mostly emitted a sulphurous or phosphoric smell. Large fissures were found open in the ground, and in other places the ground was elevated much above its usual level; and thus the most delicious plantations, gardens, pasture lands, &c. instantly became a frightful desert.

The greatest force of the earthquake seems to have been exerted in the very centre of the province, *viz.* in the vicinity, or on the western side of Aliphanete, Monte Sacro, and Monte Caulone. And from that place the greatest force seems to have proceeded in the direction of W. S. W.

The space which came within the action of this earthquake was reckoned to measure 40 miles by 20; for whatever was comprehended within it, was altered and destroyed in a dreadful manner. At Messina, in Sicily, the houses on or near the level of the sea suffered most. The Lipari islands likewise suffered their share of the disasters. The utmost boundaries at which the shock was felt, seemed to be Otranto in the kingdom of Naples, and Palermo in Sicily. A vast number of people perished under the ruins of their habitations, many were left lame and helpless, and those who survived were so terrified as hardly to know what to do. Besides the above great convulsion, four more such dreadful commotions took place, of which we shall speak presently; but in the course of the same day, the memorable 5th of February 1783; and within four hours of the great commotion, not less than 14 other shocks were felt, but their force and duration was not to be compared to the great one. Indeed, during the whole year 1783, from February forward, very few days passed without one or two or more of those shocks of various strength and duration, taking place. They became gradually less frequent in the following years, 1784, 1785, and 1786, with which the journal terminates.

We must now resume the account of the four other extraordinary commotions which followed that of the 5th of February. The next, or second great earthquake, took place at about midnight, between the 6th and 7th of the same February. It was accompanied by a dreadful rumbling noise, it lasted about one minute and an half, but it commenced and ended with the same uniform violence. About the same time the sea in many places rose several feet above its usual level, and produced great damage by its inundation. This second great earthquake, as may be easily imagined, added

EARTHQUAKE.

considerably to the scene of destruction and distress; but without repeating the same disagreeable expressions of horror, we shall proceed to state the periods of the other great commotions, and shall then add a summary of the principal facts which may demand our more particular attention.

The third great earthquake took place in the afternoon of the 7th of the same February. It lasted about two minutes and a half. The rumbling noise and the commotion commenced at the same moment. The shocks were of various sorts, such as horizontal or vertical pulsations, whirling, waving, &c.

The fourth tremendous earthquake happened very early in the morning of the 11th of March following. This also was accompanied with great subterranean noise; it lasted about a minute and 35 seconds; it was tremendously violent throughout its whole duration. The shocks were at first undulating, but after a very short intermission they changed into a sort of whirling motion.

The fifth and last great earthquake took place on the evening of the 28th of the same month of March, at about an hour and a quarter after sun setting. It lasted about two minutes. Its shocks were of various sorts, the last of which proved the most violent.

In the journal, the shocks, much inferior to the above-mentioned five extraordinary convulsions, are distinguished into four degrees of force; the first being the weakest, and the fourth the strongest. And from the statement of the whole journal, it appears that during the year 1783, the unfortunate inhabitants of Calabria felt 501 shocks of the first degree, 236 of the second degree, 175 of the third, and 32 of the fourth degree, besides the five great commotions; in all 949 earthquakes.

During the year 1784, there happened 98 shocks of the first degree, 34 of the second, 16 of the third, and three of the fourth degree. In all 151 shocks. Their number gradually diminished in the following years, so that it needs not be particularly stated.

Those dreadful and repeated commotions, shook, altered, and destroyed the whole face of the country. Sir William Hamilton observes, that if the city of Oppido, where the earthquake exerted its greatest force, be taken as a centre, and round that centre a circle be described with a radius of 22 miles, this will comprehend all the towns, villages, farms, &c. that were utterly destroyed, where the greatest mortality happened, and where the surface of the country suffered the greatest alteration. But if you describe the circle with a radius of 72 miles, this, then, will comprehend the whole country that had any mark of having been affected by the earthquake. The greatest alteration of the country took place on the western side of the mountains which have been mentioned above, *viz.* Monte Sacro, Monte Canone, &c. Many openings and cracks were made in those places; some hills were lowered, others were entirely levelled with the adjoining ground; some were split asunder; deep vallies were filled up; pieces of ground, with trees standing, were transported from one place to another, even with men upon them, who often remained unhurt. But the interruption of the rivers, in consequence of the fall of hills, and the alterations of the ground, caused an unappreciable damage. As it appeared from the survey made by professional persons, sent on purpose by the government of Naples, not less than 215 lakes, and some of them very extensive, were formed by the above-mentioned interruptions.

From the authentic statements which were transmitted to the government, it appears that 182 towns and villages were entirely destroyed, 92 were partly destroyed, but ren-

dered entirely uninhabitable, and many others suffered in a less degree.

From the statement of the population previous to, and subsequent to the earthquakes, it appears, that in the whole country that suffered, the whole population before the earthquakes, comprehending men, women, and children, amounted to 459,726 human beings; out of which number 29,451 died under the ruins, and 5709 died of diseases contracted in consequence of the earthquakes. It is now necessary to add some of those remarkable occurrences which took place at different times during the above-mentioned earthquake. It was observed, previous to most of the shocks, that the clouds, when any existed, dispersed in the atmosphere, generally collected together, and remained stationary, suspended, as it were, upon some particular spot. It is said that horses and other animals, by their moanings, dejection, or uneasiness, frequently indicated the approach of an earthquake; and it was particularly observed, that geese were soonest and most alarmed at the approach of a shock. Vivenzio relates that a physician of Cosenza, named Dr. Niccola Zupo, being impressed with the idea that electricity is the cause of earthquakes, stuck into the ground an iron rod of about 12 feet in length, and that at the time of many a shock, he observed electric fire proceed from the pointed extremity of the rod which projected above the ground.

Mount *Ætna*, in Sicily, and the volcano of *Stromboli*, had smoked less than usual before the earthquakes; but they both exhibited appearances of an eruption during the earthquakes.

Sir William Hamilton, long before the termination of the earthquakes, had the curiosity to go and examine the place with his own eyes. As he was going towards *Rofano*, and before he arrived at that place, he passed over a swampy plain, in many parts of which he was shewn small hollows in the earth, of the shape of an inverted cone. They were covered with sand, as was the soil near them. He was informed that during the earthquake of the 5th of February, a fountain of water, mixed with sand, had been driven up from each of those spots to a considerable height. This phenomenon, he thought, might be easily explained by supposing the first impulse of the earthquake to have come from the bottom upwards, which all the inhabitants of the plain attested to be the fact; the surface of the plain suddenly rising, the rivers, which are not deep, would naturally disappear, and the plain returning with violence to its former level, the rivers must naturally have returned and overflowed, as the sudden depression of the boggy ground would as naturally force out the water that lay hid under their surface. It was observed in the other parts, where the same phenomenon had been exhibited, that the ground was always low and rushy.

The surprizing case of the two tenements which had exchanged situation was fully ascertained by sir William Hamilton, who relates that they were situated in a valley surrounded by high grounds; and the surface of the earth, which was removed, had probably been undermined by little rivulets which come from the mountains, and were there plainly discernible on the bare spot which the tenements had quitted. Their course down the valley was sufficiently rapid to prove that it had not been a perfect level. The earthquake, he supposes, had opened some depositories of rain water in the clay-hills, which surrounded the valley; which water, mixed with the loose soil, taking its course suddenly through the undermined surface, lifting it with the large olive, mulberry trees, and a thatched cottage,

EARTHQUAKE.

floated the whole piece of ground, with all its vegetation about a mile down the valley, where it then stood with most of the trees erect. These two tuncments were about a mile long and half a mile broad.

The destruction in some places, and the misery that ensued, exceed description. The force of the earthquake of the 5th of February was so great at the town of Polifene, that all the inhabitants were buried, alive or dead, under the ruins of their houses, in an instant, and out of 6000, 2100 are said to have lost their lives on that day. At Casal Nuovo, the princefs Grace Grimaldi, with 4000 of her subjects, perished on the same day by the explosion; for such it appears to have been. Some, who had been dug alive out of the ruins, said, that they had felt their houses fairly lifted up, without the least previous notice. An inhabitant of Casal Nuovo was at that moment on a hill overlooking the plain, when, feeling the shock, and turning round, instead of the town he saw only a thick cloud of white dust, like smoke, the natural effect of the crushing of the buildings and the mortar flying off. That town was so effectually demolished, that no vestige of house or street remained, but all lay in one confused heap of ruins. Of the several persons that were dug out alive, some were quite unhurt; and it is singular, that some persons were buried by one shock, and liberated by another shock. These facts, however extraordinary they may appear, were well authenticated; and a priest especially, who related his own adventure to sir William Hamilton, having been buried in the ruins of his own house by the first shock, was blown out of it by the second, which immediately followed the first.

Another well-attested fact took place in the vicinity of Oppido. A man, who was ploughing his field with a pair of oxen, was transported with his field and team clear from one side of a ravine to the other, and neither he nor his oxen were hurt.

We shall close this account of the Calabrian earthquake, with the narration of the misfortune which overwhelmed the inhabitants of Scilla; and which may be considered as one of the greatest disasters occasioned by those convulsions. The city of Scilla was situated on the declivity of a mountain, the foot of which was washed by the Tyrrhene sea. The prince of Scilla having remarked, that during the first great shock of the 5th of February, part of the rock near Scilla had been detached into the sea, and fearing that the rock of Scilla, on which his town and castle were situated, might also be precipitated down, prepared some boats, together with several of his dependents and adherents, accommodated, as well as they could, in those boats, and retired to a little beach, situated at the foot of the hill. The second great earthquake, which happened about midnight, having detached the greatest part of a mountain much higher than that of Scilla, called Monafina; that enormous mass of solid matter fell into the sea, and occasioned a great wave. But Vivenzio's account says, that it was part of another hill, called Campallà, that fell some time after the above, and which might measure about a square mile and a half, and that about half a minute after this fall, two mountainous waves, accompanied by a horrid roaring, proceeded towards the shore to the altitude of about 30 feet, and swept away whatever happened to be in their way. The water retired, and came again; repeating this motion three times within about two minutes; and during this short period an immense destruction was occasioned by the impetuosity of the water. Barges, tents, men, and all were dashed against the houses, and washed away into the sea. The prince, or count of Sinopoli, with his adherents, and a vast number of

other persons, lost their lives. A few, however, had the good fortune of being saved, and among those, the singular adventure of a girl is related, who was driven by the water into the branches of a mulberry tree, situated about 30 steps from the shore, where her lar and clothes being entangled amongst the branches of the tree, detained her, at the height of about 30 feet from the ground. The formidable effects of the above-mentioned waves were also felt on the coast of Sicily, where several persons were killed.

A careful examination of the accounts of earthquakes, that have been recorded by ancient as well as modern authors, has enabled philosophers to form certain general rules or deductions, which we shall now state, but concerning which, we must observe, that none of them must be considered as being exactly certain. They are only approximations to the truth, and may be considered as rules because they agree with, or are indicated by the majority of facts, and of course they are subject to various exceptions.

1. Those countries which are within the tropics, or not very far from them, are more subject to earthquakes than those which are nearer to the poles, or have a high latitude; excepting, however, those countries in which volcanoes exist, as Iceland and other places; for in the vicinity of volcanoes, earthquakes have generally been more frequent.

2. When a volcano has continued an unusual length of time without making an eruption, then an earthquake is more likely to happen in the neighbourhood of it, than after a copious eruption.

3. Earthquakes are mostly preceded by the fall of copious rains after a long drought; and such was evidently the case with the earthquake of Lisbon, as well as with those of Calabria.

4. Several other unusual phenomena have often preceded earthquakes, and such are strong northern lights, abundance of what are commonly called shooting stars, fire-balls, which are more commonly known under the name of meteors; a peculiar thickens, or rather a want of perfect transparency in the atmosphere, and a similar dulcness or a fiery redness in the aspect of the sun.

5. The sea also is generally affected in an unusual manner previous to an earthquake happening upon the adjoining land. It either swells up to an unusual height, or bubbles up, and emits a peculiar roaring noise. The waters likewise of springs, wells, ponds, and rivers, frequently grow muddy previously to an earthquake, or give other indications of it, such as to become suddenly more abundant, or more scanty, to yield unpleasant smells, &c. It has been often observed, that the waters of ponds, rivers, seas, &c. have given indications of an earthquake having taken place at an immense distance, when no shock or tremor of the earth, or other unusual phenomenon, could be perceived in the neighbourhood of those waters.

6. At the time of an earthquake the air is generally calm and serene, though seldom very pellucid; but afterwards becomes generally obscure and cloudy.

7. A noise of various kind, *viz.* either a continued rumbling, or something like the rattling of carriages, or like the explosions of heavy cannon, is the general forerunner of an earthquake; but sometimes the shock and noise commence at the same time.

8. The nature and direction of the shocks vary much, and mostly they succeed each other in a very short time. The earth sometimes trembles, at other times it moves somewhat like the waves of the sea. The shock frequently begins with a perpendicular heave; then changes into a vi-

bratory

EARTHQUAKE.

bratory motion backwards and forwards, or in a whirling fort of movement.

9. A single shock is of short duration, scarcely ever exceeding a minute; but they frequently succeed each other, at short intervals, for a considerable length of time.

10. At the time of an earthquake, fissures, cracks, or chafms, are frequently opened in the earth, which are of various shapes and sizes; and are either shut up immediately, or they are left open. In great earthquakes, those openings of the earth frequently swallow up human beings, and other animals. And there are various instances on record of their having swallowed up even whole towns. Sometimes a fulphurous, or phosphoric smell, smoke, and flames, but more commonly waters, issue out of these openings.

11. Flame and smoke have also been emitted from the earth, when no openings were visible in it; and it is said, that flame and smoke have issued, likewise, from the water of the sea at the time of an earthquake.

12. The effects of an earthquake are felt by ships at sea, and often in a very great degree. An unusual motion of the water is mostly observed, which is either like a prodigious swell, or like a current setting in a certain direction, or somewhat like a whirling movement. The ships are affected with a sudden stroke, as if they had run a-ground, or struck upon a rock; and sometimes they are affected in a more hurtful manner, as we have mentioned above, during the earthquake of Lisbon.

13. Earthquakes are not confined to any particular district, or within any preferable limits. Some of their effects have frequently been observed at an immense distance from the actual scene of action. And if attentive observations were made, and proper machines were used, there is no doubt but that their effects would manifest themselves at a much more surprising distance.

The idea of measuring the vibrations of an earthquake, or of constructing a machine capable of indicating the motion of the earth, when affected by a moderate shock, has occurred to several persons. A Mr. Wark proposed to use a vessel partly filled with water, and having its inside surface above the level of the water, covered with powder of any light sort; for, if a vessel, so prepared, be kept on the ground, or upon any thing that is firmly fixed to the ground, the powder will remain unwashed from the inside of it, as long as the earth remains unshaken; but if the earth, and of course the vessel, happens to be moved out of its usual situation by any shock of an earthquake, then the water, by washing off some of the powder, from one side or the other of the vessel, would give an indication of that motion. (Roz. I. 376.) That the above-mentioned effect would take place, there can be no doubt; but the shortness of the radius of vibration (for a very large vessel could not be conveniently used for such a purpose.) will not render sensible any very small movements of the earth.

A watch-maker of the city of Naples, during the earthquakes of Calabria, in the year 1783, made a much better contrivance for the same purpose, which is as follows: By connecting three oblong pieces of wood, he formed a strong triangular frame, which he fixed straight up, in a very steady room, and screwed one side of it fast to the floor. From the upper angle of this triangular frame, a pendulum proceeded, which was about eight feet in length, and consisted of a rod, nicely suspended, and having a bob, or leaden ball, of a considerable weight, fastened to its lower extremity. Just under the ball there was a black lead pencil, which, by means of a delicate spring, was made to rest gently upon a sheet of paper, which was fixed horizontally under the pencil. It will be easily comprehended that, if the floor of the

room, wherein this machine was fixed, happened to be moved out of its usual level, the pendulum must necessarily move relatively to the frame, and, of course, the pencil must mark a black stroke upon the sheet of paper. The length and direction of this stroke would obviously indicate which way, and how much the floor was moved from its usual situation. This machine was used at Naples during the latter part of the earthquakes of Calabria, and its inventor had the satisfaction to observe several marks made by the pencil upon the paper, at the time that the shocks of the earthquake took place in Calabria (as it was proved by comparing the times with the information which was afterwards received from Calabria,) at the same time that no person in Naples was at all sensible of any shock. It is evident, that such a machine cannot indicate any perpendicular rising, or sinking of the ground.

The reader will easily believe, that a natural phenomenon of such magnitude, and of such consequence as an earthquake, has at all times excited the speculation of philosophers, respecting its nature and its origin. Though few experiments have been instituted with that view, yet a vast number of hypotheses have been offered, which run through all the intermediate steps, from the most evident absurdity to a degree of high probability. Almost all the ancient writers who speak of earthquakes offer some theory, or conjecture. But, as at that time, when the branches of natural philosophy were in their very infancy, in proportion to what they are at present, those theories, or conjectures, were hardly any thing more than random guesses; yet, it is to be remarked, that some of them coincide, in a great degree, with the two best modern theories, which rest upon the innumerable facts and discoveries that have been produced by the two or three last prolific centuries.

It was imagined by Anaxagoras, that vast caverns, or vaults, existed within the body of the earth, and that earthquakes were produced by subterraneous clouds, confined within those cavities, which, bursting into lightning, shook those vaults, and occasioned the shocks. Another hypothesis was, that the above-mentioned vaults, being undermined, or weakened by subterranean fires, at last fell in, with whatever lay upon them. Epicurus, and other Peripatetics, ascribed the earthquakes to the ignition of inflammable exhalations.

One of the most prevailing opinions, not only among the ancients, but also amongst the more modern, and even amongst some of the present philosophers, is, that the rarefaction of water is the cause of volcanoes; but it is curious to observe how this hypothesis has been differently modified at different times, and by different philosophers.

The very early philosophical writers were contented to say that water, reduced into steam by the heat of subterraneous fires, was the cause of earthquakes. Galenus, Kircher, Schottus, Varenius, Des Cartes, &c. supposed that there are numerous large cavities within the body of the earth, which communicate with one another. Some of these cavities contain water; whilst others contain vapour, or exhalations, arising from inflammable matter, such as bitumen, sulphur, &c. They then imagined that these exhalations were subject to inflammation, either from the effect of fermentation, or otherwise, and by their flow, or by their violent combustion, occasioned the different kinds of earthquakes. Fabri simply and judiciously supposed, that water, when prodigiously rarefied by heat, might sometimes be the cause of earthquakes. Dr. Woodward supposes, that the subterranean heat, or fire, which is continually elevating water out of the abyss, which, according to him, occupies the centre of the earth, to furnish rain, dew, springs, and rivers,

EARTHQUAKE.

rivers; may be stopped in some particular part. When this obstruction happens, the heat causes a great swelling and commotion in the waters of the abyss; and, at the same time, making the like effort against the superincumbent earth, that agitation and concussion of it are occasioned, which we call an earthquake. Mr. Amontons, of the French Academy of Sciences, offered the following hypothesis. According to the received philosophical principles, which suppose the atmosphere to be about 45 miles high, and that the density of the air increases in proportion to the absolute height of the superincumbent column of aerial fluid, it is shewn, that, at the depth of 43,528 fathoms below the surface of the earth, air is but one-fourth lighter than mercury. Now, this depth of 43,528 fathoms is only a 74th part of the semi-diameter of the earth; and the vast sphere beyond this depth, in diameter 64,451,538 fathoms, may probably be only filled with air; which will be here greatly condensed, and much heavier than the heaviest bodies we know of in nature. But it is found, by experiment, that the more air is compressed, the more does the same degree of heat increase its spring, and the more capable does it render it of a violent effect; and that, for instance, the degree of heat of boiling water increases the spring of the air above what it has in its natural state, in our climate, by a quantity equal to a third of the weight wherewith it is pressed. Whence, we may conclude, that a degree of heat which, on the surface of the earth, will only have a moderate effect, may be capable of a very violent one below. And, as we are assured, that there are in nature degrees of heat much more considerable than that of boiling water, it is very possible there may be some, whose violence, further assisted by the exceedingly great weight of the air, may be more than sufficient to break and overturn this solid orb of 43,528 fathoms; whose weight, compared to that of the included air, would be but a trifle.

This reasoning, though very specious, will not bear a careful and particular examination.

Dr. Stukeley seems to have been the first person who advanced that earthquakes were probably caused by electricity. The two earthquakes which were felt in London during the months of February and March 1749, together with that which happened in Northamptonshire on the 30th of September 1756, suggested this inquiry, upon which the doctor bestowed a good deal of attention, and he communicated his reasoning and his observations to the Royal Society in two papers, which are contained in the Phil. Trans. vol. xlvii. A summary of these papers is as follows.

That earthquakes are not owing to subterraneous winds, fires, vapours, or any thing that occasions an explosion, and heaves up the ground. Dr. Stukeley thought might easily be concluded from a variety of circumstances. In the first place, he thought there was no evidence of any remarkable cavernous structure of the earth; but that, on the contrary, there is rather reason to presume, that it is, in a great measure, solid, so as to leave little room for internal changes and fermentations within its substance; nor do coal pits, he says, when on fire, ever produce any thing resembling an earthquake.

In the second earthquake at London, there was no such thing as fire, vapour, smoke, smell, or any eruption of any kind observed, though the shock affected a circuit of 30 miles in diameter. This consideration alone, of the extent of surface shaken by an earthquake, he thought, was sufficient to overthrow the supposition of its being owing to the expansion of any subterraneous vapour.

For it could not possibly be imagined, that so immense a force, as could act upon that compass of ground instantaneously,

should never break the surface of it, so as to be discoverable to the sight or smell; when small fire balls, bursting in the air, have instantly propagated a sulphureous smell all around them, to the distance of several miles.

Besides, the operation of this great fermentation, and production of elastic vapours, &c. ought to be many days in continuance, and not instantaneous; and the evaporation of such a quantity of inflammable matter would require a long time.

He thought that if vapours and subterraneous fermentations, explosions, and eruptions, were the cause of earthquakes, they would absolutely ruin the whole system of springs and fountains wherever they had once been, which is quite contrary to fact, even where they have been frequently repeated. Mentioning the great earthquake which happened A. D. 17; when no less than 13 great cities of Asia Minor were destroyed in one night, and which may be reckoned to have shaken a mass of earth 300 miles in diameter, he asks, how can we possibly conceive the action of any subterraneous vapours to produce such an effect so instantaneous? How came it to pass that the whole country of Asia Minor was not at the same time destroyed, its mountains reversed, &c.? Whereas, nothing suffered but the cities.

To make the hypothesis of subterraneous vapours being the cause of earthquakes the more improbable, he observes, that any subterraneous power, sufficient to move a surface of earth thirty miles in diameter, must be lodged at least 15 or 20 miles below the surface of the earth, and, therefore, must move an inverted cone of solid earth, whose basis is 30 miles in diameter, and axis 15 or 20 miles; an effect which, he says, no natural power could produce.

Upon the same principle, the subterraneous cause of the earthquake in Asia Minor must have moved a cone of earth of 300 miles base, and 200 in the axis; which, he says, all the gun-powder which has ever been made since the invention of it, would not have been able to stir, much less any vapours, which could be supposed to be generated so far below the surface.

It is not upon the principles of any subterraneous explosion that we can in the least account for the manner in which ships, far from any land, are affected during an earthquake; which seems as if they struck upon a rock, or as if something thumped against their bottoms. Even the hills are affected by an earthquake. The stroke, therefore, must be occasioned by something that could communicate motion with unspcakably greater velocity than any heaving of the earth under the sea, by the elasticity of generated vapours. This could only produce a gradual swell, and could never give such an impulse to the water, as would make it feel like a stone.

Comparing all these circumstances, Dr. Stukeley says, he had always thought, that an earthquake was an electrical shock, of the same nature with those which are now become familiar in electrical experiments. And this hypothesis, he thought, was confirmed by the phenomena preceding and attending earthquakes, particularly those which happened in London and other parts of England. The weather, for five or six months before the first of these earthquakes, had been dry and warm to an extraordinary degree, the wind generally south and south-west, and that without rain, so that the earth must have been in a state of electricity ready for that particular vibration in which electrification consists. On this account, he observes, that the northern regions of the world are but little subject to earthquakes in comparison with the southern, where the warmth and dryness of the air, so necessary to electricity, are common.

All the flat country of Lincolnshire, before the earthquake

EARTHQUAKE.

in September, though underneath it is a watery bog; yet, through the whole preceding summer and autumn (as they can have no natural springs in such a level) had the drought so great on the surface of the earth, that the inhabitants were obliged to drive their cattle several miles to water. This, he says, shews how fit the dry surface was for an electrical vibration; and also, which is of great importance, that earthquakes reach but very little below the surface of the earth.

Before the earthquake at London, all vegetables had been uncommonly forward, and electricity is well known to quicken vegetation. As the weather had been uncommonly mild previous to the earthquake, it is more likely that the forward state of vegetation was owing to that circumstance, rather than to the interference of electricity, which Dr. Ingenhousz found, by a variety of experiments, not to forward vegetation, as it had been believed.

Dr. Stukeley continues to remark, that the aurora borealis had been very frequent about the same time, and had been twice repeated just before the earthquake, of such colours as had never been seen before. It had also removed to the south, contrary to what is common in England; so that some Italians, and people from other places where earthquakes are frequent, observing these lights, and the peculiar temperature of the air, did actually foretell the earthquake. For a fortnight before the earthquake in September, the weather was serene, mild, and calm; and one evening, there was a deep red aurora borealis, covering the cope of heav'n, very terrible to behold. The whole year had been remarkable for fire-balls, thunder, lightning, and comets, almost throughout England. And all these meteors are supposed to be caused by the electrical state of the atmosphere.

In these previous circumstances of the state of the earth and air, nothing, he says, is wanting to produce the wonderful effect of an earthquake, but the touch of some non-electric body, which must necessarily be had *ad extra*, from the region of the air, or atmosphere. Hence, he infers, that if a non-electric cloud discharges its contents upon any part of the earth in that highly electrical state, an earthquake must necessarily ensue. It has been observed, that the noise which commonly attends earthquakes, generally precedes the shock: whereas it must have been quite the contrary if the concussion had depended upon a subterraneous eruption. This noise attending earthquakes, the doctor thought, could not be accounted for, but upon the principles of electricity. He also thought that the flames and sulphureous smells which are frequently observed during earthquakes, are more easily accounted for, upon the supposition of their being electrical phenomena. The impression made by an earthquake upon land and water, to the greatest distances, is instantaneous, which could only be effected by electricity.

The little damage, the Dr. says, generally done by earthquakes, is an argument of their being occasioned by a single vibration, or tremulous motion of the surface of the earth by an electrical snap. This vibration impressed on the water, meeting with the solid bottoms of ships and lighters, occasions that thump which is said to be felt by them. That earthquakes are electrical phenomena, he thinks, is made further evident, from their chiefly affecting the sea-coast, places along rivers, and eminences. Lastly, the doctor adds, as a farther argument in favour of his hypothesis, that pains in the back, rheumatic, hysterick, and nervous cases; head-aches, colics, &c. were felt by many people of weak constitutions for a day or two after the earthquake; just as they would after electrification, and, so some, these disorders proved fatal.

In what manner the earth and atmosphere are put into that electrical and vibratory state, which prepares them to give or receive that snap and shock which we call an earthquake, and whence it is that this electric matter comes, the doctor does not pretend to say, but thinks it as difficult to account for as magnetism, gravitation, muscular motion, and many other secrets in nature.

Willing to throw as much light as possible upon the important and obscure subject of earthquakes, we have endeavoured to extract the most important part of Dr. Stukeley's ingenious papers, which, since their publication in the Phil. Trans. have acquired many adherents; yet it is easy to perceive, that he writes like a man who has long employed his serious thoughts upon a favourite subject; which naturally casts a veil over the merits of other subjects that may stand in opposition to the former. The doctor mostly derived his conclusions from the phenomena which attended the slight earthquakes of 1749 at London. Had he lived to examine the subsequent earthquakes of Lisbon and of Calabria, it is most likely that he would at least have altered some of his arguments. He is mistaken when he says, that the force of steam cannot possibly equal that of gun-powder. He also lays too much stress upon various effects which might be attributed to other causes as well as to the agency of electricity; and at last, his not being able to account for the accumulation of an enormous quantity of electricity in the earth or in the atmosphere, forms the greatest defect of his theory.

The similarity between the effects of electricity and some of the phenomena that attend earthquakes, has struck a great many persons, but when one examines the particulars a little beyond the bare similarity of certain phenomena, there appears to be very little reason for concluding that electricity is the cause of earthquakes. The chevalier Vivencio, in his account of the earthquakes of Calabria in 1783, expresses his perfect conviction of their being electrical phenomena; but his hypothesis of the accumulation of electric fluid under certain strata of non-conducting matter, and of the force which it must exert against those strata, is too vague to demand any particular examination. This author is not only persuaded that electricity is the cause of earthquakes, but he also proposes a remedy against their effects. In short, he proposes to fix metallic rods into the ground, as deep as it may be practicable, through which the electric fluid may pass from the earth into the atmosphere, and *vice versa*. These rods, he says, should project some feet above the surface of the earth, and both extremities of each metallic rod, *viz.* that which is within, and that which is above the ground, should terminate into a number of points, or pointed branches, somewhat like a brush. And if another set of such pointed branches was placed about the middle of each rod, it would be still better.

Whoever is acquainted with the practical part of electricity, must know how difficult it is to confine the electric fluid, especially when it is much condensed, or in large quantities. The best possible insulation, formed by the interposition of dry glass and resins, will hardly prevent the dissipation of that subtle fluid, which will endavour to fly off into the air, or to any other body which may happen to be within its reach. How difficult it is then to conceive, that an immense quantity of that fluid (for surely immense must that quantity be which can produce an earthquake) can be accumulated in any part of the earth, without its immediately rushing to the other parts of it; or, in short, that it may be accumulated at all in any part of it more than in another. It is undoubtedly true, that the earth contains various non-conducting bodies; but the manner in which they

EARTHQUAKE.

they are found to exist is such as to prevent the possibility of forming a perfect non-conducting stratum of any considerable extent: for they either exist in separate pieces, or they are intermixed with water and a variety of other bodies, so that the whole compound is far from being a non-conductor of electricity. And we may venture to add, that as far as human art has been able to descend below the surface of the earth, it is not possible to cut off from any part of it a cubic lump of 15 or 20 feet, which might be considered as a perfect non-conductor of electricity. In the atmosphere, or in the clouds, as far as we know, no very extraordinary quantity of electricity can be accumulated, beyond what may constitute a thunder-bloom; for though the *aurora borealis*, shooting stars, as they are commonly called, and other meteors, have been supposed to be electrical phenomena, yet there is no certain evidence of their being actually so.

Such, in brief, are the observations which may be advanced respecting the supposed accumulation of electric fluid, either within the earth or in the atmosphere. If, then, we proceed to examine the effects, we shall undoubtedly find, that some of those which are produced by earthquakes may be conveniently explained upon the supposition of their being electrical phenomena; and the principal of these is the effect produced upon vessels at sea. But several others cannot be satisfactorily reconciled to it: for instance, in the earthquakes of Calabria, in 1783, small shocks, strong shocks, and extraordinary commotions, followed one another at short intervals of time, without any order or regularity. Now it is difficult to comprehend how the electric fluid, which produced these shocks, could be let out of its confinement in a manner so irregular: for if a small quantity of it, which produced a slight shock, could find an exit, why a larger quantity of it (which can much more easily cut its way through any obstacle) could not come out at the same time? and yet, not long after, this large quantity comes out of its confinement, and produces a great earthquake.

Light flames, supposed to have been electric fire, have been frequently seen at the time of earthquakes; but, in the first place, these flames may have been nothing more than the combustion of hydrogen gas, dislodged from under the earth, and inflamed at the time of an earthquake; and, secondly, they may be allowed to be electric fire, without the least necessity of admitting that earthquakes are produced by electricity: for, at the time of an earthquake, the conversion of a certain quantity of water into vapour, or of vapour into water, generally and evidently takes place; and whenever this is the case, electricity must be generated, because vapour contains much more electric fluid than water, or the same quantity of water contains less of the electric fluid in that state, than in a state of vapour: therefore, when water is converted into vapour, a quantity of electric fluid is absorbed, and, of course, negative electricity is manifested;—when vapour is converted into water, a quantity of electric fluid is deposited, and, of course, positive electricity is manifested.

The communication of the shock of an earthquake to places far distant from each other, at the same or nearly at the same instant of time, has also been alleged as a proof of their being produced by electricity. But surely when a stroke of any kind, and of sufficient strength, is given to any part of an extended solid, the commotion is communicated to the most distant parts of it, if not instantaneously, at least in an exceedingly small portion of time. The least scratch of a pin, at one end of the longest beam that can be produced, is instantly heard at the other end, by a person who puts his ear in contact with the beam.

The last hypothesis which remains to be mentioned is, that earthquakes are produced by the sudden expansion of water into vapour; and this indeed coincides with the opinions of various ancient authors: but it is rendered much more probable by the facts which, of late years, have been ascertained respecting the expansibility of steam. The principal facts are as follow. Water, raised to the temperature of 212° of Fahrenheit's thermometer, in an ordinary state of the atmosphere, is converted into steam, &c. an elastic fluid, the bulk of which is not much less than 1800 times the bulk of the water from which it originated; and in that state, its elasticity enables it to support the pressure of the atmosphere. If its temperature be increased by about 50 more, so as to amount in all to about 262°, then its elastic force will be doubled; by the addition of 30 more of heat, its elasticity will be quadrupled; and so on: nor is it known how far this increase of elasticity may be extended, by increasing the temperature. Therefore, if water happens to fall upon any thing, which can instantly communicate a very high degree of heat to it, the elasticity of the vapour, which is thereby produced, may be equal to any force we may have any idea of. The only thing requisite is the ignited substance, which is to furnish a sufficient quantity of heat; and for this purpose, large quantities of melted metals are the fittest, especially those which require a very high temperature for their fusion; metallic substances being very good conductors of heat, so that when water falls upon any part of the melted matter, the caloric rushes to that spot from every part of the mass, and instantly converts the water into steam, possessed of a prodigious elastic force. Now the application of these facts to the production of earthquakes is extremely easy, as will appear from the following observations of Dr. Thomas Young. We must not, however, omit to acknowledge that there are certain circumstances, which indicate a connection between the state of the atmosphere and the approach of an earthquake, and which do not seem to admit of an explanation upon this hypothesis.

“The shocks of earthquakes,” Dr. Young says, “and the eruptions of volcanoes, are, in all probability, modifications of the effects of one common cause: the same countries are liable to both of them; and where the agitation produced by an earthquake extends farther than there is any reason to suspect a subterraneous commotion, it is probably propagated through the earth nearly in the same manner as a noise is conveyed through the air. Volcanoes are found in almost all parts of the world, but most commonly in the neighbourhood of the sea, and especially in small islands; for instance, in Italy, Sicily, Iceland, Japan, the Caribbees, the Cape Verd islands, the Canaries, and the Azores. There are also numerous volcanoes in Mexico and Peru, especially Pichincha and Cotopaxi. The subterraneous fires, which are continually kept up in an open volcano, depend perhaps in general on sulphurous combinations and decompositions, like the heating of a heap of wet pyrites, or the union of sulphur and iron-sfilings; but, in other cases, they may perhaps approach more nearly to the nature of common fires. A mountain of coal has been burning in Siberia for almost a century, and most probably have undetermined, in some degree, the neighbouring country. The immediate cause of an eruption appears to be very frequently an admission of water from the sea, or from subterraneous reservoirs. It has often happened that boiling water has been discharged, in great quantities from a volcano; and the force of steam is perhaps more adequate to the production of violent explosions, than any other power in nature. The consequence of such an admission of water into an immense collection of ignited materials, may in some measure

be understood, from the accidents which occasionally happen in founderies: thus, a whole furnace of melted iron was lately dissipated into the air, in Colebrook Dale, by the effect of a flood, which suddenly overflowed it."

We shall now conclude this article with the account of an idea of a preservative against the effects of earthquakes, which has been not only believed, but actually put in practice by various persons at different times. The idea is, that deep wells, by giving vent to the effluvia, whatever they be, that produce earthquakes, will guard cities, buildings, &c. against their effects; or rather that they will prevent the shocks of earthquake. And this effect, provided it be true, seems to be much in favour of the last-mentioned hypothesis, namely, that earthquakes are occasioned by the great expansion or elasticity of aqueous vapour. We do not mean to touch for the truth of it, but we shall briefly mention our authorities. Pliny says, "In terræ motibus est remedium, quale, et crebri specus præbent: conceptum enim spiritum exhalant: quod in certis notatur oppidis, quæ minus quantur, crebris ad cluivem cuniculis cavata. Multaque sunt tutiora in iisdem illis, quæ pendent; sicut Neapoli in Italia intelligitur."—Desunt autem tremores, cum ventus emerit." Hist. Nat. l. ii. cap. 82. In the city of Naples, there is a pyramid erected before a church, dedicated to St. Januarius, under which (Celano, in his first volume of the description of that city, says that) there is a deep well, which has several openings about the base of that pyramid, and which was made expressly for the purpose of saving it from the effects of earthquakes. Toaldo, the distinguished astronomer, is much inclined to believe that idea, and he adduces several instances in corroboration of it. (See his Saggio Meteorologico, printed at Padova, in 1770.) This author, among other instances, says, that the city of Udine, capital of the Friuli, has four very deep wells, and other excavations, made at a very remote period; for they are even mentioned by Palladio: and ancient tradition says, that they were made at a time when that province suffered frequent earthquakes; and that the expedient seems to have been attended with the desired effect. The ancient city of Nola, in the kingdom of Naples, was never known to have been damaged by earthquakes; and this city contains both within and without its boundaries a great number of wells. It is much to be wished, that such cases may be inquired into, and properly examined, wherever they may be thought likely to occur.

EARTHQUAKE, Artificial. There are two experiments, frequently described by chemical and philosophical writers, to which they have given the name of artificial earthquakes: one of them is furnished by the science of chemistry, the other by that of electricity. The former, which, by the bye, may with more propriety be called an *artificial volcano*, is prepared in the following manner: Take about twenty pounds weight of iron-slings, and an equal quantity of powdered sulphur, or of flowers of sulphur; mix these two articles with as much water as will enable you to work them into a mass like a pretty stiff paste; and in that state bury it into the ground, about a foot or two below the surface. This paste, being a sort of artificial pyrites in a moist state, will ferment and will generate heat sufficient to set it actually on fire; so that, some hours after the laying down of the above-mentioned paste, the earth over it will be seen to crack, and fire will come out of it.

By means of electricity, the artificial earthquake may be performed various ways; but the following is perhaps the best. Place the extremities of two wires upon the surface of a thick and flat piece of glass; so that they may stand in one direction, and about one inch distant from each other.

Lay a little cylinder of ivory (about three-fourths of an inch in diameter, and an inch or two high) upon that part of the surface of the glass which lies between the extremities of the two wires. Upon the upper part of the ivory cylinder, place a little board about five or six inches square; and upon this, which may represent the ground of a town, dispose, in any manner you please, little representations of houses, made either of paper, or cork, or wood, &c. Things being thus prepared, connect one of the above-mentioned wires with the outside of a pretty large Leyden phial, fully charged with electricity, and connect the other wire with the knob of the same phial: in doing which, the charge or shock will pass over the flat piece of glass, and under the ivory cylinder, from the extremity of one wire to the other. This shock hardly ever fails to break the glass, and to shake the ivory cylinder, with the board that stands over it, so as to throw down the little representations of houses, &c.; and thus it will give a faint representation of an earthquake. This experiment may be performed very commodiously, by using an electrical instrument, called the *universal discharger*; for a description of which, see the article *ELECTRICAL Apparatus*.

EARTHWORM, in Zoology. See **LUMBRICUS**.

Earthworms are by some esteemed of great virtue in medicine, and are said to be diuretic, diaphoretic, and anodyne; as also discutient, emollient, and openers of obstructions; and have been prescribed in apoplexies, spasms, and all nervous affections, and in the jaundice, dropics, and colics. See **WORM Tincture**.

EASE, in the Sea Language, signifies as much as slacken, or let go slacken.

Thus they say, ease the bowline, ease the sheet; that is, let them go slacken.

EASE the Ship, is the command given by the pilot to the steersman, to put the helm close to the lee side; or hard-a-lee, when the ship is expected to pitch or plunge her fore-part deep in the water while close hauled.

EASE, Chapel of. See **CHAPEL**.

EASEL the frame used by painters to support the tablet, or frame of canvas, upon which they are painting.

The easel in common use is too well known, and too simple, to need a figure: it is only a triangular frame, which stands on its base, and is supported in an inclined position by a leg behind; the sides of the triangle are perforated with holes to receive pegs, which support the tablet; and by placing the pegs in other holes, the canvas can be placed higher or lower on the frame. Mr. Middleton of St. Martin's Lane, London, has contrived an easel, represented in *fig. 1. Plate XII. Miscellany*, of which A A is a rectangular frame of mahogany, having grooves for a frame, *a a*, to slide up and down in; and a small spring-latch at the underside of the frame, *a a*, fixes the frame at any height the painter chuses, by locking into any of the holes made in the middle rail of the frame A A. The canvas is reeled upon a small box, *b*, at the lower part of the frame *a a*; and the box also serves as a shelf to contain spare pencils, &c. *D* is a leg to support the frame A A, which is shut up close to the frame, when the easel is not in use.

EASEL-Pieces, among *Painters*, such smaller pieces, either portraits or landscapes, which are painted on the easel.

They are thus called to distinguish them from larger pictures drawn on walls, ceilings, &c.

EASEMENT, in Law, a service or convenience which one neighbour has of another by charter or prescription, without profit; as a way through his ground, a sink, or the like. (Kitch. 105.) A person may prescribe to an easement in the freehold of another, as belonging to some ancient house, or land, &c. And a way over the land of another

other

other, a gate-way, water-course, or washing-place on another's ground, may be claimed by prescription as easements. But a multitude of persons cannot prescribe; though for an easement they may plead custom. Cro. Jac. 170. 3 Leon. 254. 3 Mod. 294.

In the civil law, easements are called *servitus predii*.

EASINGWOLD, in *Geography*, a market-town in the wapentake of Eulmer, in the North Riding of Yorkshire, England, is about 11 miles from York, and 206 from London. According to the late official report to parliament, in 1801, this town contained 269 houses, and 1467 inhabitants. Here are a weekly market on Fridays, and two annual fairs.

EASK, a lake of Ireland, in the county of Donegal; 4 miles N.E. of Donegal.

EAST, in *Cosmography*, one of the cardinal points of the horizon; being the point wherein the prime vertical intersects that quarter of the horizon in which the sun rises when in the equinoctial.

The word east is Saxon. In Italy, and throughout the Mediterranean, the east-wind is called the *levante*.—In Greek, *ανατολη* and *ανατολις*, because it comes from the side of the sun, *ανα* *ηλιος*:—in Latin, *curus*.

To find the east and west line, points, &c. see **MERIDIAN-Line**, and **DEGREE**.

EAST-Wind, is that which blows from the east point. See **WIND**.

EAST-Dials. See **DIAL**.

EAST-India Companies. See **COMPANY**.

EAST-India Silk. See **SILK**.

EAST, Mooring for. See **MOORING**.

EASTANALLEE, in *Geography*, the N.E. head branch of Alabama river, in Georgia, North America, on which stands the town of Eastanallee.

EAST ANDOVER, a town of America, in York county, and state of Maine, 90 miles N.W. of Portland, containing 175 inhabitants.

EAST BAY, an arm of lake Champlain, projecting eastward from its south point.

EAST BETHLEHEM, a township of America, in the county of Washington and state of Pennsylvania, having 1461 inhabitants.

EASTBOURNE, a parish in the hundred of Eastbourne, and rape of Pevensey, in the county of Sussex, England, is one of those places that has obtained some degree of celebrity, in consequence of being frequented in the summer months, for bathing. It is situated in a valley, nearly surrounded by hills, which are mostly appropriated to sheep-walks. The country is very similar to parts of Salisbury plain; and, like that, consists of a substratum of chalk and flint, with a thin stratum of mould, which produces a fine sweet herbage for sheep. The village is about one mile from the sea, near which is the hamlet of Southbourne, where are several modern houses built and fitted up for visitors. In the parish is a free-school for 15 boys, a small theatre, and barracks for horse and foot soldiers. In the church, which has some claim to antiquity, are several fine monuments. Lord George Cavendish has a handsome seat here. At a place called Holywell is a spring of chalybeate water, which is said to possess similar qualities to the Bristol waters. On this coast the cliffs are very lofty in places, particularly that promontory called *Beachy-head*, which is noted by mariners as a place of danger. Here are many caverns in the cliffs, which are much frequented by smugglers. See a Guide to Eastbourne.

EAST CAMP, a village of New York, in the county of

Columbia, on the east bank of the Hudson, 7 miles above Red Hook; 13 miles N. of New York.

EAST CAPE, the easternmost point of the continent of Asia, and the dominions of Russia. N. lat. 66° 15'. W. long. 169° 32'.

EAST CAPE, the easternmost land of the coast of New Zealand. S. lat. 37° 42' 3". W. long. 181°. The cape is high, and has white cliffs.

EAST CHESTER, a township of America, in the state of New York and county of West Chester, on Long Island Sound, about 8 miles S.W. of Rye, and 17 N.E. of New York, containing 738 inhabitants.

EASTER, in *Chronology* and *Ecclesiastical History*, a feast of the church, held in memory of our Saviour's resurrection.

The Greeks and Latins call it *Πασχα*, *pascha*, originally a Hebrew word, signifying *passage*, applied to the feast of the Passover, which is held among the Jews much about the same time. In English it is called Easter, from *Eastre*, a goddess worshipped with peculiar ceremony in the month of April.

The observation of this festival is as ancient as the time of the Apostles; for it is certain that the Christians of the second century celebrated anniversary festivals in commemoration of the death and resurrection of Christ, and of the effusion of the Holy Ghost upon the apostles. The day which was observed as the anniversary of Christ's death was called the paschal day, because it was considered as the same with that on which the Jews celebrated their Passover. But towards the close of this century, a dispute commenced about the particular time in which this feast was to be kept. The Asiatic churches kept it on the 14th day of the first Jewish month, and three days after commemorated the resurrection of the Redeemer, pleading on behalf of this practice the authority of the apostles, Philip and John, and the example of Christ, who held his paschal feast on the same day that the Jews celebrated their passover. The western churches celebrated their paschal feast on the night that preceded the anniversary of Christ's resurrection, and thus connected the commemoration of his death with that of his resurrection; and they pleaded the authority of the apostles Peter and Paul. One principal inconvenience attending the Asiatic method was, that this great festival was commonly held on other days of the week than the *first*, or Sunday, which was the day of Christ's resurrection. Hence very vehement contentions arose between the Asiatic and Western Christians. About the middle of the second century, during the reign of Antoninus Pius, the venerable Polycarp came to Rome, to confer with Anicet, bishop of that see, upon this matter; but the conference, though conducted with great decency and moderation, was ineffectual for terminating the disputes. Polycarp and Anicet, however, agreed in opinion, that the controversy ought not to dissolve the bonds of charity. Towards the close of this century, Victor, bishop of Rome, attempted to force the Asiatic churches, by the pretended authority of his laws and decrees, to follow the rule which was observed by the western churches: they refused to submit, and were excommunicated by Victor. However, in consequence of the mild interposition of Irenæus, bishop of Lyons, the disputants retained their own customs till the fourth century, when the council of Nice abolished that of the Asiatics, and rendered the time of the celebration of Easter the same through all the Christian churches.

Easter is one of the most considerable festivals in the Christian calendar; being that which regulates and determines the time of all the other moveable feasts.

The rule for the celebration of Easter, fixed by the council

E A S T E R.

council of Nice, in the year 325, is that it be held on the Sunday which falls next after the full moon following the 21st of March; *i. e.* the Sunday which falls next after the first full moon after the vernal equinox.

The reason of which decree was, that the Christians might avoid celebrating their Easter at the same time with the Jewish passover, which, according to the institution of Moses, was held the very day of the full moon.

To find Easter agreeably to this rule, the method that obtained throughout the church, from the time of Dionysius Exiguus to that of the reformation of the calendar under pope Gregory, and which still obtains in countries where the Gregorian correction is not admitted, is, by means of the golden numbers, duly distributed throughout the Julian calendar. See *METONIC CYCLE*.

To find Easter by the golden number, see *NUMBER OF DIRECTION*, and *METONIC CYCLE*.

In the new or Gregorian computation, in lieu of golden numbers, the time of Easter is found by means of epacts contrived for that purpose. See *EPACT*, and *METONIC CYCLE*.

Having the dominical letter and the epact, Easter-day may be found by the two following rules: 1. For finding Easter limit, or the day of the paschal full moon from March the first inclusive; add 6 to the epact; and if this sum exceeds 30, 30 must be taken from it; the remainder subtracted from 50 will give the limit, which is never to exceed 49, nor fall short of 21. 2. From the limit and dominical letter, Easter-day may be found, by adding 4 to the number of the dominical letter, subtracting the sum from the limit, and the remainder from the next higher number, which is exactly divisible by 7; add the last remainder to the limit, and the sum will give the number of days from the 1st of March to Easter-day, both inclusive. Thus for the year 1809, the epact is 14, and the dominical letter A: $6 + 14 = 20$; $20 - 20 = 30$ paschal limit; $30 - 5$ the sum of 4 and the dominical letter, = 25; and $28 - 25 = 3$, which added to 30, the limit, gives 33, or the number of days from March the 1st inclusive to Easter-day, or 2d of April.

The following table renders the finding of Easter in the Gregorian year from the year 1700 to the year 1900 very easy.

Epacts.	Paschal full Moons.	Epacts.	Paschal full Moons.		
X.	13 April,	E.	IX.	4 April,	C.
XI.	2 April,	A.	XX.	24 March,	F.
XXII.	12 March,	D.	I.	12 April,	D.
III.	10 April,	B.	XII.	1 April,	G.
XIV.	30 March,	E.	XXIII.	21 March,	C.
XXV.	18 April,	C.	IV.	9 April,	A.
VI.	7 April,	F.	XV.	29 March,	D.
XVII.	27 March,	B.	XXVI.	17 April,	B.
XVIII.	15 April,	G.	VII.	6 April,	E.
			XXVIII.	26 March,	A.

Now, to find Easter for any given Gregorian year, seek the dominical letter and the Gregorian epact, as shewn under *EPACT* and *METONIC CYCLE*. Find the epact in the table, and note the paschal full moon, with the weekly letter corresponding to the same.

E. gr. the dominical letter of 1809 is A, and the epact XIV. consequently the paschal full moon falls on the 30th of March E, which is therefore Thursday, and Easter-day is the 2d of April, as before.

Though the Gregorian calendar be doubtless preferable to the Julian, yet it also has its defects. It cannot, for instance, keep the equinox fixed on the 21st of March, but it will sometimes fall on the 19th, and sometimes on the 23d.

Add, that the full moon happening on the 20th of March, might sometimes be paschal; yet it is not allowed as such in the Gregorian computation; as on the contrary, the full moon of the 22d of March may be allowed for paschal, which it is not. See Iger and Calvisius have also proved other inaccuracies in this calendar. See *CALENDAR*. See an excellent paper on this subject by the earl of Macclesfield, in the Phil. Trans. vol. xl. p. 417. See *METONIC CYCLE*, and *EPACT*.

EASTER, in *Geography*, an island in the South Pacific ocean, commonly supposed to be *Davis's land*, from its having been visited by Capt. Davis in 1686, but touched at by Roggewin in April 1722, is situated in S. lat. $27^{\circ} 5' 30''$. and W. long $109^{\circ} 46' 20''$. The French editor of La Perouse's voyage is of opinion that Davis's land does not exist: but that there are islands in the 27th degree of S. latitude, about 20 leagues from Copiapo, which are the islands of St. Felix and St. Ambrose, laid down erroneously in all the maps; and that these islands are the pretended land of Davis. Easter is about ten or twelve leagues in circuit, having a hilly and stony surface, and an iron bound shore. The hills are so high that they may be seen at the distance of 15 or 16 leagues. Off the S. end are two rocky islets lying near the shore: the north and east points of the island rise directly from the sea to a considerable height; between them, on the S.E. side, the shore forms an open bay, in which Capt. Cook, who visited this island in March 1774, supposes that the Dutch anchored. He anchored on the west side of the island, three miles to the north of the fourth point, in a road which is very good with easterly winds, but dangerous with those that are westerly, as the other on the S.E. side must be with easterly winds. This bay, called "Cook's bay," is easily known, says La Perouse; for after doubling the two rocks off the S. point of the island, and running along shore at the distance of a mile, a small creek may be perceived, which is the most certain landmark. When this creek bears E. by S. and the two rocks just mentioned are shut in with the point, there is anchorage in twenty fathoms water over a bottom of sand, at three quarters of a mile from the shore. Nothing, however, but necessity, says Cook, will induce any one to touch at this isle, unless it can be done without going much out of the way, in which case it may be done with advantage, as the people readily part with such refreshments as they have, and at an easy rate. Generally speaking, this island affords no safe anchorage, no wood for fuel, nor any fresh water worth taking on board. Nature has been very sparing of her favours to this spot. As every thing must be raised by dint of labour, it cannot be supposed that the inhabitants plant much more than is sufficient for themselves, and as they are but few in number, they cannot have much to spare to supply the wants of strangers who may chance to visit them. La Perouse says, that scarcely a tenth part of the island is cultivated; and such is its fertility, that three days' labour is sufficient to produce the Indian subsistence for a year. The lands already cleared are in an oblong form, and very regular, without any inclosure; the rest of the island is covered with a very coarse grass, which extends to the summit of the mountains. The people seemed to have no implements of agriculture; and therefore it is probable, that when they have cleared the land, they make holes with flukes, and then plant their yams and potatoes. However, in the cultivation of the soil they manifest great

intelligence,

intelligence, as they pull up the weeds, burn them in heaps, and thus fertilize the soil. The banana trees are planted in a strict line by a cord. The produce of the island is sweet potatoes, yams, taro or root, plantain, and sugar canes, all of which are tolerably good, and the potatoes peculiarly excellent in their kind. They have some few gourds. Their tame fowls, such as cocks and hens, were few and small, but well tasted. They have also rats, which they eat: of land birds there are scarcely any, and their sea birds are few; these were men of war, tropic and egg birds, noddies, tern, &c. The coast did not seem to abound with fish. The soil is kept cool and moist by large stones, that lie loose upon the earth, and supply the place of the salutary shade, of which the inhabitants have deprived themselves by felling their trees. This practice, which has exposed their soil to be burnt up by the sun, and precluded the existence of floods, rivulets, or springs, must have taken place in very remote periods. The inhabitants did not seem to exceed 6 or 700 in number, and of these above two-thirds were males, according to Cook's account; but La Perouse, in 1785, estimated them at 2000: and the disproportion between the males and females not so considerable. Their population did not seem to be on the decline. In colour, features, and language, they bear such affinity to the people of the more western isles, that they are without doubt of the same origin. Their language, physiognomy, and manufactures, are the same with those of the other islands of the South sea. They are generally of a slender race; so far from being giants, as one of the authors of Ruggewin's voyage asserts, not one of them was seen who measured six feet. They are brisk and active, have good features, and not disagreeable countenances; are friendly and hospitable to strangers, but as much addicted to pilfering as any of their neighbours, nor do they seem to attach any disgrace to it. But they are well apprized of the injustice they commit, for they instantly fly to escape the punishment, which they evidently expect. The practice of tattooing or puncturing the skin is much used in this island, both by the men and women; but less by the latter than by the former. Their clothing is a piece or two of quilted cloth, about six feet by four, or a mat. One piece wrapped round their loins, and another over their shoulders, made a complete dress. But the men are generally naked, or wear nothing but a slip of cloth between their legs, fastened by each end to a cord or belt passing round their waist. Their cloth, like that of Otaheite, is made of the bark of the cloth-plant. Their hair is commonly black, worn long by the women, and sometimes tied up on the crown of the head; but the men wear their hair and beards cropped short. Their head-dress is a round fillet adorned with feathers; and both men and women have very large holes, or rather slits in their ears, extended to the length of nearly three inches. Their ear ornaments are the white down of feathers, and rings made of some elastic substance and rolled round like a watch spring. The women offer their favours to those who are disposed to purchase them by presents; and the men urge the acceptance of them, and while the women lavish their caresses, they take away the hats and the handkerchiefs of those who comply. All seemed to be accomplices in these thefts, and as soon as they were committed, ran away like a covey of birds. Some of them dragged girls thirteen or fourteen years of age, solely with the hope of receiving the reward of panders; but their repugnance evinced, that in them the laws of the country were violated. Although these islanders seem to be harmless and friendly, they are not destitute of offensive weapons, such as short wooden clubs and spears; the latter of which are crooked sticks about six feet long,

armed at one end with pieces of flint. Their houses are low miserable huts, constructed by setting sticks upright in the ground, at six or eight feet distance, then bending them towards each other, and tying them together at the top. The building is so contrived as to be high and broad in the middle, and lower and narrower towards each end. To these sticks are affixed others in a horizontal direction, and the whole is thatched over with leaves of sugar-cane. The door way is in the middle of one side, formed like a porch, and so low and narrow as just to admit the entrance of a man crawling upon all fours. The largest of these huts seen by Capt. Cook was about 60 feet long, eight or nine feet high in the middle, and three or four at each end; its breadth being nearly equal to its height. But La Perouse measured a house, constructed since Cook's visit, which was 300 feet in length, 10 in breadth, and in the middle 10 in height. Its form was that of a canoe inverted; and it had no entrance except by creeping on the hands through two doors, both less than two feet high. This house was capable of containing 200 persons; and, together with two or three others not far distant, formed a village. Some dwellings are subterraneous, and are a kind of caverns or vaulted houses, constructed with stone. In these under-ground habitations, which are numerous in the interior part of the island, Capt. Cook and some of his officers imagine that the inhabitants conceal their women and children. They dress their victuals in the same manner as at Otaheite, with hot stones, in an oven or hole in the ground. The straw, or tops of sugar-canes, plantain-heads, &c. serve as fuel to heat the stones. In every district there is probably a chief, who superintends the plantations, of which Capt. Cook imagined he was the proprietor. The most probable conjectures concerning the government of these islanders are, that they compose but a single nation divided into as many districts as there are "morais;" for it was observed that their villages are built near these cemeteries. The productions of the earth appear to be common to all the inhabitants of the same district; and as men offer their wives to strangers without the least delicacy or reserve, it must be supposed that they do not belong to any man in particular, and that as soon as children are weaned, they are delivered to other women, who in each district are charged with the management of them. The island abounds with several monuments and statues, of a gigantic size, which appear to be very ancient; and they are placed in a kind of morai, or burying-ground, which might be inferred from the number of bones that were near them. Instead of the colossal mausolea of pride and vanity, these islanders have substituted small heaps of stone in the shape of a pyramid, the upper stone of which is whitened with lime water. These little monuments are erected near the sea-shore; and an Indian clearly expressed to La Perouse and his companions the object to which these heaps of stones were appropriated, by laying himself down and afterwards lifting up his head towards heaven, which evidently expressed his belief in a future existence. However, they observed no trace of religious worship among them, and the gigantic statues are not regarded as idols by the present inhabitants, though they express a kind of veneration for them. They are placed on platforms of masonry, some of which are 30 or 40 feet long, 12 or 16 broad, and from 3 to 12 feet in height. They are faced with heavy stones of a very large size; and the workmanship is not inferior to the best plain piece of masonry we have in England. They use no sort of cement, and yet the joints are exceedingly close, and the stones mortised and tenanted into one another in a very artful manner. The side walls are not perpendicular, but inclining a little inwards; like the breast-

works, &c. that are built in Europe; and yet notwithstanding all the skill manifested in their construction, these curious structures are moldering by the ravages of all-devouring time. The colossal statues, the largest of which is only fourteen feet six inches high, seven feet six inches broad across the shoulders, three feet thick in the belly, and six feet broad, and five feet thick at the base, rest upon platforms as their foundations. They are formed by a rude kind of sculpture out of a volcanic production, known among naturalists by the name of "lapillo," says La Perouse, a stone so light and friable, that some of Capt. Cook's officers thought it might be a factitious substance, composed of mortar indurated by the air. Although the workmanship is coarse, the features of the face are not ill formed, particularly the nose and chin; but the ears are long beyond proportion; and, as to the bodies, there is nothing like a human figure about them. In order to elevate them upon the platforms, and to place large cylindrical stones upon their heads, Capt. Cook supposes that they raised the upper end by little and little, supporting it by stones as it was elevated, and building about it till it became erect; and thus a sort of mount or scaffolding would be formed, upon which they might roll the cylinder, and place it upon the head of the statue; and then the stones might be removed from about it. We may hence infer the ingenuity and perseverance of the islanders at the period in which they were constructed. Besides these monuments of antiquity, which were numerous, on or near the sea-coast, there were many smaller piles of stones along the coast, as we have already mentioned. These stones were lavas of different densities. The canoes of these people are of the same form with those of the Society islands; but they were mean in their structure, being built of many pieces of wood sewed together with small line. There were only about three or four of them observed on the island; about 18 or 20 feet long, head and stern carved or raised a little, very narrow, and fitted with out-riggers. They seemed capable of carrying no more than about four persons, and unfit for any distant navigation. As they have no trees on the island, they must have obtained the wood large enough for their purpose, either from that left here by the Spaniards, or from that drifted on the shore from some distant land. At the southernmost extremity of the island, M. de Langle and other companions of La Perouse found the crater of a volcano, whose size, depth, and regularity, excited their admiration. It resembled the frustum of a cone, whose upper and lower basis appeared more than two miles in circumference; the depth was at least 800 feet. At the bottom was a marsh, containing several considerable pools of fresh water, whose surface appeared to be above the level of the sea. This marsh was surrounded by the finest plantations of banana and mulberry trees. The grass on the sides of the cone, the marsh at the base, and the fertility of the adjacent lands, prove that the subterranean fires have been long extinguished. The inhabitants of this island, as we have reason to believe, were more numerous when the island was better wooded. If they had sufficient industry to build cisterns for preserving water, they would remedy one of the principal inconveniences of their situation, and might even prolong their lives; for M. de Langle informs us, that they did not see one man who appeared to be more than 65 years of age, as far as they were capable of judging. The ingenuity of these people may well surprize us, when we consider the meanness of their working-tools, which, like those of all the other islanders in this ocean, are made of stone, bone, shells, &c. They little value iron, or iron tools; and as presents, they preferred pieces of painted cloth, half an ell long, to nails, knives, and beads. But the chief object of their wishes was

hats, which they greedily accepted or stole whenever they had an opportunity. Cook's 2d Voyage, vol. i. La Perouse's Voyage, vol. i.

EASTER TERM. See TERM.

EASTERLING. See STERLING.

EASTERN. See ORIENTAL.

EASTERN Amplitude, Church, Horizon, Ocean. See the substantives.

EASTERN District, in Geography, a district of Upper Canada, constituted as such by the name of the district of Lunenburg, in the province of Quebec, by lord Dorchester's proclamation, July 24, 1788, and taken principally from the well end of Montreal. It derives its present name from an act of the provincial legislature. It is bounded by the province of Lower Canada on the east; to the south by the river St. Lawrence; northerly by the Ottawa river; and westerly by a meridian line passing through the mouth of the Gananoque river in the township of Leeds.

EASTERN Island, an island on the E. side of Chesapeake bay, at the mouth of Chester river.

EASTERN Precinct, a precinct of America, in the state of New Jersey, and county of Somerset, which contained, in 1790, 2068 inhabitants, including 468 slaves.

EASTERN River, a settlement of America, in the state of Maine, and county of Hancock, containing, in 1790, 240 inhabitants.

EASTON, a village of America, in Dauphin county, Pennsylvania, on the E. side of Susquehanna river, 4 miles N. by W. of Harrisburg, and 111 N. by W. of Philadelphia.

EAST FLORIDA. See FLORIDA.

EAST GREENWICH. See GREENWICH.

EAST GRINSTEAD. See GRINSTEAD.

EAST HADDAM. See HADDAM.

EASTHAM, a post town of America, in the state of Massachusetts, and county of Barnstable, 6 miles long and 2½ wide, seated on the peninsula of Cape Cod, between Orleans and Wellfleet; distant 94 miles from Boston. Since the forests have been cut down, a part of this township is become a desert of sand; and though it has thus sustained considerable damage as an arable district, the fertile lands are likely to be preserved by inclosures. The number of families is 122, including 659 inhabitants in 99 dwelling-houses, of which only seven are two stories high. At the distance of a mile, a light-house was erected on the high lands of Cape Cod in the year 1798. The town contains a meeting-house and two school-houses. The Nauset Indians formerly occupied this town and Orleans. N. lat. 41° 51'. W. long. 69° 56'.

EAST HAMPTON. See HAMPTON.

EAST HARTFORD. See HARTFORD.

EAST HAVEN. See HAVEN.

EAST ISLAND, an island so called by Cook, in 1769, that lies off EAST CAPE, on the coast of New Zealand. It is of a small circuit, high and round, and appears white and barren.

EAST KINGSTON. See KINGSTON.

EAST MAIN. See MAIN.

EAST MEATH. See MEATH.

EAST NESS, or EASTONNESS, a cape in the German ocean, on the east coast of England, between Southwold and Lowestoff.

EASTON, a post town of America, in the state of Pennsylvania, and capital of Northampton county, pleasantly situated at the mouth of the Lehigh, and on the W. side of Delaware river; containing about 150 dwelling houses, a church, court-house, register's office, and an academy, and

7045 inhabitants; 12 miles N.E. of Bethlehem, and 70 N. of Philadelphia.—Also, the chief and post-town of Talbot county, Maryland, formerly called Talbot court house, is seated on the E. side of Chesapeake bay, near the forks of Treadhaven river; 12 miles from its junction with Choptank river. It has a handsome court-house and market-house, about 150 dwelling-houses, and several stores for the supply of the adjacent country; 5 miles S. westerly of Williamsburg, 37 S. of Chester town, and 118 S.W. of Philadelphia.—Also, a township in Washington county, New York; containing 3069 inhabitants.

EASTON, or *Egstown*, a poll-town, important for its iron manufactures, situated in the county of Britton, and state of Massachusetts, near the head of Raynham river, six miles N.W. of Raynham and 12 W. of Bridgewater, and containing 1550 inhabitants. The art of making steel was introduced here by captain Eliph. Leonard in 1786; which serves by its excellent quality for plough-shares, hoes, shoes, &c. that require hard steel: but for edge-tools, in general, it is inferior to that which is imported. The best mill-saws in the state are manufactured here. The manufacture of linseed oil began here in 1792; and from an annual stock of 3000 bushels of seed, there have been annually produced near 5000 gallons of oil.

EASTON'S Beach and Bay, a beach and bay of America, which lie at the southern end of Rhode island.

EASTOWN, a town of America, in the county of Washington, and state of New York, seated on the east bank of Hudson river, and containing 3072 inhabitants.

EAST POINT, the extreme east point of the island of St. John, in the gulf of St. Lawrence.—Also, the N.E. extremity of New Holland. S. lat. 10° 42'.

EAST PORT, a poll-town of Washington county, in the state of Maine. This township forms the western cape of Passamaquoddy bay, and the mouth of Kobbekook river; situated 888 miles N. E. from Washington.

EAST RIVER, a river of America, in the state of New York, forming a communication between North river and Long island, along the eastern side of New York island.

EAST RIVER. See **QUINEPAUGE**.

EAST TOWN, a town of America, in Chester county, and state of Pennsylvania, containing 444 inhabitants.

EAST WHITELAND, a township of America, in Chester county, Pennsylvania, containing 642 inhabitants.

EAST WINDSOR. See **WINDSOR**.

EATON. See **ETON**.

EATON, a township of Lower Canada, E. of Ascot, having 400 inhabitants. A southern branch of St. Francis river runs through this town.—Also, a town of America, in the northern part of Stafford county, N.W. Hampshire, three miles N. of the Great Ossipee lake, and about 50 N. by W. of Portsmouth; incorporated in 1766, and containing 381 inhabitants.

EATOOAS, in *Modern History*, a name given at Otaheite to a class of enthusiastic persons, so called from a persuasion, that they are possessed with the spirit of the divinity. They appear as if they were bereaved of their senses, and pretend to extraordinary gifts. During the paroxysms of their fits they do not seem to know their most intimate acquaintance; and if any one of them happen to possess property, he will give away every moveable unless his friends put it out of his reach; and when he recovers, he will inquire for those very things, which he had, just before, distributed, not seeming to have the least remembrance of what he had done, while the fit was upon him. Cook's Third Voyage, vol. ii. p. 19.

EATUAS, in *Modern Mystology*, a name which the in-

habitants of Otaheite in the South sea give to an imaginary inferior race of deities; 2 of whom, they say, at some remote period of time, inhabited the earth, and were the parents of the first man. The term is derived from *eatoh*, which signifies *finished*. These subordinate deities are very numerous, and are of both sexes; the male are worshipped by the men, and the female by the women, in separate morais, and under the direction of distinct priests. There are also morais common to both. Hawkw. Voyages, vol. ii. p. 239.

EAU ARQUEBUSADE. See **ACQUA Vulneraria**.

Eau de Luce, is a kind of volatile liquid soap, of a strong, penetrating smell. The following instructions will serve for making it: take four ounces of rectified spirit of wine, and in it dissolve ten or twelve grains of white soap; filtrate this solution, then dissolve in it a dram of rectified oil of amber, and filtrate again: mix as much of this solution with the strongest volatile spirit of sal ammoniac, in a crystal-glass bottle, as when sufficiently shook, shall produce a beautiful milky-liquor. If upon its surface be formed a cream, some more of the oily spirit of wine ought to be added.

Eau Rabel. See **RABEL**.

EAVES, the margin or edge of the roof of a house, being the lowest tiles, slate, or the like, which hang over the walls to throw off the waters to a distance from the wall.

EAVES-LATH, a thick feather-edged board, generally nailed round the eaves of a house for the lowermost tiles, slate, or shingles to rest upon.

EAVES Droppers, in *Law*, are persons who liken under walls or windows or the eaves of a house, to hearken after discourse, and thereupon to frame slanderous and mischievous tales. These are a common nuisance, and preventable at the court leet, or indictable at the quarter sessions, and punishable by fine, and finding sureties for good behaviour. 1 Hawk. P. C. 132.

EAUZE, in Latin *Eulisa*, in *Geography*, a very ancient town of France, in the department of the Gers, chief place of a canton, in the district of Condom, situated on the river Gelise, near the ruins of the ancient Eulsa, which was the chief city of Novempopulania; 24 miles S.W. of Condom, and 30 miles N.W. of Auch. It has a population of 3300 individuals. The canton contains 14 communes, and 9224 inhabitants, upon a territorial extent of 28 $\frac{1}{2}$ kilometres.

EBBING and Flowing of the Sea. See **TIDES**.

EBDOMARY, **EBDOMADARIUS**, an officer anciently appointed weekly in cathedral churches, to supervise the regular performance of divine service, and prescribe the particular duties of each person attending in the choir, as to reading, singing, and praying. To this purpose, the ebdomary, at the beginning of his week, drew up in form, a bill, or writing, of the respective persons, and their several offices, called *tabula*, and the persons there entered were styled *intabulati*.

EBDOME, *Ebdome*, in *Antiquity*, a festival kept on the seventh of every lunar month, in honour of Apollo, to whom all seventh days were sacred, because one of them was his birth-day; whence he was sometimes called *Ebdomenagenes*. For the ceremonies of this solemnity, see *Poet. Arcaol. Græc. lib. ii. cap. 20. tom. i. p. 385*.

EBEDJESU, in *Biography*, a learned Syrian writer, of the sect of the Nestorians, was bishop of Nisibis, called by the Syrians Soba, in the latter part of the 13th century, and died in the year 1318. Dr. Alesman first published an accurate edition of his catalogue of ecclesiastical writings at Rome, in 1725. Ebedjesu having, in his catalogue, mentioned the writers of the Old Testament, proceeds to enumerate those of the New, arranging the gospels, the Acts of the Apostles, three Catholic epistles, and St. Paul's 14 epistles

epistles in the order which now obtains among us, and specifying the places and languages in which the several gospels of Mattheus, Mark, Luke, and John, were written, agreeably to the common opinion of the Syrians in general. Accordingly, he says, that Matthew wrote his gospel in Hebrew, and published it in Palestine; that Mark preached in Latin at Rome; Luke taught and wrote at Alexandria, in the Greek tongue; and John wrote his gospel at Ephesus, in the same language. He mentions only three Catholic epistles, omitting the 2d of Peter, and 2d and 3d of John, and the epistle of Jude; conforming, in this respect, to the common sentiments of the Syrians. He likewise omits the book of Revelation; which book, and also the three Catholic epistles, are omitted in the ancient Syriac version. Dr. Lardner very justly remarks, that Ebedjesu should not have passed over in silence the four Catholic epistles, and the book of Revelation, whatever might have been the general opinion of the Syrians concerning them; because he could not be unacquainted with them. And if they were not equally respected with the other books of the New Testament, he might have so said. Lardner's Works, vol. iv. p. 442.

EBELEBEN, in *Geography*, a small town of the kingdom of Saxony, belonging to the prince of Schwarzburg-Sonderhausen, with a castle and a grammar school, remarkable for several learned professors, among others Paul Götz, known among historians by the name of Paulus Jovius.

EBELING, C. D. in *Biography*, of Hambro', well merits notice among German dilettanti, for his excellent taste, sound judgment, and extensive knowledge of the history of the musical art and its votaries; many excellent tracts and critiques have flowed from his pen, to which he never set his name. He was many years in strict friendship with the incomparable Emanuel Bach, whose superior genius and abilities he very early felt; and on the death of Telemann, he, perhaps, first taught the Hamburgers to appreciate his merit. His collection of music and musical curiosities, 30 years ago, surpassed that of any other private gentleman of that city. M. Ebeling was then in partnership with M. professor Buech, in the celebrated Academy of Commerce. He is author, among other works, of the "History of the American War," which has been much approved; but the present article extends no further than his skill, performance, and knowledge in music, faculties which he has, unhappily, long ceased to enjoy, except by memory, and reflection, from an almost total deafness.

EBELSTADT, or **EBELTOFT**, in *Geography*, a small town of Denmark, in the province of North Jutland, with a good harbour, on the gulf of the same name, on the east side of Jutland. In Latin, it is called *Ebelostia*, or *Pomagrium*. Ebeltoft is in the diocese, or general government, of Aarhus, in the circle of Stierholm.

EBENEZER, a town of America, being the capital of Effingham county, in the state of Georgia, seated on the S.W. bank of Savannah river; 25 miles N.N.W. of Savannah, and 860 S.W. of Philadelphia. It was settled in 1735, by Protestants, driven by persecution from Saltburg, in the electorate of Bavaria; but is now declining, and reduced to less than 12 decaying houses.

EBENFELD, a town of Germany, in the duchy of Carinthia; 3 miles S. of Stein.

EBENFURTH, a town of Germany, in the archduchy of Austria, seated on the Leyta, built by the knights Templars: 18 miles S. of Vienna.

EBENHAUSEN, a small town of Germany, in the former bishopric of Wurtzburg, which was secularized at

the peace of Luneville, and given as an indemnity to the grand duke of Tuscany.

EBENOXYLUM, in *Botany*, from *εβνος*, ebony, the name of a valuable wood in Theophrastus, Pliny, &c. and *ξύλον*, wood. Loureir. Cochinch. 613. Clafs and order, *Diacia Triandria?*

Gen. Ch. Male. Cal. none. Cor. Petals three, longish, acute, a little spreading, incurved. Stam. . . . Female. Cal. and Cor. as in the male. Nectary stellated. Style one, short. Berry small, ovate, smooth, of one cell. Seeds three, oblong, angular.

Ess. Ch. Male. Cal. none. Petals three. Female, Cal. none. Petals three. Nectary stellated. Style one. Berry with three seeds.

Sp. *Ebenoxylum verum*, Lour. A tall tree, with ascending branches. Bark rough, greenish-brown. Wood with a thick, heavy, white, uniform albumen, and a very black, very heavy, and peculiarly uniform heart. Leaves scattered, stalked, lanceolate, broadish, entire, small, smooth, firm, shining, flat, of a brownish-green. Flowers white, on many-flowered terminal stalks. Berry reddish-yellow. Native of the vast woods of Cochinchina, about the 11th degree of north latitude, where Loureiro says he had often seen it, but not being then attentive to botany, he neglected to collect the flowers. The generic characters above given are, therefore, taken from Rumphius, who in his Herb. Amboin. part 4. t. 1, figures what he terms *Ebenus vulgaris*, and appears to be the plant of Loureiro. Whether it may be the same with any of the trees we have already mentioned under *Diospyros*, (which see,) and how far the above characters are faithful, we have not materials to determine.

EBENSFELD, in *Geography*, a town of Germany, in the duchy of Stiria; 6 miles W. of Pettau.

EBENTHEL, a town of Germany, in the duchy of Carinthia; 2 miles S.S.E. of Clagenfurt.

EBENUS, in *Botany*, Linn. Gen. 386. Schreb. 491. Clafs and order, *Diadelphia Decandria*. Nat. Ord. *Leguminosæ*, Juss. *Papilionacæ*, Linn. *E. cretica*, Linn. Sp. Pl. 1076. Alpin. Exot. t. 278. The only species upon which this genus was founded by Linnæus, is reduced to *Anhyllis* by Jussieu, who is followed by La Marck, and by Willdenow, Sp. Pl. v. 3. 1019. The latter defines it "shrubby; leaves pinnate, or terrate, equal, villose; flowers spiked." It is a native of Crete; a slender elegant shrub, with silky leaves, and rose-coloured flowers. Prosper Alpinus conceived this to be one of the plants comprehended by Theophrastus under his *εβνος*, or *ebony*, as the wood is hard and black, and the shrub has an affinity to *Cytisus*. Hence, the above name was retained by Linnæus (see *Diospyros* and *EBENOXYLUM*.) *Ebenus pinnatis*, Art. Hort. Kew. v. 3. 27. Desfont. in Aët. de la Soc. d'Hist. Nat. de Paris, v. 1. t. 3. apparently of the same genus as the above, is *Anhyllis sericea*, Willd. 1014. This grows in Barbary and the Levant. Vahl makes it an *Hedysarum*. The stem is not shrubby, but herbaceous, and the root biennial.

EBERACH, in *Geography*, a small town of the kingdom of Bavaria, with a rich abbey, which was secularized at the peace of Luneville, and the revenues of which were made over to Bavaria.

EBERARDI, LA TERESA, in *Biography*, one of the most elegantly simple and pleasing Italian singers of the second class, that we remember on our opera stage. She was here from the year 1760 to 1765, and performed the second woman's part in serious operas under the Mattei, and in the comic, under the Paganini, while Elmi was here.

Whoever

"Whoever heard her sing Galuppi's Sicilian strain, "La pastoralla al Prato," in Il Filosofo di Campagna, and "Sono Amante," in La Pesatrice, will never forget her modest, unadorned, and unpretending manner of singing, which pleased, by mere purity of tone and natural sweetness of expression. And though her style and appointment were so inferior to the two great singers, with whom she alternately appeared, she was scarcely ever suffered to quit the stage, till she had repeated her songs.

EBERBACII, in *Geography*, a small town of the kingdom of Bavaria, situated on the Neckar; 2 miles W. of Mofsbaeh, and remarkable for its good wine.—Also, a small town of France, in the department of the Lower Rhine; 9 miles of Haguenau, in the district of Straßburg.

EBEREMORTH, or **EBEREMORS**, in our *Old Law*, the same as eberemurdrum, or eberemurder. See **ABEREMURDER**.

EBEREMURDRUM, or **ABEREMURDRUM**, in our *Old Writers*. See **ABEREMURDER**.

EBERMANSTADT, in *Geography*, a town of Germany, in the circle of Franconia, and bishopric of Bamberg, seated on the Wilent; 13 miles E.S.E. of Bamberg.

EBERN, a small town of Germany, in the former bishopric, now grand duchy of Würzburg, situated on the river Baunach, and chief place of a district of the same name.

EBERSBURG, a small town of the kingdom of Saxony, belonging to the counts of Söllberg, and remarkable for a very ancient tower, and the ruins of an old castle, and for a rich coal-mine, at a very little distance, near the village of Herрманfacker.

EBERSTEIN, a small town of Germany, in the grand duchy of Baden, near the Black forest, the district of which was formerly an earldom. It is five miles S.E. of Baden.

EBHER, a town of Persia, in the province of Irak, seated on a river of the same name, in a fertile country, containing about 2500 houses, and many mosques, caravanferas, bazars, and other handsome buildings. The Turkish language is spoken in one part of the town, and the Persian in the other. It is distant 40 miles W. from Cablin.

EBIN, or **YBIN**, one of the smaller Philippine islands, in the East-Indian sea.

EBINGEN, or **EKINGEN**, a town of Germany, in the circle of Swabia, and duchy of Wurtemberg; 36 miles S. of Stuttgart, and 22 S. of Tubingen.

EBIONITES, in *Ecclesiastical History*, the denomination of persons who rose in the church in the very first age of it, and formed themselves into a sect in the second century, denying the divinity of Jesus Christ.

Origen takes them to have been so called from the Hebrew word *ebion*, which, in that language, signifies *poor*; because, says he, they were poor in sense, and wanted understanding. Eusebius, with a view to the same etymology, is of opinion, they were thus called, as having poor thoughts of Jesus Christ, taking him for no more than a mere man, born of Joseph and Mary; and esteeming the ritual ordinances of the law necessary to be observed by them. Others, he says, do not deny, that Jesus was born of a virgin by the Holy Ghost. Nevertheless, they do not acknowledge his pre-existence, as God the Word; and, like the others, they are fond of the external observances of the law of Moses. They also reject Paul's epistles, and call him an apostate from the law.

It is more probable the Jews gave this appellation to the Christians in general, out of contempt; because, in the first times, there were few but poor people that embraced the Christian religion. This opinion, Origen himself seems to

give into, in his book against Celsus, where he says, that they called Ebionites, such among the Jews as believed that Jesus was truly the expected Messiah.

It might even be urged, with some probability, that the primitive Christians assumed the name themselves, in conformity to their profession. It is certain, Epiphanius observes, they valued themselves on being poor, in imitation of the apostles. The same Epiphanius, however, is of opinion, that there had been a man of the name *Ebion*, the chief and founder of the sect of Ebionites, contemporary with the Nazarenes and Cerinthians. He gives a long and exact account of the origin of the Ebionites, making them to have risen after the destruction of Jerusalem, when the first Christians, called *Nazarenes*, went out of the fame to live at Pella.

As to the origin of their name, many learned men are now of opinion, that there never was any man named Ebion, the leader of a sect; but that the Ebionites were so called from their low opinion concerning the person of Christ, and their attachment to the external rites of the law of Moses. To this opinion the judicious Dr. Lardner seems to incline. We cannot deny, says this candid writer, (vol. vii. p. 21.) that there were some believers, who supposed Jesus to have been born as other men; but he apprehends, that the number of them was very small, nor does he recollect any Christian writing, now extant, where that opinion is maintained. Although we allow that there were some, who rejected the apostle Paul, whilst they received the other apostles, these he supposes to have been few in number. He adds, that he does not know any work of an ancient author, now remaining, who speaks disrespectfully of him, excepting only the "Recognitions," or "Clementine Homilies."

The Ebionites are little else than a branch of Nazarenes; only that they are said to have altered and corrupted, in many things, the purity of the faith held among those first adherents to Christianity. For this reason, Origen, as well as Eusebius, distinguishes two kinds of Ebionites, in his answer to Celsus: the one believed that Jesus Christ was born of a virgin; and the others, that he was born after the manner of other men. The first were orthodox in every thing, except that to the Christian doctrine they joined the ceremonies of the Jewish law, with the Jews, Samaritans, and Nazarenes, together with the traditions of the Pharisees. They differed from the Nazarenes, however, in several things, chiefly as to what regards the authority of the sacred writings; for the Nazarenes received all for scripture contained in the Jewish canon; whereas the Ebionites are said to have rejected all the prophets, and held the very names of David, Solomon, Isaiah, Jeremiah, and Ezekiel, in abhorrence. They also rejected all St. Paul's Epistles, whom they treated with the utmost disrespect.

They received nothing of the Old Testament but the Pentateuch; which should intimate them to have defended rather from the Samaritans than from the Jews. They agreed with the Nazarenes in using the Hebrew Gospel of St. Matthew, otherwise called the Gospel of the Twelve Apostles; but they are charged with having corrupted their copy in abundance of places; and particularly with having left out the genealogy of our Saviour, which was preserved entire in that of the Nazarenes, and even in those used by the Cerinthians.

Irenæus, Eusebius, and Epiphanius, concur in saying, that the Ebionites received the gospel of St. Matthew only. Epiphanius informs us, that the gospel of the Ebionites began with the third chapter of Matthew, a little altered, and he says expressly, that it is defective and corrupted.

Some,

Some, however, have made this gospel canonical, and of greater value than our present Greek gospel of St. Matthew. See *Gospel of St. MATTHEW and NAZARENES*.

Beside the Hebrew gospel of St. Matthew, the Ebionites had adopted several other books, under the names of St. James, John, and the other apostles; they also made use of the travels of St. Peter, which are supposed to have been written by St. Clement, but had altered them so, that there was scarce any thing of truth left in them. They even made that faint tell a number of falsehoods, the better to authorize their own practices. See St. Epiphanius, who is very diffusive on the ancient heresy of the Ebionites, *Herz.* 30.

But his account deserves little credit, as, by his own confession, he has confounded the other sects with the Ebionites, and has charged them with errors, to which the first adherents to this sect were utter strangers.

Dr. Priestley, in his 'History of Early Opinions concerning Jesus Christ, &c.' (vol. iii.) zealously maintain the identity of the Ebionites and Nazarenes; and in opposition to those who assert, that they were subsequent to the destruction of Jerusalem by Titus, and to others who have fixed their origin so late as the delation of Judea by Adrian, he endeavours to shew, that persons distinguished by these appellations were supposed to have existed in the time of the apostles. Irenæus, says this writer, who gives no other name to any Jewish Christians besides that of Ebionites, whom he always speaks of as denying the pre-existence and divinity of Christ, and likewise the miraculous conception, objects to the Gnostics, that they were of late date, but he says nothing of the Ebionites in that respect. Eusebius also says, that "the first heralds of our Saviour" (meaning the apostles) "called those Ebionites, which in the Hebrew language signifies poor; who, not denying the body of Christ, shewed their folly in denying his divinity."

Epiphanius makes the Ebionites contemporary with the Nazarenes; and he mentions the Ebionites as well as the Nazarenes among those who gave great alarm to the apostle John. Dr. Priestley further maintains, that there was no difference between these two sects; and that both of them were equally believers in the simple humanity of Christ. To this purpose he alleges the testimonies of Origen, Eusebius, and Jerom; but some have thought that the passages he produces do not decidedly warrant the inference which he deduces from them. (See the preceding part of this article, and the title NAZARENES.)

In favour of the identity of the Ebionites and Nazarenes, this author observes, that the latter are not mentioned by name by any writer, who likewise speaks of the Ebionites, before Epiphanius, who was fond of multiplying heresies, though the people so called were certainly known before his time. The term Ebionites occurs, he says, only in Irenæus, Tertullian, Origen, and Eusebius. None of them make any mention of Nazarenes, though they must have been more considerable in the time of these writers than they were afterwards. It was not till the time of Epiphanius, that the term Nazarenes, by which the unbelieving Jews still continued to call the Christians among them, was applied to a sect different from that of the Ebionites. M. Le Clerc, and many other eminent critics of the last age, maintained the opinion, that the Ebionites and Nazarenes were the same people. Mr. Jones "On the Canon" (vol. i.) observes, that there was a very great agreement between these two ancient sects, but at the same time he intimates, that the Ebionites had made some addition to the old Nazarene system. Our author, after having remarked that the peculiar opinions of the Ebionites and Nazarenes are represented by the most respectable authorities as the very same, adds, that some have thought that

the Nazarenes believed the miraculous conception, which the Ebionites denied; but that this opinion has no authority whatever among the ancients. Against this assertion, however, many objections might be urged. (See NAZARENES.)

Tertullian, it is observed, is the first Christian writer who expressly calls the Ebionites *heretics*. Although Irenæus professes his dislike of their doctrine, he never confounds them with the heretics. Justin Martyr makes no mention of them, but is supposed to include them under the general denomination of "Jewish Christians;" and it is asserted, on the authority of Jerom, that the Ebionites were anathematized solely on account of their adherence to the Jewish law, the yoke of which many of them were desirous of imposing on the Gentile Christians. Epiphanius, with great injustice, as it seems, charges the Ebionites with the peculiar doctrines of the Gnostics; whereas by the testimony of ancient writers, the heresy of the former was the very reverse of that of the latter.

The Ebionites, as we have already said, made use of no other gospel than that written in Hebrew, which was their own language, and this gospel is commonly said to be that of St. Matthew, originally composed in their language, and for their use. Their copies of this gospel, however, began with the third chapter.

Epiphanius says, as we have already observed, that they also made use of the travels of Clement, with which they might be pleased, as it was an Unitarian work. But they made no use of the epistles of St. Paul, because they disapproved the slight, which he put upon the law of Moses, which they held in the greatest veneration. Epiphanius further says concerning the Ebionites, that they detest the prophets. However, from other accounts it appears, that they acknowledged the authority of all those books which we admit into the canon of the Old Testament. Synmachus was an Ebionite, and Theodotus, according to Jerom, was of the same sect, and as they both translated the other books of the Old Testament, as well as the Pentateuch, and without making any distinction between them, it is probable that they considered them as entitled to equal credit. To this purpose Irenæus expressly says, that the Ebionites expounded the prophets too curiously.

EBISMA, in *Ancient Geography*, a town of Arabia Felix, in the country of the Adramites, according to Ptolemy.

EBLANA, a town of Hibernia, now *Dublin*.

EBODA, a town of Arabia Petrea, according to Ptolemy; but placed by Pliney in Arabia Felix.

EBOES, a name given in the West Indies to those negroes who are imported from those parts of Africa that are bounded westward by an extent of coast of about 300 leagues, called the bight of Benin. (See BENIN.) These negroes are, with regard to their complexion, much yellower than those of the Gold Coast and Whidah. They appear of a sickly hue, and their eyes seem to be suffused with bile, even when they are in perfect health. The conformation of their face, in general, resembles that of the baboon. The great objection to these Eboes, as slaves, is their constitutional timidity and dependency of mind, which prevail to such a degree, that they often seek, in a voluntary death, a refuge from their own melancholy reflections. They therefore require mild and gentle treatment to reconcile them to their situation; and with this treatment their confidence may be gained, and they then manifest as great fidelity, affection, and gratitude, as can be expected from men in a state of slavery. The females are better labourers than the men, probably from their having been more hardly treated in Africa. It is said, however, that these Eboes are more savage than any nation of the Gold Coast; inasmuch as many.

many of them, especially those of the Moor tribe, have been accustomed to the shocking practice of feeding on human flesh. As to their religious opinions and modes of worship, it is said, that, like the inhabitants of Whidah, they pay adoration to certain reptiles, of which the guana, a species of lizard, is in the highest estimation. They universally practise circumcision; and it is, moreover, affirmed, that they frequently offer up human sacrifices in their worship of the guana. Edwards's Hist. W. Indies. vol. ii.

EBOLICS, EBOLICA. See ECNOTICS.

EBONY OF CRETE, in Botany. See EBENUS.

EBONY OF THE ALPS. See CYTISUS.

EBONY, *Fulje*. See POINCIANA.

EBONY, *Mountain*. See BAUHINIA.

EBONY-WOOD is brought from the Indies, exceedingly hard and heavy, susceptible of a very fine polish, and on that account used in Mo-ſaic and inlaid works, toys, &c.

There are divers kinds of ebony; the most usual among us are black, red, and green, all of them the product of the island of Madagascar, where the natives call them, indifferently, *bazou manthi*, *q. d.* black wood. The island of St. Maurice, belonging to the Dutch, likewise furnishes part of the ebony used in Europ.

Authors and travellers give very different accounts of the tree that yields the black ebony. By some of their descriptions, it should be a sort of palm-tree; by others, a cytisus, &c. M. Flacourt, who resided many years at Madagascar, as governor thereof, assures us, that it grows very high and big, its bark being black, and its leaves resembling those of our myrtle, of a deep, dusky, green colour.

Tavernier says, that the islanders always take care to bury their trees, when cut down, to make them the blacker, and to prevent their splitting, when wrought. F. Plazier mentions another black ebony tree, discovered by him at St. Domingo, which he calls "spartium portulacae foliis aculeatum ebeni materia." Candia also bears a little shrub, known to the botanists under the name of *ebenus Cretica*, above described.

Pliny and Dioscorides say, the best ebony comes from Ethiopia, and the worst from India; but Theophrastus prefers that of India. Black ebony is much preferred to that of other colours. The best is a jet black, free of veins and rind, very massive, astringent, and of an acrid pungent taste. This is the *diostyros ebenum*, according to Dr. Roxburg's account, and is found in the woods of Ceylon. See DIOSPYROS. Leuroiro makes a distinct genus of it under the name of *Ebenoxylum*, which see. Its rind, infused in water, is said to purge pituita and cure venereal disorders; whence Mathioux took guaiacum for a sort of ebony. It yields an agreeable perfume when laid on burning coals: when green, it readily takes fire, from the abundance of its fat. If rubbed against a stone it becomes brown. The Indians make statues of their gods, and sceptres for their princes, of this wood. It was first brought to Rome by Pompey, after he subdued Mithridates. It is now much less used among us than anciently; since the discovery of so many ways of giving other hard woods a black colour.

As to the green ebony, besides Madagascar and St. Maurice, it likewise grows in the Antilles, and especially in the isle of Tobago. The tree that yields it is very bushy; its leaves are smooth, and of a fine green colour. Beneath its bark is a white blea, about two inches thick; all beneath which, to the very heart, is a deep green, approaching towards a black, though sometimes streaked with yellow veins. Its use is not confined to Moſaic work; it is likewise good in dyeing, as yielding a fine green tincture.

As to red ebony, called also *grenadilla*, we know little of it more than the name.

The cabinet makers, inlayers, &c. make pear-tree, and other woods, pass for ebony, by giving them the black colour thereof. This some do by a few washes of a hot decoction of galls; and when dry, adding writing ink thereon, and polishing it with a stiff brush, and a little hot wax; and others heat or burn their wood black.

EBORA, in *Ancient Geography*, now *Exora*, a town of Spain, in the S. W. part of Lusitania. According to Bochart, its name, in the Eastern language, signifies abundance; which corresponds to *Cerealis*, derived from Ceres, an appellation given to it by Pany.

EBRBUHARITES, a sect or order of religious, among the Mahometans; thus called from their founder Ebrbuhard, a disciple of Nacſchibendi.

The Ebrbuharites, notwithstanding the extraordinary sanctity they make profession of, with an absolute dereliction of all worldly things, are regarded, by the Mussulmans, as no better than heretics, because they do not esteem themselves obliged to go in pilgrimage to Mecca. To excuse themselves from this labour, they urge, that the pureness of their souls, their sublime contemplations, ecstasies, &c. shew them Mecca and Mahomet's tomb, without stirring out of their cells.

EBREUIL, in *Geography*, a small town of France, in the department of the Ailier, chief place of a canton, in the district of Gannat, with a population of 2205 individuals. The canton has an extent of 207 kilometres and a half, and contains 13,043 inhabitants, dispersed in 17 communes.

EBRICATIONUM, a term used by Paracelsus to express the partial loss, or deprivation of reason, as it happens during drunkenness; but with the addition of the epithet *calyste*, it signifies, with the same author, a much more exalted state, a sort of divine enthusiasm, or inspiration, such as the Sybils of old boasted of; and, among the moderns, the French prophets, and some other religious sects, have pretended to. Paracelsus himself pretended, at times, to be under some such influence; but his mad fits seemed to have very little of inspiration in them.

EBRIETAS. See DRUNKENNESS.

EBRILLADE, in the *Mangee*, a check of the bridle, which the horseman gives to the horse by a jerk of one rein, when he refuses to return. An ebrillade differs from a *faccade*, the latter being made with both reins at once, and the former only with one. Most people confound these two words under the general name of a check or jerk of the bridle, called in French *coup de bride*. It is a chastisement, and no aid, and is diffused in acacias.

EBRIZIUS COLOR, a term used by some of the old writers, to express a very fine yellow. The word seems originally to have been ebrizium, and was certainly derived from the aurum obryzum, or fine gold, of which this ebrizus expressed the colour.

EBRO, in *Geography*, the ancient *Iberus*, from which Spain took the name of Iberia, is a considerable river of Spain, which has its source on the boundaries of the Asturias and Old Castile, in the mountains near Santillana, runs through Biscay and Arragon, begins to be navigable at Tudella, passes by Saragossa, where commences a canal, into which the Ebro falls at Bocal, and then flows through Catalonia into the Mediterranean sea, about 25 miles below Tortosa. Its water is remarkable for its salubrity. Its course is from north-west to south-east, through the greatest part of northern Spain.

The Ebro served as a limit to the conquests of Charles the Great, in the South, and the French did not penetrate further

further into Spain in 1795. But at the end of the year 1808, and in the beginning of 1809, their conquests extended to a considerable distance beyond this river, which is to form the boundary between France and Spain, in case Joseph Buonaparte maintains himself on the throne of the united kingdom of Spain and Portugal.

EBRODUNUM, in *Ancient Geography*, *Embrun*, a town of Gaul, belonging to the *Caturiges*. It is also called *Eborudora*, *Hebridano*, and *Eluorono*. It lies at the foot of the Alps, and is therefore referred to Italy by Ptolemy.

EBROIN, in *Biography*, mayor of the palace under the French kings Clotaire III. and Thierry I., is supposed to have been a German by birth. At the succession of Clotaire, in 656, he was raised to the dignity of mayor, and in this capacity he governed the kingdom in conjunction with the queen-mother Batilde. During ten years the administration of public affairs was conducted with impartiality and peace, but at the end of this period disputes ran high between Ebroin and two bishops, which so disgusted the queen, that she withdrew to a convent. Ebroin now held the reins of government with a high hand, and made the principal people in the state his enemies; who, at the death of Clotaire, rose in arms, plundered the minister, and dethroned Thierry, whom he had proclaimed as king. For a short time Childeric, king of Austrasia, reigned in the room of Thierry, but, in 670, the death of Childeric made room for the deposed monarch, who was replaced on the throne, and on this event Ebroin left the monastery, to which he had retired, and scrupled the use of no means to regain his former post, which he at length obtained, when he became as despotic as he was powerful, and insisted on his enemies the most cruel torments. He was himself assassinated in the year 681, by one whom he had fined for mal-practices in the offices which he held. *Moreri*.

EBROMAGUS, or **EBROMANUS PAGUS**, in *Ancient Geography*, a place of Aquitanic Gaul. Anton. Itin.

EBRUS, a river of Illyria, according to Diodorus Siculus.—Also, a river of Greece, in Thessaly, which passed by the town of Larissa.

EBSTORF, in *Geography*, a town of Germany, in the circle of Lower Saxony, and principality of Luneburg: celebrated for its honey, which the inhabitants sell annually to the amount of several thousand crowns; 7 miles W.N.W. of Uitzen.

EBU-HANIFA. See **SONNITES**.

EBULLITION, in *Physics*, the act of emitting bubbles, by a vehement agitation of the parts of a fluid, produced by fire, or otherwise. See **BOILING**.

EBULLITION, or *Effervescence*, in the language of Sydenham, and some other humoral pathologists, signified the exacerbation, or hot stage of an intermitting fever, before the sweating stage had commenced. This expression was deduced from the comparison of a paroxysm of fever, with the chemical process of fermentation; whence the subsequent sweating stage was denominated the *depression* of the febrile humours: the hot stage, in which the circulation appears to be in a state of tumultuous action, being supposed to resemble the intestine motion of a vat of fermenting liquor; and the sweating stage, to represent the throwing off of the scum and froth from the surface. See Sydenham, *sect. i. c. 5.* Van Swieten *ad Aph. 750.*

EBULUS, in *Botany*, *Dane-wort*, or *Dwarf Elder*, see **SAMBUCUS**. A scetid and rather dangerous plant, which was vulgarly supposed to have sprung up from the blood of some of the Danes who were killed in invading England.

The roots and leaves of dwarf-elder are said to be brisk

cathartics. The juice of this plant has been recommended in the dropsy, gout, and scorbutic disorders. The flowers are esteemed sudorific; and the leaves boiled, till perfectly soft, make a good cataplasm for the sciatica. See **ELDER**.

EBUR; **FOSSILE**, in *Natural History*. See **Fossile** **IVORY**.

EBUR fossile variegatum, in the *Natural History* of the ancients, a name given to the substance which we now call the rough or native turquoise.

Fossil ivory, and the bones of other animals, are frequently found buried at great depths in the earth, and are found to have preserved their substance, texture, and colour in different degrees, according to the nature of the matter among which they happen to have lain. Sometimes they are firm and solid, and scarce altered in colour; and sometimes more or less hardened, and tinged to different colours by the different matters in which they have been deposited.

Of this kind was the spotted fossil ivory of the ancients, which was in all respects the same with our rough turquoise of many places, which are no other than the teeth and bones of animals accidentally lodged in the way of particles of copper. See **TURCOIS**.

EBURA, or **EBORA**, in *Ancient Geography*, a town of Spain, now *Alcala-real*, between *Grenada* and *Cordova*.

EBUROBRICA, or **EBUROBRIGA**, a place of Gaul, between *Auxerre* and *Troie*, now *St. Florentin*.

EBUROBRITIUM, a place of Spain, in *Luftania*, now *Ebora de-Alcobaga*.

EBURONES, an ancient people of Belgica, whose country corresponded to the duchies of *Clèves*, *Juliers*, and *Guedre*. Their chief town was *Atuataca*. A legion of *Cæsar*, which wintered there, was defeated by *Ambiobrix*; and by way of retaliation, he threatened to exterminate them. His treatment of them was very severe. They were succeeded by the *Tongri*.

EBURUM, an ancient town of Germany, in the country of the *Quadi*, according to Ptolemy; supposed to be *Olmutz*, a town of *Bohemia*.

EBUSUS, now *IVICA*, an island of the Mediterranean, near the coast of Spain. This island was fertile in the production of vines, olives, and large figs, which were exported to *Rome*, and other places.

EBUTIANA, a town of Italy, in *Samnium*, N.W. of *Alife*.

ECACOATE, in *Zoology*, a name by which the natives of some parts of America call the rattle-snake.

ECALLESIA, *Εκαλλεσία*, in *Antiquity*, a festival kept in honour of *Jupiter*, surnamed *Hecalus*, or *Hecalusius*, from *Hecale*, one of the borough-towns in *Attica*.

ECARTELE, in *Heraldry*. See **QUARTERLY**.

ECATAPHYLLUM, in *Botany*, *Browne's Jamaica* 299, t. 32, f. 1. See **HEDYSARUM** and **DALBERGIA**.

ECASTOR, in *Antiquity*, an oath wherein *Castor* was invoked. It was a custom for the men never to swear by *Castor*, nor the women by *Pollux*.

ECATESIA, *Εκατεσία*, an anniversary solemnity, observed by the *Stratoniceans*, in honour of *Hecate*.

The Athenians likewise had a public entertainment, or supper, every new moon, in honour of the same goddess. The supper was provided at the charge of the richer sort; and was no sooner brought to the accustomed place, but the poor people carried off all, giving out, that *Hecate* had devoured it. For the rest of the ceremonies observed on this occasion, see *Pott. Arch. Græc. lib. ii. cap. 20.*

ECATÆA, *Εκαταία*, statues erected to the goddess *Hecate*, for whom the Athenians had a great veneration, believing that she was the overseer of their families,

and that she protected their children. *Yott. Arch. Græc. lib. ii. cap. 20. tom. i. p. 380.*

ECATOMBÆON, *Εκατομβαιον*, in *Chronology*, the first month of the Athenian year. It consisted of thirty days, and began on the first new moon after the summer solstice, and consequently answered to the latter part of our June and beginning of July. The Bœotians called it Hippodromus, and the Macedonians *Gros*. (See *Μονη*.) The word is a derivative from the Greek, *εκατομβαιον*, a hecatomb, because of the great number of hecatombs sacrificed in it.

ECAVESSADE, in the *Manege*, is used for a jerk of the cavesson.

ECBASIS, *Εκβασις*, in *Rhetoric*, is used for a digression, which see.

ECBATANA, in *Ancient Geography*, a celebrated city of Asia, the capital of Media, and the residence of the Median and Persian kings, was built by Dejeoces the first, who reigned in Media, after the inhabitants had shaken off the Assyrian yoke. In the book of Judith it is said to have been built by Arphaxad, supposed by some to be Dejeoces, and by others Phraortes his successor, who might have repaired the city or made some additions to it. It was situated on a plain, about 12 stadia from mount Orontes, according to Diodorus, who says that it was 250 stadia in circuit. The walls of this city are much celebrated by the ancients, and particularly described by Herodotus. (l. i. 93.) They were seven in number, all of a circular form, and gradually rising above each other by the height of the battlements of each wall. The situation of the grounds, which gently ascend, might suggest the design of thus building them. The royal palace and treasury were within the innermost of these seven circles. In the book of Judith we read, that the walls of this stately metropolis were 70 cubits high, and 50 cubits broad; that the towers on the gates were 100 cubits in height, the breadth in the foundation 60 cubits, and the walls built of hewn and polished stone, each stone being six cubits in length, and three in breadth. The timber of the palace was, according to Diodorus, (l. xi. 13.) cedar or cypress: and various parts of it were cased with gold or silver. The whole was pillaged about the time of the arrival of Alexander. We read in the 2d book of Maccabees, that Antiochus Epiphanes was at Ecbatana, when he received intelligence of the defeat of his armies in Palestine. There are now no monuments remaining of the superb palace, where the monarchs of Asia generally passed their summer; nay, there is a disagreement among our modern travellers about the place where that stately metropolis stood. Sir John Chardin thinks it most probable, that Tauris is the ancient and famous Ecbatana. Others suppose it to be Hamadan.

ECBATANA, a city of Syria, at the foot of mount Carmel, on the side of Ptolemais. In this city the unfortunate Cambyses died, in his return from Egypt towards Susa.

ECBATANA, an ancient city of Asia, called "the City of the Magi," to distinguish it from those of Media and Syria. It belonged to the Magi. Darius removed it towards the mountains. This place is mentioned by Pliny.

ECBOLAS, in *Botany, from *εκβαλλω*, to cast out, is, according to some authors, the name of a fig supposed to cause abortion. See **ECBOLIUM**.*

ECBOLE, or **ELEVATION**, in the most ancient Greek music, was the alteration of the enharmonic genus, when a string was accidentally raised five dièses above its usual tuning.

ECBOLE, *Εκβολη*, in *Rhetoric*, is also used for a digression.

ECBOLICS, **ECBOLICA**, from *εκβαλλω*, I cast, in the writings of the ancient physicians, a term used to express such

medicines as were given to promote delivery in child-birth; and also such as caused abortion. See **DELIVERY**.

ECBOLIUM, in *Botany, from *εκβαλλω*, to cast out, (whence also *εμβολιον* is an appellation for any drug that promotes delivery or abortion,) has been applied by Rivinus and others to the genus now called *Juslicia*, in allusion to the elastic force with which its capsules project the seeds. The original *Ecbolium* of Rivinus is the Maabar tree, *Juslicia Ailthatala* of Linæus. *Juslicia Ecbolium* of Linæus is a distinct species, though usually related to the former.*

ECBRASMATÀ, from *εκβρασμα*, I cast hearts, in the writings of some of the earlier physicians, a word used to express eruptions, or pustules, of a fiery and inflamed nature appearing on different parts of the body. Virgil calls these *ardentes papule*, and seems to attribute them to the wearing cloaths made of the wool of sheep which had died of a mercurial, which he describes.

ECBRYOSOMATA, from *εκβρω*, I cause to spread, a word used by Galen, and the old physicians, for those emences or protuberances of the bones at the joints, which appear through the skin.

ECCANTHIS, or **ENCANTHIS**, in *Medicine*. See **ENCANTHIS**.

ECCARD, or **ECKHARD**, JOHN GEORGE, in *Biography*, a learned antiquarian, was born at an obscure village in Germany. Having received a good education, he removed to Leipzig, where he became acquainted with Leibnitz. By the recommendation of this celebrated man, he obtained the professorship of history at Helmitadt, in 1706, and in 1713 he was appointed a counsellor of the elector of Hanover, and historiographer. He now assisted Leibnitz in his "Origines Cæulphicæ," and, in 1717, succeeded him as librarian at Hanover. Shortly after this he travelled at the expence of GEORGE I. through a considerable part of Germany in search of MSS. and other materials to enable him to prosecute the compilation of the work which he had undertaken. Some other literary occupations procured him the favour of prince Eugene, and count Von Zindendorf, and through the means of the latter, he was raised by the emperor Charles VI. to the rank of nobility. The friendship of the great produced him honour, but he was extremely poor, and presented a poem to his sovereign, in which he gave a picture of his distressed situation, and begged for relief; before, however, the necessary forms could be complied with, he was obliged to abscond; he proceeded to Cologne, where, in Feb. 1724, at the college of the Jesuits, he formally abjured the Lutheran religion. After this he entered the service of the bishopric of Wurzburg; where he was entrusted with the care of the library belonging to the court and the university. The dean and chapter committed to his charge the MSS. contained in the diplomatic archives of the cathedral, which he arranged and classed with great ability. He next projected improvements in academical lectures, and other works of public benefit. He printed, in two magnificent folios, his "Commentarii de rebus Franciæ orientalis," and undertook a history of Wurzburg, which he did not live to finish; in this he comprehended the principal German events from the emigrations of the Franks to king Conrad I. While defining, in his preface, the boundaries of the bishopric under St. Burckhard, he was suddenly seized with a mortal disease, which put a period to his life in February, 1730. Eckhard was a very voracious writer. His most interesting work is entitled "Corpus historiæ mediæ ævi," which is compiled from materials collected with great labour during many years. This is considered by Lenglet du Fresnoi as the production of one of the ablest men in Germany: he adds that it contains a great many curious pieces

well arranged, and not to be found in any other collection. Eckhard was deeply skilled in history, geography, and antiquities. He had also made etymology his study many years, with a view of publishing a dictionary of the German language. A list of his works is given in the General Biography, to which our readers may be referred.

ECCATHARTIC, in *Medicine*, a term synonymous with *cathartic*, but not now in use.

ECCE-HOMO, among *Painters*, a name given to a picture, wherein our Saviour is represented in a purple robe, with a crown on his head, and a reed in his hand, such as he was presented before Pilate by the Jews.

The phrase is Latin, borrowed from the words of the Jews themselves: *q. d.* this is the man.

ECCENTRIC. See **EXCENTRIC**.

ECCENTRICITY. See **EXCENTRICITY**.

ECCHELLENSIS, **ABRAHAM**, in *Biography*, who flourished in the 17th century, is famous for the assistance which he rendered M. le Jai, in preparing for the press the magnificent Polyglot Bible. He also furnished the Arabic and Syriac texts of the book of Ruth, with the Latin version. He was unfortunately engaged in some disputes, which were little creditable to the contending parties. One of his opponents charged him with incapacity for the undertaking in which he had embarked; but he repelled the accusation, and conducted himself in such a manner as to obtain the appointment of professor of the Syriac and Arabic languages, in the College Royal at Paris. He was next engaged by the college "De propaganda Fide," to assist in translating the scriptures into Arabic, which employed him from the year 1636 to the year 1652. He was likewise made professor of the Oriental languages at Rome; and was chosen by the archduke Ferdinand II. to translate out of the Arabic into Latin the 5th, 6th, and 7th books of "Apollonius's Conics," in which he was assisted by Borelli. The whole work was printed at Florence, with Archimedes's book, "De Assumptis," in 1661, in folio. He published many other works, and died at Rome in the year 1664. *Moreri*.

ECCHYMOSIS, in *Surgery*. This term signifies a livid or blue discolouration of the skin, in consequence of the rupture of vessels, and extravasation of blood.

The word is derived from the Greek *εκχυω*, to pour out; an ecchymosis being in fact only a kind of swelling, formed by an effusion of blood from the vessels.

An ecchymosis is usually produced by falls, blows, and sprains, which rupture many of the small vessels on the surface of the body, and occasion an extravasation of fluid, unattended with any external breach of continuity. Contusions are always attended with a degree of ecchymosis. (See **CONTUSION**.) A very considerable ecchymosis may be produced by bruises and blows, when any of the ruptured vessels are sufficiently large to pour out a copious quantity of blood into the cavities of the cellular substance.

In general, an ecchymosis does not exhibit the discolouration which characterises it, until some time has elapsed after the receipt of the violence. We may indeed remark, that it is not till after several hours that the blue and livid discolouration of the skin becomes most conspicuous. A black eye, which is one of the most common examples of an ecchymosis, is always most disfigured six or eight hours after its occurrence.

In the common operation of bleeding, an ecchymosis often arises at the time when the blood is flowing out. This happens in consequence of the fluid not having a ready vent, so that some of it gets into the cellular substance, near the

opening in the vein. When the patient changes the posture of his arm, after the puncture is made, the orifice in the skin sometimes slips a little away from the wound made in the vessel; and as the blood still continues to flow from the latter, it necessarily produces an ecchymosis, by insinuating itself into the cellular substance.

Common cases of ecchymosis are in general easily cured, by applying discutient lotions, and administering one or two doses of any mild purgative salt. The best topical applications are vinegar, the lotio salis ammoniaci, spiritus vini camphoratus, and aqua ammoniac acetata. The grand indications are to prevent inflammation, and to promote the absorption of the effused blood.

Every man of experience must be so well aware of the success which attends the practice of dispersing collections of extravasated blood, by exciting the action of the absorbents, that he can hardly picture to himself a case of ecchymosis, in which it would be proper and advantageous to make an incision for the discharge of the effused fluid. We have frequently seen tumours on the head, formed by extravasations of blood, and containing four or five ounces of this fluid, subside with wonderful rapidity, while the treatment merely consisted in employing general antiphlogistic remedies, and applying a discutient lotion.

On the contrary, when an opening is made into these swellings, the whole of the blood can very seldom be entirely pressed out, owing to its coagulated state; and the portion, which remains behind, becoming exposed to the air, soon putrefies, and acquires an irritating quality; and the too frequent consequences are a great deal of inflammation and suppuration, which need not be induced.

ECCLES, **JOHN**, in *Biography, was the son of Solomon Eccles, a performer on the violin, and author of several grounds, broken into common divisions, of common chords, without improving the tune. Bellamira, one of his grounds, has words set to it in the Beggar's Opera. From the instructions of his father, John became an eminent and popular composer for the theatre, furnishing it with act tunes, dance tunes, and incidental songs, in most of the new comedies, after the death of Purcell. The air which he set to "A Soldier and a Sailor," sung by Ben, in Congreve's comedy of "Love for Love," is so truly original and characteristic, that it can never be superseeded for any other air. He set an ode, written by Congreve for St. Cecilia's day in 1701. He likewise set Congreve's "Judgment of Paris," when there was a contention for prizes, and gained the second, of 50 guineas. Several of his single songs were the best of the time, and have still the merit of originality. Indeed we never remember to have seen the slightest composition by Eccles, whether catch, ballad, or rope-dancing tune, that was not stamped with some mark of genius. Upon the death of Dr. Staggins, about the year 1698, Eccles, at a very early period of his professional life, was appointed master of queen Anne's band; and after the decease of Dr. Crofte, in 1727, he seems only to have set the odds, and to have retired from all other professional employments to Kingdon, for the convenience of angling, in which amusement he appears to have been as much delighted as Walton. He died in 1735, and was succeeded as master of the king's band and composer to his majesty by Dr. Green.*

Eccles had two brothers, *Henry*, a performer on the violin, said to have been in the king of France's band, and author of 12 excellent solos for his own instrument, printed at Paris, 1720. These we have never heard or seen, even in a catalogue. *Thomas*, who had been taught the viola by Henry, and had the character of a very fine player, but

preferred the life of a strolling fiddler at taverns to that of a regular professor, and was more fond of drinking than either of good company or clean linen.

He seems to have been one of the last vagrant bards, who used to inquire at taverns if there were any gentlemen in the house who wished to hear music? Since smoking has been discontinued, few evenings are spent in taverns, which has diminished the number of modern minstrels, particularly such as are as well qualified to amuse good company and lovers of music as Tom Eccles, who used to regale his hearers with Corelli's solos and Handel's best opera songs, which he executed with precision and sweetness of tone, equal to the most eminent performers of the time. He survived his brother, John, more than 20 years; and continued to officiate as a priest of Bacchus to the last.

ECCLESBOURN, in *Geography*, a river of England, which runs into the Derwent, in Derbyshire.

ECCLESFECHAN, a town of Scotland, in the county of Dumfries: 15 miles E. from Dumfries.

ECCLESFIELD, a large parish in the wapentake of Strathforth and Tickill, in the West Riding of the county of York, England, is a very populous district, comprising 984 houses, and 5114 inhabitants. The principal part of these are employed in the various branches of cutlery and hardware goods. The place is only 5 miles from Sheffield, which has long been noted for its large manufactories of knives, and forks, scissars, razors, &c. In the vicinity of Ecclesfield are some remains of a Roman encampment, which is known by the name of the Devil's ditch.

ECCLESHALL, a market-town and parish in the hundred of Pirchill, Staffordshire, England, was, at a former period, the seat of the bishops of Lichfield. In the time of the civil wars, it was garrisoned for the king, but being taken by the parliamentary forces, was nearly destroyed; after which it was rebuilt by bishop Lloyd. The town is pleasantly situated on the banks of the river Sow, about 7 miles from Stafford, and 148 from London. It contains 590 houses, and 3487 inhabitants. Here are a weekly market on Friday, and three annual fairs. The living is a vicarage, in the patronage of the bishop of Lichfield.

ECCLESIA, a Latin, or rather Greek term, signifying church.

In our ancient law-books, Fitzherbert observes, that ecclesia, *ecclesiarum*, properly signifies a parsonage. Whence, if a presentation were made to a chapel, as to a church, by the name of ecclesia, it changed the name thereof, and it presently commenced a church.

When the question was, Whether it were ecclesia, aut capella pertinet ad ecclesiam? the issue was, whether it had baptisterium & sepulturam? For if it had the administration of the sacraments and sepulture, it was in law judged a church. See CHAPEL.

ECCLESIA, *Restitutione extracti ab.* See RESTITUTIONE.

ECCLESIAE, *Reso de advocacione.* See RECTO.

ECCLESIAE, *Wardia.* See WARDIA.

ECCLESIAE Sculptura, the image or sculpture of a church in ancient times was often cut out in plate or other metal, and preserved as a religious treasure or relique; and to perpetuate the memory of some famous churchmen.

ECCLESIANI, **ECCLESIANI**, in *Church History*. Upon any falling out, or misunderstanding, between the emperors and the churchmen, the adherents to the emperor called such as adhered to the interests of the church and churchmen, ecclesiani, a term of reproach, answering to our high-church men.

ECCLESIASTES, one of the books of the Old Testament thus called, from a Greek word, signifying preacher; because the author in it declaims or preaches against the vices and vanities of the world; or because of the peculiar gravity and dignity of the subjects, of which he treats.

This is Mericana's judgment: Grotius thinks otherwise; taking the book to derive its appellation from its being a collection of fine sentences and reflections on the vanity of the things of our earth, &c. from the word עֵצָה, which signifies to amass or collect. *עצות ודברים*. Some Hebrew doctors, supposing the same etymon, will have it to have been thus called on account of its amassing a great deal of wisdom; others, because the author's aim is to assemble and call together all such as are willing to consult their safety, and avoid the dangers of the world, which is the opinion of Gejerus. Lasty, others, with Calovius, deduce it from his assembling them about him, as a preacher assembles his auditors: accordingly Ludolphus observes, that the word *Cohelēib*, in the Ethiopic language, signifies a circle, or a company of men gathered together, in the form of a circle.

There are different sentiments as to the author of this book: the most common is, that it is Solomon's, who is supposed to have written it towards the close of his life, to give tokens of his penitence to posterity.

Grotius, indeed, takes the work to be posterior to Solomon, and to have been written after his death, by six authors, unknown, who, to give their book the greater authority, put Solomon's name to it, and represented him as a repentant. What he chiefly founds his opinion on is, that we meet with words in this book which are no where else seen, but in Daniel, Ezra, and the Chaldee paraphrases; whence he thinks it probable, that it was written after the captivity in Babylon; but it is certain, all Hebrews, Greeks, and Latins, have always spoken of it as a work of Solomon. Indeed there are authors who have attributed all the books of Solomon to Isaiah; but these are only to be understood as if that prophet had collected them. If it be true, that there are Chaldee words in the Ecclesiastes, it is easier to suppose Solomon understood that language than to deny him to be the author of the book. The Talmudists ascribe this book to Hezekiah; rabbi Kimchi, to Isaiah; and Grotius, to Zorobabel.

Calovius assures us, that the true reason why Grotius would not allow Solomon to be the author of the book of Ecclesiastes, is, that it speaks too clearly and precisely for his time, of the universal judgment, eternal life, and the pains of hell; but these are truths established before Solomon, in the Psalms, Pentateuch, and Job.

There appears no reason, therefore, for denying this book to Solomon, but several for ascribing it to him. As, 1. The title of the book, which asserts its author to be the son of David, and king of Jerusalem. 2. Several passages in the book, which agree to nobody but that prince, as chap. i. ver. 12. chap. vii. ver. 25. chap. xii. ver. 9, &c. And, 3. The constant tradition of the ancient Jews and Christians.

The design of the author is to discover what constitutes the chief good or complete felicity of man. Accordingly this book consists of two principal parts: the first of which, comprehended in the 6 first chapters, contains a recital and confutation of men's false opinions about their chief good; and the other teaches in what our genuine true and solid felicity consists, both in this life and the next. In both he shews, what is the end to which a man should direct all his counsels, studies, and endeavours; what he ought to follow, as above all things most desirable; and what to avoid, as the worst of all evils.

The Talmudists, and other Rabbins note, that it was some time before the book of Ecclesiastes was put in the canon. See the Gemara on the Pirke Abboth. fol. 1. col. 1. Mafsch. S-habbath, cap. ii. fol. 30. col. 2. Aben Ezra on the Ecclesiastes, vii. 4. Maimonides, Moreh. Nebuchim, lib. iii. cap. 28. and Mercerus, Calovius, and Gejerus, on this book.

ECCLESIASTIC, or ECCLESIASTICAL, something belonging to, or set apart for the church, in contradistinction to civil or secular, which regard the world. See **CIVIL.** &c. There are ecclesiastical things and persons; ecclesiastical law, jurisdiction, history, ceremonies, discipline, preferences, &c. Ecclesiastical persons are those whose functions consist in performing the service and maintaining the discipline of the church. See **CLERGY.** Ecclesiastical persons are either regular or secular. (See **REGULAR** and **SECULAR.**) In the empire there are three ecclesiastical electors, *viz.* the archbishops of Mentz, Treves, and Cologne.

ECCLESIASTIC chambers, community, corporation, courts, faith, patronage, tradition. See the different substantives.

ECCLESIASTICAL JURISDICTION. By stat. 37 Hen. VIII. c. 17, the doctors of the civil law, although they be laymen, &c. may exercise ecclesiastical jurisdiction.

ECCLESIASTICAL Law. See **CANON Law** and **Ecclesiastical Courts.**

ECCLESIASTICAL State, in Geography, the pope's dominions in Italy, reaching from the Po to beyond Terracina, a length of more than 260 British miles, comprehending about 13,808 square miles, and containing little more than two millions of inhabitants.

These dominions have been differently divided by former geographers; but the most regular and convenient division was into the following territories: 1. The duchy of Ferrara, acquired in 1598. 2. That of Bologna, gained by Julius II. in 1513, and now supposed to contain 80,000 inhabitants. 3. The province of Romagna. 4. The duchy of Urbino, acquired in 1626. 5. The marquisate of Ancona, gained in 1532, and now containing about 20,000 inhabitants. 6. The Perugian. 7. The Orvietano. 8. The duchy of Castro. 9. The Patrimony of St. Peter. 10. Campania di Roma. 11. Sabina. 12. The duchy of Spoleto al Umbria. 13. The country called Citta di Castello. Beside which, the pope formerly possessed the following countries out of the papacy, *viz.* the duchy of Benevento, in the kingdom of Naples, annexed to the pope's dominions in the 12th century; the counties of Avignon and Vauclain, in the southern parts of France. He had, besides, a considerable number of fiefs in Italy, which hold of the papal see: the principal of which were the kingdom of Naples, and the states of Parma and Placentia. See **NAPLES,** &c. &c.

The pope may be considered in two respects, as the spiritual head and monarch of the Roman church, and as a considerable temporal prince in Italy. In the first character, his subjects may be divided into two classes, *viz.* clergy and laity; the former may not unfitly be compared to a spiritual standing army, whose business is to maintain his rights and conquests; and the rest, the laity, as his tributary subjects, who are oblig'd to maintain those forces at their own charge; and if one may judge of the greatness of their number, by what pope Paul IV. used to boast, that he had 228,000 parishes under his jurisdiction (all of which have at least one or more priests), and 4400 monasteries, it will appear no inconsiderable army. But their number has been much lessened since the Reformation and the Revolution of France.

In the second view, the pope was formerly considered as a potent prince in Italy, whose sovereignty was chiefly supported by the jealousy between Spain, France, and the Em-

pire; though in most other respects, it was not to be compared with that of other princes of Europe. His revenues were very considerable, and he was able to maintain a great military force. But by the new conquests and arrangements of Buonaparte, the emperor of France, the dominions of the pope are so dilapidated and curtailed, that he retains very little of the secular power that formerly belonged to him, and he has been despoiled of the greatest part if not the whole of his importance as a temporal prince. By the 8th article of the treaty of Campo Formio 1797, the three legations of Bologna, Ferrara, and Romagna are annexed to the *Cisalpine republic*, which see. See also **ITALY.**

ECCLESIASTICO primo beneficio habendo. See **PRIMO.**

ECCLESIASTICUS, an apocryphal book, composed by Jesus the son of Sirach, and admitted by the Romish church into the canon of the Old Testament.

It is frequently cited by the abbreviation, *Eccle.* to distinguish it from the Ecclesiastes, which is cited by *Eccle.* Some of the ancients have denominated it *πρωϊστως*, *i. e.* the book of every virtue; but the most usual name among the Greeks is that of "the Wisdom of Jesus the son of Sirach."

It is called Ecclesiasticus, as some say, because the ancients divided the books of the Old Testament into four sorts, *viz.* the Pentateuch, the Prophets, the Hagiographa, and the Ecclesiastical, or Apocryphal books, as not being in the Jewish canon. Among the latter, this of Jesus the son of Sirach, being the most remarkable and useful, was called *καθ' ἑσπεραν*, or by way of eminence, Ecclesiasticus, whilst the rest of the same class have lost their name. According to others, this title was given to it by the Latins, to denote its use in the church, as it was read for edification in the public religious assemblies; or, because, like Solomon's Ecclesiastes, which it resembles in name, as well as matter, it teaches such as attend to it by the admirable precepts which it delivers, and earnest exhortations to wisdom, which is another word for religion.

Lidore, lib. vi. Etym. cap. ii. and among the moderns, Grotius and Druhus, deny the author of Ecclesiasticus to be Jesus the son of Sirach, grandson of the high-priest Jesus, who returned from Babylon with Zerobabel. Genebrard asserts, that Jesus the son of Sirach, was of the race of Jesus son of Josedec; but this does not appear. Some of the ancients have erroneously ascribed this book to Solomon. Cyprian, and Ambrose have cited it under his name.

St. Jerom assures us, in his preface to the books of Solomon, that he had seen this book in Hebrew; and that the Hebrews intitled it *Parables, or Proverbs*: from which the Jesuit Mariana concludes, that the high-priest Jesus wrote this book in Hebrew, as it appears likewise from the prologue to the book itself; and that his grandson translated it into Greek, which likewise appears from the prologue; that he made this translation in Egypt, where the author lived in his thirty-eighth year; that it was done under the reign of Ptolemy Evergetes, successor of Ptolemy Philadelphus, who began to reign in the year of Rome 508, 246 years before Christ; that the grandfather had entitled it *Parables*, which the grandson changed into Ecclesiasticus: lastly, that the book, however, is attributed to the translator, because he changed, and added many things to the original.

Fa. Calmet takes the book of Ecclesiasticus to have been composed under the Pontificate of Onias III. son of Simon, and the reign of Antiochus Epiphanes, king of Syria, about 171 years B. C. He adds, that neither the author of the Latin translation, nor the time when it was made, is known.

but

but being quoted regularly by all the ancient fathers, there is no doubt of its being very ancient. He takes it to have been done by the translator of the Book of Wisdom.

Mosler and Fagius mention Hebrew copies of this book, as well as St. Jerom; but Scaliger, Drusius and Huettius think that none of these were the original, but either Ben Sirach's a phabet, or some late version made from the Greek. It is probable, that many useful maxims of the Hebrew Sirachides, as well as some of his own, were added by the last Jesus, the son of Sirach, to his grandfather's book, or from marginal additions of other men's sayings, of the like nature; which being too few to fill a book of themselves, were joined to this larger work. We cannot otherwise account for the variations in the several Greek copies of Ecclesiasticus, and the translations of it, nor for the entire sentences, which are found in some and wanting in other copies. The Hebrew Sirachides wrote his book, as we may reasonably suppose, in the language of the Jews of Jerusalem, such as was used after their return from the captivity, probably either in the Chaldee dialect, or Syriac, as a manual for the Jews in Egypt. The learned suppose that the original work itself is come down to us imperfect, either through the author's death, or the loss of some part of it in Egypt (See Bishop Chandler's Vindic. of Def. p. 81—85.); and this may account for the great incoherence, and abrupt transition in many places. How long the original was preserved, we are not now able to ascertain. The Greek is the present only original; and it is the most early and authentic translation of this work, made for the use of the Jews in Egypt in their dispersion, who had then almost forgotten their native tongue; and so this, as well as other books not canonical in their language, might easily be lost. This seems to have been too literal a translation, which often occasions the sense to be either obscure or deficient. The translator himself has the modesty to acknowledge, that he doubts his having succeeded in expressing the full spirit of the then language, whether it was the ancient and pure, or more modern and corrupt Hebrew, and ingeniously apologizes for not attaining to the exact propriety and expressiveness of the original. Drusius is of opinion, that, besides this inaccuracy, he has sometimes actually mistaken the meaning of the original in some of the more obscure and intricate passages. There is a strange transposition of chapters in the best Greek copies of this book from ch. xxx. to ch. xxxvi.; besides the transposition of whole sentences or verses; so that the printed editions greatly differ from one another, which is very much owing to the carelessness of transcribers; in consequence of which, the present state of this book is corrupt and mutilated. And as to the Greek translation itself, the language is neither beautiful, nor altogether correct. This latter circumstance is chiefly owing to the idiom of the Greek Macedonian language, and the particulars now referred to are not so properly faults, as modes of that adopted tongue. In this book there occur frequent allusions to Grecian rites and customs; from which we may infer, that the Jews had learned their philosophy, and embraced several of their opinions, ever since their intercourse with that people under Alexander the Great, the Ptolemies, and Seleucide his successors, who reigned in Egypt and Syria. The old versions, particularly the Syriac and Arabic, so much differ from the Greek, as almost to lead one to suspect, that they were not made from it, and yet there is no reason to think, that they translated from any Hebrew copy. Nor do the Oriental versions agree any better with the Latin.

As to the Vulgate, it is uncertain what copy it follows, or what was its authority. It sometimes adds whole sentences,

which have nothing corresponding to them in the Greek; so that Huettius conjectures, that the translator inserted some parallel maxims from some other work. It does not appear to have been interpolated; or that any alterations have been made by the pious fraud of some Christians in order to make it conform to, or countenance, any favourite sentiments and opinions, as Grotius intimates. Bossuet, Calmet, and other commentators, follow the Vulgate too implicitly, and make that version the foundation of their annotations; and it is no wonder that the popish expositors should religiously adhere to a version, which the council of Trent has confirmed and ratified. The old English versions, as Coverdale's and the Bishops' Bible, generally copy the Vulgate too closely; but the Geneva often departs from it with advantage. Our last translators seem chiefly to have regarded the Complutensian, which, though it lies under a suspicion of conforming its Greek to the Vulgate, yet exhibits a text in this book, according to Dr. Grabe (Prolegom. olim. § 1.) "non nuper fictum aut interpolatum, sed jam olim a Patribus ita lectum." However they scruple not occasionally to prefer the Latin to the Greek, where they think it gives a better sense, and sometimes even to adopt conjectures, unsupported by any copy, for the same purpose. After all we may observe, that their rendering is in very many places inaccurate and obscure, and in some, faulty and mistaken.

This book was originally composed for the instruction and benefit of those, who were disposed to regulate their lives agreeably to the laws of God; and with this view the grandson of Ben Sirach rendered it into Greek. and with the same design it has been translated into many other ancient and modern languages. In the western church it has met with general esteem, and it was introduced by our first reformers, and the compilers of the articles of our established church, into the public service. It begins with an exhortation to the pursuit of wisdom; and this is followed by numerous moral sentences or maxims, as far as the 44th chapter, where the author begins his eulogy of the patriarchs, prophets, and famous men among the Jews, which he continues to the 51st chapter, containing a prayer to God. Calmet says, that it is a received opinion of the Catholic church, that this book was placed in the canon of scripture, and that it may be demonstrated by the testimony of several fathers, and by the tradition of all Christian churches, and by its being quoted by a great number of ecclesiastical writers, as a work inspired by the Holy Ghost. But these assertions are unfounded. Episcopius, in order to show the agreement of Christian churches with the Jews in this point, enumerates the decisions of nine of the Eastern, nine of the Western, and two of the African churches, which determine for the canon as we now have it, and exclude all others, but the 22 books received by the Jewish church, and contained in the Hebrew Bible. The authority of the church of Rome cannot outweigh the decisions of those of Jerusalem, Alexandria, Antioch, and Constantinople, to the contrary. As to the respect paid to it by ancient ecclesiastical writers, we may observe, that they used the term scripture in a very lax sense for any book that contained excellent and pious instructions; and when either the Greek or Latin fathers attribute to any books the title of Holy Writings, they do not place them in any higher rank than that of scriptures, which are of inferior, imperfect, and doubtful authority. Dupin's Compleat History of the Canon, b. i. chap. 3. § 16. Arnold on the Apocrypha. See ΑΠΟΚΡΥΦΑ, BIBLE, and CANON.

ECCLISISIS, from *εκκλησις*, I decline, a word used by Hippocrates, and from him by many other of the old physicians, for

for a recession of a bone from its proper situation, that is, a luxation.

ECCOPÆUS, from *εκκοπίω*, *I cut*, the name of an instrument, described by some of the ancient writers in *Medicine*, and used for the same purposes for which the modern surgeons employ a lenticular or raspatory. The ancient instrument was a sort of knife, with which they cut down morbid eminences of bones, or took out bones, in case of a fractured skull.

ECCOPE, *Εκκοπή*, in *Surgery*, the same with excision, or amputation.

The word is formed from the Greek, *εκκοπίω*, *excindere*, *to cut off*.

ECCOPE is likewise used for a kind of fracture, or solution of continuity, of the skull, by a simple incision.

ECCOPROTICS, *Εκκοπρωτικά*, in *Medicine*, laxative, or loosening remedies, which purge gently, by softening the humours and excrements, and fitting them for expulsion.

The word is composed of the Greek particle *εκ*, and *κοπρωσις*, *excrement*.

ECCRIMOCRITICA, from *εκκρίσις*, *excretion*, and *κριτικός*, *signs to judge of a dilemma*, from particular excretions.

ECCRINOLOGICA, from *εκκρίνω* and *λογος*, a term used by some writers, for that part of medicine which relates to the doctrine of excretions, or the discharge of any of the excrements out of the body.

ECCRISIS, an excretion of any excrementitious or morbid matter from any of the natural emunctories, as it happens in a perfect crisis. The matter thus excreted is also sometimes called by this name.

ECDICI, *Εκδικος*, among the *Ancients*, patrons of cities, who defended their rights, and took care of the public money. Their office resembled that of the modern syndics.

ECDORA, from *εκδωρο*, *I excoriate*, a word used by the ancient physicians, to express any kind of excoriation, but in a more particular manner that of the urethra.

ECDORIA, a term used by the ancient writers in *Medicine* for such caustic or escharotic medicines, as have a power of taking off the skin.

ECDYSIA, *Εκδυσια*, in *Antiquity*, a festival observed by the Phœnicians in honour of Latona.

ECETRA, in *Ancient Geography*, a town of Italy, belonging to the Volsci.

ECHALAR, in *Geography*, a town of Spain, in Navarre; 20 miles N. of Pamplona.

ECHALLENS, a town and bailliage of Switzerland, in the canton of Bern, belonging to the cantons of Bern and Friburg, conquered by the Swis in 1475, and ceded to the two cantons in 1474; 6 miles from Lausanne. On an eminence in this bailliage stands the castle of St. Burthelemi, in one of the most beautiful positions in Switzerland; about three miles from Orbe, near the high road from Lausanne to Yverdon.

ECHANBROIGNES, LES, a small town of France, in the department of the two Seves; six miles N. of Châtillon sur Sevre, and three miles E. of Maulevrier.

ECHAPE, in the *Manege*, is used to denote a horse got between a stallion and a mare of a different breed and country.

ECHAPER, is used in the French academies for giving the horse head, or putting him on full speed. Hence they say, *laisser echapper de la main*.

ECHARD, LAWRENCE, in *Biography*, was son of a clergyman, and born near Beccles in Suffolk, in 1671. Having laid a foundation of classical learning, he went to Christ's college, Cambridge, where he took his degree of A.M., and was afterwards admitted into holy orders. His

first settlement was in Lincolnshire, where he published, in 1600, "The Roman History from the Building of the City to the Settlement of the Empire by Augustus," which was followed by a continuation from that period to the time of Constantine. These were afterwards printed in 3 vols. 8vo. In 1702, he published "A General Ecclesiastical History from the Birth of Christ to the Establishment of Christianity." This work, which was printed in folio, was exceedingly popular, and was in the course of a few years reprinted in an octavo size five times. He next published "The Gazetteer, or Newsmen's Interpreter," being a geographical index, or dictionary, of all the principal places on the globe. This run through many editions, and may be regarded as the forerunner of our present improved gazetteer, than which few books are more popular. Mr. Echard published likewise a history of England, from the invasion of Julius Cæsar, to the end of James I.'s reign, which he afterwards brought down to the revolution: he translated some of the comedies of Plautus, and took a part in the translation of Terence: he compiled a volume of maxims and discourses, moral and divine, from the works of archbishop Tillotson. His church preferment was the appointment to the archdeaconry of Stow, in 1712: he was also made prebend of Lincoln, and chaplain to the bishop of that diocese; and towards the latter end of an useful and industrious life he was presented by the king to the livings of Rendlesham, Sudborne, and Alford, in Suffolk, to which county he removed; but the change was unfavourable to his health, and he died in 1750. *Biog. Brit.*

ECHARPE. See *BATTERY en echarpe*.

ECHARRI, in *Geography*, a town of Spain, in Navarre; 17 miles W. of Pamplona.

ECHAUFOUR, a small town of France, in the department of the Orne, situated on a rivulet which flows into the Risle between Laigle and Sées; 12 miles N.E. of Sées, in the district of Alençon.

ECHAUGUETTE, in the French *Military Art*, an elevated and covered place for a sentinel. Richelet explains it by the Latin *specula, exculis*. See *GUERITE*.

Some distinguish the exchauguette from the guerite, giving the former name to entry-boxes, made of wood, and square; and the latter name to those made of stone, and round.

ECHEBRUNE, in *Geography*, a small town of France, in the department of the Lower Charente; fifteen miles off Santes.

ECHEDAMIA, in *Ancient Geography*, a town of Greece, in the Phœnicæ, according to Pausanias.

ECHEDORAS, a river of Macedonia, in the Amphaxitide territory, according to Ptolemy, called Chidoros by Herodotus, who places its source in Crestonia. He says, that it traverses Mygdonia, and pursues its course along a marsh near the river Axius, into which it discharges itself.

ECHÆIA, harmonic-vases used in the ancient theatres for the augmentation of sound. Vitruvius, book v. cap. 5, tells us, that they were placed in cells or niches, between the rows of seats occupied by the spectators, to which the voice of the actor had free passage; that they were made of brass, or earthen-ware, and proportioned in magnitude to the size of the building; and lastly, that in the small theatres, they were tuned in harmonical proportions of fourths, fifths, and eighths, with their replicates; and in theatres of great magnitude, there was a vase to correspond with every found in the diatopason, or great musical system, in all the genera.

The Romans, according to the same author, were obliged to the Greeks for this invention, as well as for tragedy itself. For the ecchæia were brought first into Italy from Corinth,

by Mummius. Perhaps they had something of the effect of the whispering gallery at St. Paul's church, which, by its orbicular form, augments found in the same manner as the belly of an instrument, a hog's-head, or a draw-well.

Sir Francis Bacon long since observed, that sound diffuses and wastes itself in open air, but if inclosed and confined in a canal, or narrow limits, its force is augmented: and adds, that inclosures not only increase and fortify sound, but preserve it. Resonance is but an aggregate of echoes, or of quick repetitions and returns of the same sound, which soon uniting into one point, are consolidated and embodied; and by this means, the force of the tone first given is greatly augmented upon the delivery, and preserved some time after the first cause ceases. This constitutes the ringing of musical instruments, and places favourable to found; but with respect to the whisper, which is instantly carried from the person who utters it, to the opposite side of the gallery, it runs along the smooth surface of the wall, and arrives at the place of its destination with nearly the same degree of force as it is delivered.

It is not easy now, however, to describe, or even to conceive, the form and effects of the theatric vases; but their existence and use having been recorded by so scientific a writer as Vitruvius, has excited much curiosity, and produced many conjectures, and, as yet, ineffectual experiments. Our smaller theatres, luckily, are in want of no such helps; but this is certain, if these vessels were tuned to musical tones and intervals, nothing but noise and confusion could be produced from them by common speech, or such as is used in modern declamation. For if any one cough, speak loud, or strike forcibly upon the case of a harpsichord, with the lid propped up, or on any hard body near it, the shock will make every string in the instrument found at the same instant; but if a fixed and musical tone be produced by the voice, or upon a vio in or flute, none but the unison will be heard upon the harpsichord; and though the cloathing of the jacks be in close contact with all the strings, which ren-

ders it impossible to produce a clear tone from any one of them, by the common means of quills, or hammers, yet if any person sing near them, every note will be exactly echoed by the instrument.

If, therefore, these echeia were of the use related by Vitruvius, it must have been from the voice approaching them in fixed and musical tones, modulated in unison with the tones of the vases.

The best commentary upon this obscure subject in Vitruvius is that of Perrault, who has given an engraving of part of an ancient theatre, on purpose to exhibit the situation of the harmonic vases. "Les dix Livres d'Architecture de Vitruve," Par. 1684. 2d edit. folio. Kircher, whose pen was never impeded by doubts or difficulties, has not only described, but given them imaginary forms resembling bells. See *Musurgia*, tom. ii. p. 285.

Every thing was upon a large scale in the ancient theatres. The figure, features, and voice, were all gigantic. The voice was, in a particular manner, the object of an actor's care; nothing was omitted, says father Bumeoy, that could render it more honourous; even in the heat of action it was governed by the tones of instruments, that regulated the intervals by which it was to move, and to express the passions.

When a new opera-house was built at Turin about 30 or 40 years ago upon a very large scale, all the architects, mathematicians, and the learned in (phonics) harmonics, or the philosophy of found, were consulted about the form and situation of those vases; but the problem we believe has not yet been solved.

ECHELLE, Fr. a scale, or gammut. The names which French musicians give to the eight notes of C major, *ut, re, mi, fa, sol, la, si, ut*, are retained in all keys, whether the notes so denominated are flat, sharp, or natural. This scale is generated by the harmonics of three bases, C, G, and F; or the key note and its two fifths, the fifth above and the fifth below the key note.

This is termed the natural or diatonic scale, that is, composed of tones and semitones.

But the moderns have another scale, which they call semitonic or chromatic, from its proceeding by semitones, or what are called half-notes. For a base to this chromatic scale, see *Mus. Plate XXIV.* and prepared base to ditto, *Plate XVI.* This scale furnishes the means of modulation into what key we chuse to make the fundamental, and of transposing our ideas from the natural to the fictitious or artificial keys as they are called.

ECHELLE NEUVE, or SCALA Nuova, in *Geography*, as sea port town of Turkey, in Asia, situated in the province of Natolia, about 50 miles off Smyrna. The English and the French had considerable mercantile establishments at this place till the middle of the 17th century, when the jealousy of the custom house officers of Smyrna caused this port to be shut to all European nations. Its principal trade now consists in exporting annually about 2000 bales of cotton

and cotton yarn, some wax, Morocco leather, and fine sponges. *Dict. de Geogr. Commercante.*

ECHELLES, LES, in Latin *Scala*, a small town of France, in the department of Mont Blanc, chief place of a canton, in the district of Chambéry, with a population of 1245 individuals. The canton contains nine communes and 6464 inhabitants, on a territorial extent of 120 kilometres.

The high road of the Echelles Bourgades, 16 kilometres W. of Chambéry, behind the mountain of the grotto on the road to Lyons, may be considered as the boldest work that was ever undertaken. Charles Emanuel II., duke of Savoy, caused a monument to be erected here, of which the French mutilated one of the finest parts, as well as the inscription, during their revolutionary frenzy in 1793.

ECHELSELK, a small town of France, in the department of the North; six miles N. of Bergues, with a very fine castle.

ECHEMBROTUS, in *Biography*, an Arcadian, who, according

According to Pausanias, in his enumeration of the musical contests that were added to the ancient Pythic games, at the close of the Cressian war, accompanied upon the flute, Cephallon, the son of Lampus. The Amphictyons afterwards retrenched the flute accompaniment, on account of that instrument being too plaintive, and fit only for lamentations and elegies, to which it was chiefly appropriated. A proof of this, says Pausanias, is given in the offering which Echembrotus made to Hercules of a bronze tripod, with this inscription:

"Echembrotus, the Arcadian, dedicated this tripod to Hercules, after obtaining the prize at the games of the Amphictyons, where he accompanied the elegies that were sung in the assembly of the Greeks, with the flute." See PYTHIC GAMES.

ECHENAY, in *Geography*, a town of France, in the department of the Upper Marne, and district of Joinville; seven miles E.N.E. of Joinville.

ECHENEIS, in *Ichthyology*, a genus of the thoracic tribe, having the head naked, flat above, and transversely furrowed, the gill-membrane furnished with ten rays, and the body destitute of scales.

Three species of this singular genus are described, one of which, the *remora*, is sufficiently well known to the English navigators in the Mediterranean by the name of the sucking fish. The species *neurates* is less frequent, and exceeds the other in size. The third, *lineata*, is a recently discovered kind, of which a particular account occurs in the Linnean Transactions.

Species.

REMORA. Tail furcated; back of the head with eighteen freaks. *Erbenis remora*, Forsk. Arab. *Remora Imperati & Aldrovandi*, Will. *Echeneis*, Plin. &c.

Native of the Atlantic and Mediterranean seas, in the latter of which it is most abundant. Its length is usually from twelve to eighteen inches, the body of moderate thickness, with the head pointed, and the general colour brown; deepest on the back, and becoming white on the belly; the fins small, invested with a thick skin, and of a cinereous colour, edged with brown. The skin is smooth, marked with numerous impressed points, and covered with a thick mucus.

The extraordinary faculty which this fish possesses, of adhering at pleasure to other bodies by means of the organ at the back of the head, is mentioned by many writers. Pliny, and some other authors among the ancients, do not hesitate to affirm that the remora is able to arrest the progress of a ship in full sail, by fastening against its hull. The moderns arc more moderate, and simply relate that it is known to affix itself to any smooth surface so firmly, as not to be removed without a considerable exertion of strength; it would be difficult, it is said, for the strongest arm to effect its separation, unless it be pulled in a lateral direction, so as to slide it along the surface of the body to which it adheres. This ability of adhesion appears to be a peculiar property designed by nature to facilitate its means of obtaining food; for the remora swims so feebly and indifferently, that it is necessary to avail itself of other methods of pursuing its course in the water, the most convenient of which is to fasten itself to some larger fish, or other floating body. The remora for this reason is almost constantly found attached to whales, sharks of the more gigantic kind, and other voracious animals.

NEURATES. Tail entire; head with twenty-four freaks. *Hasselq. Echeneis in extremo subrotunda*, Scha. *Iperuquiba* at *Piraguiba brasiliensis*, Marcg.
Vol. XII.

This species grows to the length of five, six, or even seven feet; the body is of a more lengthened form than the preceding, and the tail is ovate. The head is of a moderate size; the body above the lateral line olive green, beneath white; the fins yellowish, edged with violet; the skin is marked with numerous minute pores as in the other. This species is confined principally to the Indian and American seas. Comersson relates, that it is very common about the coasts of Mozambique, where it is sometimes employed in catching turtle. The process is altogether singular: a ring is securely fastened round the tail of the fish to prevent its escape, and a long cord being tied to the ring, the fish is carried in a vessel of sea water till the boatmen observe a turtle sleeping on the surface of the water, when they approach as near as possible without disturbing it, and throw the remora into the sea. The fish instinctively directs its course to the sleeping turtle, which, by the length of its cord, it is enabled to reach, and immediately fastens itself so firmly on its back, that the turtle is drawn by the men into the boat, by means of the cord, with very little trouble.

LINEATA. Tail cuneated; head with ten freaks. *Echeneis lineata*, Menz. Linn. Transf. 1. p. 187. pl. 17. f. 7.

A new species found in the Pacific ocean, and described as above in the Transactions of the Linnean society. The body is about five inches long, subulate, smooth, and of a dark brown colour, dotted all over with minute darker spots, and ornamented with two whitish longitudinal lines on each side, which begin at the eyes and end in the tail; the under mandible is a little longer than the upper, and both are furnished with minute teeth; the clypeus on the top of the head has but ten transverse freaks. The specimen described was found adhering to a turtle.

ECHETLA, in *Ancient Geography*, a town of Sicily, towards the springs of the river Aclates. It was formerly a very strong place, and during the Punic war, it was situated on the frontiers of the Carthaginians and Syracusans. It is now *Ochula* or *Aquila*.

ECHETRA. See ECETRA.

ECHEVIN. See ESCHEVIN.

ECHIDNA, in *Ichthyology*, a species of *Murena*, which see.

ECHIDNA, in *Natural History*, a name given, by some authors, to the several kinds of opilites, or serpent-flour, from *echiva*, a viper, or serpent.

ECHILLEÛSE, in *Geography*, a small town of France, in the department of the Loiret; 9 miles E. of Pithiviers.

ECHINARACHNIUS. See ECHINUS.

ECHINASTRUM, in *Botany*, a name given by some persons to the *Geranium tuberosum* of Bauhin and Linnaeus, on account of the resemblance of its root to the *Echinus* or Sea-Urchin.

ECHINATUS, is a term applied to any thing beset with spines, like a hedge-hog, as the fruit of the horse-chestnut. It is nearly synonymous with *muricatus*. It gives the generic character of *Hydnum*, a fungus whose head is *subtus echinatus*, prickly underneath.

ECHINI FOSSILES. It is a very remarkable observation of Augustino Scilla, that all those fossil echini which he had found in the Messirese and Calabrian hills, and about Malta, were, when bruised, as was frequently the case, always bruised by a perpendicular pressure. See ECHINITES.

ECHINI SPATANGI. It is observed, that the fossil echini spatangi, or spatangi, are very frequent in the island of Malta, and people who are for having all fossil shells to be real terrestrial bodies, produced of seeds in the earth, and never to have been parts of real animals, object to these having ever been such, their being found so plentifully in this fossil slate, and so rarely in the native or recent one. This is no objec-

tion of weight; because the cornua ammonis give a much stronger, which are a more common fossil, and have never been found recent at all. This is no argument of weight, however, since it is easy to conceive, that the sea, at the time of the universal deluge, might throw up shells from its deep bottom, which we never can get at in fishing or otherwise. And Scilla has proved the absurdity of the objection, in regard to the echini spatangi, and shewn that those people who raised it, have been led into it by their ignorance. For he has affirmed, that they may be picked up by hundreds at a time in the port of Messina, and that himself once took up more than a hundred recent ones in an hour.

The shells of this species, found fossil in the island of Malta, are very frequently full of the marl of which the upper stratum of that island consists; and some of them are cracked, and have been depressed a little inwards. This is an evident proof that they once were real shells, having, in this case, given way, as far as the included marl would let them, on the pressure of some external force. See ECHINUS.

ECHINITES, or ECHINITÆ, in *Natural History*, the name given by authors to the fossil shells of the several species of echini marini, and to the stones formed in them. Of these there is almost an endless variety in the fossil world. Many of those which we daily find in our chalk pits are the same with those now known to us in their recent state, or living in the sea; but we have numbers of others, of which our imperfect knowledge of the animal world gives us no certain account, in their recent state.

The shells of some of these are found scarce at all altered from their original condition. In many others we have plated spar filling the places of the shells, and retaining every lineament of them. But their most frequent appearance is in the form of masses of hard flint, or other stone, which have been cast and formed in them, having been received, while in a fluid state, into the hollow of the shell, and therefore retaining all the lineaments of the inner surface. And, not unfrequently, these also are coated over with a sparry or stony matter, supplying the place of the shell they were formed in; and having been made, by the insensible deposition of hard matter, in the place of the particles of the shell insensibly waisting away; these retain all the lineaments of the outer part of the shell, as the formed flint does of the inner one. Sometimes pure crystal is found in the place of flint in these, and often crystal, but lightly debased by earth; and these make very elegant specimens.

The various genera of fossil echini, or echinitæ, are known among some authors by the names of spatangi, cordati, galeati, pileati, discoides, ovari, pentaphylloides. See ECHINUS.

What is generally understood by the word *echinitæ*, is a sort of arched shells, or stones formed in them, covered with divers eminences and cavities, some of which are disposed into beautiful lines, diverging from the summit; and always having two apertures, the one for the mouth, the other for the anus of the animal. Of these,

The echini cordati are such as have a remarkable furrow on one side, or end, which is usually broader than any other part of the body, and by means of this furrow, represents, in some degree, the figure of a heart on cards.

The galeati are such as have the basis somewhat oblong, and the apertures, one in the very margin, and the other near the margin, on the opposite side. (See *Galeaster* under ECHINUS.) The pileati, and discoides, are sub-distinctions of this kind.

The pileati are higher, and approach to a conic figure.

The discoides are flatter, and more compressed.

The ovari have only one aperture at the base, and have large and unequal tubercles and papillæ.

The pentaphylloides have rows of fiord lines, which are so disposed as to represent a cinquefoil leaf.

The spatangi is a very comprehensive term, taking in most of the others as sub-distinctions. It comprehends all that have two apertures in the base, and that are covered with small tubercles. See ECHINUS.

ECHINOXYAMUS. See ECHINUS.

ECHINODERMA, in *Natural History*, the name of the sea animal more commonly known by the name of the *echinus marinus*, or sea hedge-hog. See ECHINUS.

ECHINODISCUS. See ECHINUS.

ECHINOGLYCUS. See ECHINUS.

ECHINOMELOCACTUS, in *Botany*, the Turk's-cap, or Melon-thistle. See CACTUS, sect. 1.

ECHINOMETRA, a name given by some to the several depressed species of the echinodermata. See ECHINUS.

ECHINOPHORA. See ECHINUS.

ECHINOPHORA, in *Botany*, (*spinosa*, a hedge-hog, and *fero*, to bear, alluding to its prickly heads of flowers and seed.) Prickly Sampire, or Sea Parinet, Linn. Gen. 129. Schreb. 180. Willd. Sp. Pl. v. 1. 1379. Sm. Fl. Brit. 293. Juss. 225. Class and order, *Pentandria Digynia*. Nat. Ord. *Umbelliferae*.

Gen. Ch. *General umbel* of numerous rays, of which the inner ones are shortest; *partial* of numerous flowers, the central one sessile. *General involucrem* of about five unequal, sharp-pointed, permanent leaves; *partial* turbinate, of one leaf, in six acute unequal segments, permanent. *Perianth* minute, with five unequal teeth, deciduous. *Cor.* *Universal*, irregular, radiated; *male flowers* numerous, with abortive pistils; *female* solitary, in the centre of each partial umbel; *partial* of five unequal, spreading, plaited, inflexed, and cloven petals. *Stam.* Filaments five, simple, longer than the petals; anthers roundish. *Pist.* Germen of the female, flowers oblong, inferior, imbedded in the partial involucrem; styles two, simple, longer than the petals; stigmas simple. *Peric.* none, except the hardened, spinous, partial involucrem. *Seed* one or two, ovate-oblong. Sometimes stamens are found in the central, or female flower.

Obs. The above description is corrected from the manuscripts of Linnæus, compared with nature.

Ess. Ch. *Partial involucrem* turbinate, of one leaf, in six segments. *Marginal flowers* radiant, male, stalked; central one female. *Seeds* imbedded in the partial involucrem.

1. *E. spinosa*, Linn. Sp. Pl. 344. Sm. Prod. Fl. Græc. v. 1. 179. Cavan. Ic. t. 127. Mart. Mill. Dict. v. 2. (Crithrum spinofum; Dod. Pempt. 705. Ger. Em. 533. *Pastinaca marina*; Lob. Ic. 710. Bauh. Hist. v. 3. 196.) "Leaflets awl-shaped, spinous, three-cleft, or undivided, entire." A native of sandy sea-shores, especially of the Mediterranean, and in the Levant, flowering from July to September. There are so many authorities on record for its having been found, in former times, in various parts of our own coasts, that though no recent inquiries on the subject have been successful, it could not be refused a place in the *Flora Britannica*. We have gathered this plant near Genoa, Mr. Salibury at Montpellier, and Dr. Sibthorp in Greece, and Asia Minor. A most admirable drawing of it by Mr. Ferd. Bauer, exists among those destined for the *Flora Græca*. *Root* perennial, tap-shaped, often branched, long, fleshy, whitish, eatable, having the taste and smell of a parsnip. Turra says it is diuretic and aphrodisiac. *Plant* so repeatedly branched, and armed with such a multiplicity of spinous leaves, that it forms an impenetrable, inaccessible, hemispherical bush, two or three feet in diameter, decorated with

with numerous, white, or reddish, large, radiant umbels, well contrasted with the rather glaucous, somewhat downy, foliage, so as to be not deficient in beauty. The inflexed point of each petal is curiously fringed. The juices of the whole abound with alkaline salt. *E. orientalis montana spinosa*; Tourn. Cor. 45. Buxb. Cent. 5. Append. f. 27; is scarcely distinct from this species.

2. *E. tenuifolia*, Linn. Sp. Pl. 344. Sm. Prod. Fl. Græc. v. 1. 179. Mart. Mill. Dict. v. 2. (Pastaïna echinophora apula; Column. Eeprh. 98. t. 101.) Leaflets pinnatifid, sinuated, flat, scarcely spinous. Native of exposed places near the sea, in Greece, Asia Minor, and the western side of Italy, flowering in July and August. Root perennial, long, slender, blackish. Herb much branched, downy. Leaves bipinnate; leaflets sinuated and pinnatifid, their points somewhat pungent, scarcely spinous. Umbels numerous, small, of a dull yellow. Columna reports the roots to be very good food, like carrots.

3. *E. trichophylla*. Leaflets thread-shaped, elongated, undivided, scarcely spinous. Native of the Levant, preserved in the herbarium of the younger Linnæus. Herb smooth. Leaves twice or thrice ternate; leaflets undivided, very long, and slender, so as to be almost capillary, slightly channelled above, their points acute, but not spinous. Umbels the size of the first species, on long stalks, each with a dark-purple convex tumour in the centre; partial ones, when in seed, globose, muricated. Petals whitish. The plant abounds with gum. S.

ECHINOPHORA, in *Ichthyology*, a name given by Rondeletius to a species of sea-snail, of the round-mouthed kind, or class of the cochleæ lunares.

He calls it echinophora, because it is all over beset with tubercles; but this is a very ill-chosen name, as it confounds it with the echini, or sea-eggs; he had much better have called it cochlea tuberculosa. See LUNARIS cochlea.

ECHINOPHTHALMIA. This surgical term is derived from *εχμος*, a hedge-hog, and *οφθαλμος*, an inflammation of the eye. It signifies an inflammation of the eye-lids, attended with a projection of the eye-lashes, which project out like the quills of a hedge-hog.

ECHINOPS, in *Botany*, (altered by Linnaeus from *Echinopus*, a name which seems to have been first given by John Bauhin, from *εχμος*, a hedge-hog, and *οπις*, aspect, or appearance, more especially alluding to the resemblance of its round prickly heads, to a sea urchin.) Globe Thistle, Linn. Gen. 453. Schreb. 592. Willd. Sp. Pl. v. 3. 2396. Juss. 175. Gærtn. t. 169. Mart. Mill. Dict. v. 2. Class and order, *Syngenesia Polygamia-segregata*. Nat. Ord. *Compositæ*, Linn. *Cinacrocéphala*, Juss.

Gen. Ch. *Cal.* The common one of many awl-shaped totally reflexed leaves, containing many flowers; partial, to each flower, inferior, oblong, imbricated, angular, of numerous, awl-shaped, erect, permanent, leaves, spreading in their upper part. *Cor.* of one petal, the length of the calyx, tubular; its limb five-cleft, reflexed, a little spreading. *Stam.* Filaments five, capillary, very short; anthers united into a cylindrical five-toothed tube. *Pistil.* Germen oblong; style thread-shaped, the length of the corolla; stigmas two, oblong, somewhat depressed, revolute. *Peric.* none, except the enlarged calyx. *Seed* solitary, ovate-oblong, tapering at the base, obtuse at the summit. *Down* obsolete. *Common receptacle* globose, nearly naked.

Eff. Ch. Partial calyx single-flowered. Flowers all perfect. Corolla tubular. Receptacle nearly naked. Seed-down obsolete.

1. *E. sphaerocephalus*, Linn. Sp. Pl. 1314. Mill. Illustr. t. 70. "Leaves pinnatifid, white, and cottony beneath.

Stem branched." A native of Italy and Germany, a common hardy perennial in our gardens. This is the best known species. Its stems are four or five feet high. Leaves a foot or more in length, pinnatifid with angular lobes, downy above, white and cottony beneath. Heads of flowers numerous, terminal, near two inches in diameter, globose, white, or bluish, viscid to the touch, and exhaling a faint sweetish smell, like some sorts of pomatum. Five more species are enumerated by Willdenow, chiefly found in the south of Europe, smaller, or more slender, than the above, and more prickly.

Propagation and Culture.—The most of these are hardy perennials, easily propagated by seed, but requiring to be frequently renewed by the same means, like many plants of warm or dry climates, when kept in our gardens. The first species scatters itself widely in furberries, so as to become a weed.

ECHINOPUS. See ECHINOPS.

ECHINORINCHUS, in *Zoology*, a genus of intestinal vermes, the body of which is long and cylindrical, and the anterior part furnished with a short retractile proboscis, armed at the tip with recurved prickles.

All the species of this numerous genus live in the viscera of various quadrupeds, birds, reptiles, and fishes, generally in the intestines. None have yet been found in man. They adhere very firmly by means of their recurved prickles at the anterior extremity to the viscera, in which they usually form a kind of trough, and remain fixed in one spot during the whole life of the animal upon which they prey. The hooked prickles vary in form, and are more or less numerous in different species, and are in some kinds disposed with more regularity than in others.

These destructive creatures are gregarious. They subsist on the lymphatic humours and other fluids, which they copiously extract, by wounding and irritating with the hooked prickles, before mentioned, those parts to which they are immediately attached. Nor is it very unfrequent with them to perforate the membranes, and thereby expose to destruction the life of the animal in which they are nourished. Contrary to the commonly received opinion, that these animals are hermaphrodites, we have reason to conclude, there are both males and females of the several species in this genus; and that they are of the oviparous kind, is inferred from the number of small oval bodies found in the supposed females. The species of this genus, at present ascertained, are very numerous; but their manners of life, and the maladies occasioned to the more valuable kinds of animals, from the ravages of these voracious inmates, are far less clearly ascertained than the importance of the inquiry merits. The following species are described by Müller, Goëze, and other writers, who treat on this subject.

* *Insesting Mammiferous Animals.*

PHOCÆ. Body pale; intestine milk-white, and spiral. *Ascaris phocæ*, Fabr.

Found in great numbers in the intestines of the harp and rough seal, which it often devours. The body is pellucid, membranaceous, tapering to both ends, and from three to eight inches long.

TUBIFERA. Whitish, glabrous, and tapering behind into a fine hair. *Ascaris tubifera*, Fabr.

Length one inch. Discovered in the stomach of the harp seal.

GIGAS. Clear white; without neck; proboscis sheathed, with numerous rows of hooked prickles; orifices of function seven. Goëze. *Tænia hirundinæca*, Pallas.

Found in the intestines of swine; and grows to the length

ECHINORINCHUS.

of eighteen inches; the filaments of the proboscis appear as if united by two lateral ligaments.

BALÆNA. Inhabits the intestines of the whale. Phipps' Journ.

** Infesting Birds.

BUTEONIS. Clear white; vesicles of the tail bluish and lentiform. Gœze.

Found in the intestines of the buzzard, and rather exceeds two inches and a quarter in length.

SCOPIS. Proboscis covered with numerous prickles. Gœze.

Inhabits the larger intestines of the strix scopis.

ALUCONIS. Body sub-rugose and opaque; proboscis thick. Müll.

Discovered in the stomach of strix aluco.

STRIGIS. Proboscis clavate. Gœze.

In the larger intestines of strix fridula.

PICI. White, without neck; proboscis with small serrated prickles. Gœze.

Lives in the intestines of some wood-peckers; has been found in those of the two species viridis and erythrocephalus. The species is gregarious, and half an inch long.

BOREALIS. Found in the intestines of the cider duck. Phipps' Journ.

BOSCADIS. Neck filiform; proboscis rather prickly. Gœze.

In the intestines of the common duck.

ANATIS. Scarlet; body ovate; thorax and proboscis covered with prickles, with a long smooth neck between them. Gœze.

Inhabits the intestines of the velvet duck.

MERGI. Head and neck armed with prickles.

Length an inch and a half. This kind is found in considerable numbers in the intestines of the mergus minutus.

ALCE. Body with lateral wrinkles beneath on the fore-part. Müll.

In the intestines of the awk tribe. The length of this kind is four inches; the body is roundish, beneath flat, pointed at the anterior part, and terminating behind in an extremely fine point; colour whitish, with a black line down the back.

ARDEE. Body striated; proboscis clavated. Gœze.

The body is conic behind, and sinuated, each in the middle. A species found in the great white heron.

VANELLI. Tail with a white vesicle. Gœze.

In the intestines of tringa vanellus.

MERULE. Ovate; thorax prickly.

In the intestines of the black-bird.

*** Infesting Reptiles.

RANA. White; proboscis united by two slender white filaments within. Gœze. *Tenia heruca*, Pallas.

A species of a greenish, or greyish colour, found in the intestines of frogs.

FALCATUS. Proboscis long, and armed with many longitudinal rows of hooks; body marked on the fore-part with a pellucid blotch, and the posterior with a pellucid dot of the same. Froelich.

Found in the salamander.

**** Infesting Fishes.

ANGUILLE. Body white and smooth; proboscis globular. Schreb.

In the intestines of the eel.

XIPHIE. In the intestines of the xiphias gladius. Redi.

Often perforates the intestines, and occasions the death of those fishes.

CANDIUS. Body opaque, subrugose, and wrinkled. Müll. *Acanthrus splancooides*, Aët. Stockh.

Length three inches; the body pale-ash, variable to brown, yellow, &c. Inhabits the intestines of many fishes, both of the fresh and salt water kinds.

LINDOLATUS. Body with transverse brown lines, interrupted in the middle. Pallas, &c.

Inhabits the intestines of the cod fish; length two inches.

LONGICOLLIS. Reddish-white; head rounded, and longitudinally striated; neck filiform; proboscis slightly hooked. Gœze.

Found in the intestines of the torok.

PLEURONECTIS. Sides of the body with undulated impressions. Müll.

In the intestines of the turbot.

ATTENUATUS. Globiferous; body equal, yellow, and smooth; neck filiform. Müll.

In the intestines of the flounder.

ANNULATUS. Globiferous; body ending in a point; neck wrinkled. Müll.

In the intestines of the torok and bream.

PLATESSOIDE. Snout pointed; body with an elevated terminal belt behind. Müll.

Body pale, smooth, and about two inches and a half long; found in the stomach of pleuronectes platessoides.

PERCÆ. Body soft, wrinkled, and obtuse at each end. Müll.

In the intestines of the perch.

CERNUÆ. Proboscis armed with from ten to twelve rows of prickles. Schreb.

In the perca cernua.

COBITIDIS. Striated; proboscis clavated. Gœze.

In the cobitis barbatula.

SALMONIS. Body clavated, smooth; proboscis cylindrical. Müll.

Found in the intestines of the salmon.

SUBLOBATUS. White globiferous, and somewhat lobate at the sides behind; neck cylindrical and annulate, proboscis with sixteen series of ten hooks each. Müll.

In the intestines of the salmon, when young.

QUADRIROSTRIS. White; tail rounded and inserted into the body; proboscis quadruple. Gœze.

In the liver of the salmon.

TRUTTÆ. In the intestines of the trout. Gœze.

MARENÆ. Fusiform, smooth and slightly wrinkled; behind tapering, and rather obtuse. Mart. Aët. Stockh.

In the intestines of salmo marena.

LUCII. Body pellucid and smooth. Schreb.

Body yellowish, narrower, and obtuse behind.

ARGENTINA. Inhabits the intestines of the argentine. Aët. Hafn.

ALOSE. Body filiform; anterior part clavated and reddish, with eight rows of loose prickles; proboscis pale, with eight rows of denser prickles. Herrmann.

Length two inches. Found in the intestines of the shad.

BARBI. Ovate, yellow, fasciated; neck long, white, cylindrical, and glass-shaped. Schranck.

Intestines of the barbel.

CARPIONIS. Inhabits the intestines of the carp. Koelr.

IDBARI. Inhabits the intestines of cyprinus idbarus. Müll.

AFFINIS. Inhabits the intestines of cyprinus rutilus. Müll.

RUTILI. Proboscis tuberosus and prickly at the tip;

body

body with a single mouth or sucker on one side, and four on the other: Müll.

Found in the same fish as the former, but less frequently.

BRAMÉ. Neck filiform; proboscis armed with very minute prickles. Goëze.

Inhabits the intestines of the bream.

LOPHII. In the intestines of lophius piscatorius. Müll.

STURIONIS. Rounded and white. Goëze.

In the intestines of the sturgeon.

ECHINOS, in *Ancient Geography*, islands of the Ionian sea, called by the Greeks Echinæ and Echinades, situated over-against Etolia and the mouth of the river Achelous. They are now called *Cucuzolivi*.

ECHINOÛ, in *Geography*, a town of European Turkey, in the province of Albania; 8 miles N.E. of Zeiton.

ECHINUS, in *Ancient Geography*, a town of Greece, in Acarnania.—Also, a town of Greece, in the Phthiotide territory, situated, as Piny says, at the mouth of the river Sperchius; or, as others say, at the bottom of the Mahæ gulf.

ECHINUS, in *Architecture*, a member or ornament, near the bottom of the Ionic, Corinthian, and Composite capitals; which, from its circular form or contour, is called by the French, *quart de rond*, and by the English, *quarter round*, or *boulfin*; and from its being usually carved, or cut with figures of eggs, &c. is called also by the Latins, *ovum*; by the Italians, *ovolo*; the French, *auf*; and the English, *eggs* and *anchors*. Lastly, the eggs being encompassed with a cover, and thus bearing some resemblance to a chestnut cut open; the Greeks have called it *εχνοος*, *echinus*, a word which denotes the prickly cover of a chestnut.

ECHINUS, in *Botany*, Loureir. Cochinch. 633. a diocious tree of Cochinchina, suspected by Loureiro to be the *Ullasium* of Rumph. Amboin. book 4. chap. 18. t. 23. It appears to belong to the natural order of *Amentacea*, and he describes the fruit as two united roundish mucricated capsules, with a round smooth black seed in each. The leaves are scattered, ovate, pointed, undivided or three-cleft, entire, reticulated with veins, downy beneath. Flowers many together on a stalk. Whatever may be determined concerning this genus, its name is untenable in botany, being pre-occupied in zoology.

ECHINUS. See *SALSOLA* and *STATICE*.

ECHINUS is also used by some botanists for the prickly head or top of any plant; thus called from its likeness to a hedge-hog, or the cover of a chestnut.

ECHINUS, the hedge-hog, in *Zoology*. See *ERINACEUS*.

ECHINUS, a genus in the Linnæan system, included in the mollusca order of vermes. These have the body roundish, covered with a bony crust, and furnished in general with moveable spines; the mouth placed beneath, and mostly consisting of five valves.

This is the character ascribed to the echinus genus by Linnæus, and retained by Gmelin. A slight attention to the genus, as it stands thus defined, will be sufficient, it is presumed, to convince every impartial naturalist that some amendment is requisite in the classification of these bodies, admitting only those species which Linnæus describes; and if this be allowed, it will be seen that the Gmelinian arrangement, being far more copious, is much more liable to objection. Linnæus includes three or four distinct natural genera under his genus echinus; Gmelin, no less than ten; and many of these so remote in character, as to bear no affinity whatever with each other, except in being, as Linnæus expresses it, of a roundish form, covered with a bony crust, beset with spines, and having the mouth placed beneath.

By some it may be urged, that this really constitutes them of the echinus genus; and every other difference, whether in figure or any other peculiarity, ought to be regarded as distinctions of species and not of genera. To a certain extent we concede the truth of this; but from the many examples before us, which this extensive tribe presents, there can be little difficulty in discriminating which characters define natural families, and which form distinctions of species only; the former of which will not fail to afford the best general distinctions that can be adopted in the arrangement of this tribe of animals. That considerable reformation is requisite in the Linnæan arrangement, we think, must be allowed; nor can we hesitate in believing that Linnæus would himself have made much amendment in his classification of the echini, had he been acquainted with half the number of species which have been discovered since his time. Were we, in fact, to regard all bodies, which may be safely included within the definition of his echinus, as appertaining strictly to one genus, we might with equal consistency recast the whole system of conchology, and consolidate every species of whatever families into a single genus. All shells have a greater or less degree of tendency to a roundish form, whether multivalve, bivalvs, or univalve, and have the covering alike of a testaceous substance. All echini have a greater or less degree of tendency to a roundish form, and have the covering alike of a bony substance: yet, how absurd would it appear to admit the first as a general distinction, though from habit we implicitly admit the latter? It is indeed added, that the echini have moveable spines; to which, in speaking of shells, we may contrast the circumstance of the spines on shells, when present, being always immovable. This parallel might be pursued still further; but enough, we conceive, has been advanced to prove that the definition of echinus, as retained by the Linnæan school, admits of far more general application than can be consistent with a general distinction: and it will be hereafter shewn, that the several families, which in the latitude of its expression that genus embraces, exhibit as prominent generic features as the several tribes of shells.

That no improper blame be attached to Linnæus, it should be recollected, that so lately as the publication of the tenth edition of the "Systema," no more than seventeen species of echinus were known to that author; and though these included examples of several distinct natural genera, when we consider the concise amount of these, he is not altogether inexcusable for retaining them together: had he divided them into about three genera, it might have been sufficient. Gmelin possessed every advantage, and has still done little towards improvement. When Linnæus wrote, his most material assistance was derived from the works of Rumphius, an early edition of Klein, and Breyous; and lastly, some few specimens in the cabinet of count Tessin. For the disposal of these in methodical order, he formed two sections: one for those having the body of regular form, and the vent vertical; the other irregular, and having the mouth and vent beneath. The first of these sections contain eleven species; and the second, six. Gmelin derived very assistance from better authors: the labours of Müller on this subject, in "Zoologia Danica;" Pelsmus's work, entitled, "Briesaan C. Nozeman over de Gewel-Siekken of Zee-eglen;" and, more especially, the Lestæian edition of Klein's "Naturalis Dispositio Echinodermatum, &c.;" all which appeared subsequent to the time of Linnæus. From these publications, Gmelin found the tribe of echinus to be far more numerous than had been before conceived; and clearly saw the necessity of extending the genus to a considerable length for their reception, if he adhered to the

Linnæan method; or of constituting several new genera, if he deviated from it. The former presented difficulties; the latter, innovation and trouble. Those writers had not only described many species which belonged to either one or another of the families proposed by Linnæus, but many more, which, without great impropriety, could not be referred to either; the species altogether amounting to above one hundred subjects. The only circumstance to be regretted was the want of harmony in the different systems; for, although the several writers agreed in the most essential point, namely, the necessity of forming a number of new genera, they were either disposed to accord in the construction of those genera, or in the application of names, even to those particular families, which in any system might be designated by the same appellation. Gmelin does not attempt to unravel these, and overcome the perplexity: he at once severs the gorgon knot, by rejecting the genera of every author indiscriminately, and referring the whole of the species to the genus *echinus*. For the admission of these, he forms twenty-seven principal and secondary divisions; and, in this state, it may be truly observed, that there is no genus whatever, throughout the whole Linnæan system, the cancer perhaps excepted, which presents such an incongruous assemblage.

Any arrangement formed on such a plan must prove defective; and the *echinus* genus, as constructed by Linnæus, ought rather to be considered, in the present time, as the character of an extensive order of vermes than as a genus. There is in each of the systems which have appeared much to commend; and none, however, which in our opinion is so constructed as to deserve entire approval. Some of those established by Leske, and others by Müller, are excellent; and several of the new genera of La Marck ought in particular to be retained. In the following arrangement of genera, we have endeavoured to combine the advantages of each; and are inclined to believe, that no difficulty can occur in referring any of the known species of Linnæan *echini* to its natural genus, according to the method now proposed. The several genera, though considered distinctly, are brought together into one point of view, to avoid that perplexity to the Linnæan reader which must necessarily arise, were each genus referred to its alphabetical order through the work.

Before we conclude this topic one point must be considered. It must be confessed that there is one radical fault in the arrangement of these bodies, in which all writers have participated, with the exception of Linnæus; and that is, the incorporation of the recent with the remains of fossil species. Some of the former we have occasional opportunities of examining, in a perfect state, in museums and collections; while, on the contrary, the others occur almost constantly in a state of mutilation, or are so enveloped and disguised in stony matter, as to render their characters ambiguous. The latter, when tolerably elucidatory of the species, or especially with any remains of the spines affixed, are deemed inestimable. The remains of fossil *echini* mentioned by writers are, therefore, to be at all times received with caution; and some within our own knowledge must be rejected: neither is it advisable to form any genera of the fossil kinds, except from such examples as perfectly display every character of the general form, together with both the situation of the mouth and the anal aperture.

Naturalists have entertained very different opinions concerning these bodies. Aristotle, who is one of the earliest writers on the subject, calls them *echinos*, *echinometra*, and *spatagus*, placing them with multivalve shells. This example is followed by Pliny, and many much later writers. Among the moderns, it should be mentioned that Bruguiere forms a distinct class of these, and the *asterias*; Cuvier re-

fers them to the *zophytes* class, and La Marck to his *radi-ares*, the class in which he comprehends the *asterias* and *holothuria*.

The recent animals of this class are inhabitants of the sea, and those species which occur in a fossil state are found most commonly in secondary calcareous rocks, or more frequently in chalk and flint. The crust or covering is composed of a great number of plates, amounting, in many species, to nearly a thousand in a single shell; their form is various in different families, and the perforations of the shell disposed as variously. These perforations in the shell are the apertures to which the tentacula of the inclosed animal are protruded. The surface of the shell is also more or less beset with tubercles, upon which the spines are situated. These in the living animal are attached by very strong ligaments, but almost constantly fall off when the animal dies. The mouth, which is placed beneath, consists of five or six teeth of a triangular form. Their internal organization, notwithstanding the investigations of Cuvier, remains in considerable obscurity, and their sexual organs are unknown. They are ascertained to be oviparous, and to spawn in the spring. The spines are the instruments of motion, an interesting account of which appeared from the pen of Reaumur, in the Memoirs of the French Academy of Sciences, in 1772. Their tentacula are the processes by means of which they adhere very securely to the rocks, or seize upon their prey, and by the assistance of which they conduct it to their mouth. They live chiefly on crabs and testaceous animals, marine worms, &c.

The succeeding appear to be the principal natural families into which the Linnæan *echini*, ascertained at this time, may with propriety be divided; and which, as before remarked, to avoid confusion, are concentrated in the present article.

ECHINUS.

Body hemispherical, globular, or suboval, with avenues of pores, which diverge equally on all sides from the vent to the mouth; vent vertical; mouth beneath and central.

ESCULENTUS. Hemispherical-globular, with ten avenues of pores, the spaces between covered with small tubercles supporting the spines. *Echinus esculentus*, Linn. *Echinometra*, Rondel. *Melo marinus*, Plancus. *Cidaris miliaris*, Klein.

Native of the Mediterranean and other European seas, and one or more of its varieties found in India. The body is generally reddish and yellow, varied with green or purple spines, which fade in colour, and fall off after the death of the animal. The flesh is eatable.

SPHERA. Spherical, red, with blueish spines. Müll. Inhabits the northern seas, and is by some supposed to be the young of the species *esculentus*.

DRABACHENSIS. Hemispherical, pale, with long pale spines. Müll.

Found in the northern seas.

MILIARIS. Hemispherical, depressed with ten avenues of pores, the spaces between with two rows of protuberances. Gmel. *Cidaris miliaris saxatilis*, Klein. *Echinus ovarius*, Rondel.

An European species.

BASTERI. Shell depressed, with few tubercles, and serrated line down the middle of the spaces; pores of the avenues placed in alternate rows of two and three foramina. Klein.

A native of Europe, and by some authors considered as a variety of the former. The colour is greenish-grey, variable to olive or reddish violet. The larger spaces are marked

ECHINUS.

marked with eight rows of small tubercles, and sprinkled with a few others of smaller size; the lesser spaces with two rows of larger, and as many small tubercles; avenues with a triple row of double pores; spines striated whitish.

HEMISPHERICUS. Hemispherical, depressed, with ten avenues of pores, the spaces with a serrated future down the middle, and transverse lines; mouth pentangular, the angles obtuse. Klein.

Resembles *E. efulentus*. Colour red with paler avenues, the base ochraceous; rough with larger and smaller protuberances.

ANGULOSUS. Hemispherical; the spaces granulate and bifariouly warted, the larger ones bipartite by a serrated future down the middle; avenues trifariouly porous. Klein.

Shell grey, with a violet tinge; spaces with rows of granulations and protuberances; avenues with double distant pores. Klein describes also a variety of this species of a smaller size, and greenish grey colour.

EXCAVATUS. Hemispherical; spaces granulated, and bifariouly tuberculated; avenues excavated and bifariouly porous. Klein.

Found in a petrified slate at Verona.

GLOBULUS. Hemispherical, sub-globular, with ten avenues, the spaces muricated at the sides, and porous in the middle. Linn.

Inhabits the Indian ocean.

SPHEROIDES. Hemispherical, gibbous; avenues ten, muricated throughout, and porous in the middle.

Native of the Indian ocean.

GRATILLA. Hemispherical, gibbous; avenues ten, triplicate, the spaces muricated in a decussate manner. Linn. Inhabits same seas as the latter.

LIXULA. Hemispherical, with ten avenues in contiguous pairs, the spaces transversely muricated and punctured. Linn.

Native of the Indian ocean.

SAXATILIS. Hemispherical, depressed; pores of the avenues in a curved line, the curves oblique at the base. Linn. *Cidaris rufephris*, Klein.

Several supposed varieties of this species are found in the Mediterranean and Indian seas. The colour is commonly violet-grey or white, with the protuberances reddish or yellowish in two or three longitudinal rows; pores of the avenues double; spines rigid, reddish-brown, with violet tips.

FENESTRATUS. Orbicular, with a flat fenestrate base; spaces ten, with unequal small and large tubercles; mouth with ten angles. Klein.

White, and granulated throughout; in the larger spaces are six rows of papillous warts; avenues broad with three pair of pores; spines violet-black; vent pentangular.

SUBANGULARIS. Hemispherical, orbicular, with ten spaces, the lesser ones elevated, and ten rows of tubercles in each. Klein.

Shell greenish-grey, rather inclining to chestnut; spaces with four tubercles placed in a rhombic form; pores of the avenues curved in four or five pairs.

Native place unknown.

OVARIUS. Ovate, the larger spaces bifariouly tuberculate. Plott, &c.

Found in a fossil state in England.

DIADEMA. Hemispherical, depressed, with five avenues longitudinally tuberculate; the spaces lanceolate. Linn.

Inhabits the Indian seas. The shell is orbicular with the top depressed, colour generally bluish; mouth large; vent circular, and surrounded with a pentangular skin; spaces bifariouly tuberculate, the tubercles perforated at the tip;

avenues with three pair of pores at the base and one at the tip; spines violet and blue-grey. There are several varieties of this species differing in colour and disposition of the spots, &c.

CALAMARIUS. Spheroid, depressed; avenues five, with black porous margins, granulated in the middle with a row of larger prominent dots. Pallas.

Native of the Indian sea, the colour greenish-white; the spines resemble the stem of the equisetum, and are whitish annulated with green and grey at the tip.

ARANEIFORMIS. Orbicular, grey, with purple-grey spines thicker in the middle. Gmel. *Spinnekopf*, Phell.

Inhabits American seas.

STELLATUS. With the lower spines capillary. Gmel. *Kleine Komet*, Phell. *Echinometra purpurea americana*, Seba. *Erinaceus marinus*, Pontopp. Norrk. Naturh.

Found in the American seas.

RADIATUS. With five radiated avenues, forked at the tip. Klein. *Groote Komet*, Phell. *Echinanthus major spinis ortus*, Seba.

Native place unknown.

CIRCINATUS. With ten granulate spaces, bifariouly tuberculated, the larger ones excavated, the lesser ones elevated, and sub-pulvinate at the base. Leske. *Echinometra circinata*, Breyn. *Krunsj*, Phell.

Found in a fossil state.

CIDARIS. Hemispherical, depressed, with five flexuous linear avenues, the spaces alternately bifarious. Linn.

Many very dissimilar kinds of echini are included by Gmelin as varieties of this species, several of which we are persuaded will be found on further investigation to be distinct. *E. cidaris* inhabits European and Indian seas.

MAMMILLATUS. Hemispherical, oval, with ten winding avenues; the spaces muricated and warty, the narrower ones abbreviated. Linn. *Cidaris mammillata*, Klein.

Inhabits the south seas, is of a depressed form and yellowish ash-colour inclining to brownish, beneath paler.

LACUNTUR. Hemispherical-oval with ten flexuous avenues; spaces muricated, the narrower ones longitudinal. Gmel. *Cidaris lacuntur*, Klein.

Variable in colour from yellow-cinereous to bluish or blackish. The species inhabits the Indian ocean.

ATRATUS. Hemispherical-oval and slightly depressed; with very short obtuse-truncate spines; the marginal ones clavated and depressed. Klein.

Orbicular cinereous inclining to violet; spines violet. Native of the Indian seas.

CORONALIS. Hemispherical-orbicular with ten spaces alternately narrower and covered with scattered papillæ; avenues flat, uniting in confluent pairs before the area of the crown. Leske.

Found in a fossil state in chalk and flint in various parts of the world.

ASTERIZANS. Orbicular depressed; tubercles furrowed with a groove up to the tip, and surrounded with a circle of granulations, Leske. *Sterrewart Zee-egel*, Phell. *Zee-egel*. A mineralized species met with in chalk.

ASSULATUS. Shell scutellate, the scutels united by transverse futures. Klein.

SARDICUS. Orbicular depressed tuberculate, with ten impressed avenues; the spaces multifariouly tubercled, with an impressed future down the middle. Klein. *Sardische Zee-egel*, Phell.

A large species, found in the Tuscan and Adriatic seas; the colour grey, tinged with yellowish red; the base nearly flat and yellow; larger spaces with tubercles disposed in

about

ECHINUS.

about twelve rows, with lesser ones and small granulations in the interstices; the lesser spaces with about six rows of smaller tubercles; avenues with five pairs of pores placed in an arched series; mouth small.

FLAMMEUS. Hemispherical depressed; the spaces void of tubercles in the middle towards the upper parts, the lesser ones more elevated; avenues narrow and bounded each side by a row of tubercles. Klein. *Gez. samde Zee-egel*, Pfeiff.

Native place unknown. The colour is olive green, with the tubercles and base whiter; larger spaces with twelve rows of tubercles at the broadest part. Lesser spaces with three; each tubercle surrounded with a circle of lesser ones; mouth small, vent surrounded with pentagonal scales.

VAREGATUS. Orbicular tubangular; middle spaces rosy, rich green each side; avenues whitish-green; base whitish. Leske. *Zantg. samde Zee-egel*, Pfeiff.

A rare kind, the native place unknown.

PUSTULOSUS. Larger spaces divided in the middle by a future, with numerous transverse rows of tubercles increasing in number towards the middle; lesser spaces more elevated. Klein.

This is a small species, about an inch in height and two in diameter, the colour brownish-grey inclining to red, the lesser spaces paler, base whitish, and protuberances tinged red. Mouth with broad sinuities. Country unknown.

GRANULATUS. Sub-orbicular, sub-angular; middle of the spaces naked and divided by a future serrated each side, the larger ones with seven rows of tubercles, the lesser ones with four. Klein. *Zand-korlige Zee-egel*, Pfeiff.

About one fourth less than the former; colour dull green, with the margin of the larger spaces, and the base inclining to greyish; avenues with three pair of pores placed in a triangle; vent circular with ten scales at the margin expanded like a rose.

TRISELLATUS. With ten spaces divided in the middle by a future, and tessellated; avenues ten biporous; mouth circular. Klein. *Leydenak*, Pfeiff.

Found in a fossil state.

BOTRYOIDES. Spaces divided by a longitudinal future in the middle, the larger ones bifariouly tuberculated; avenues with a double curved row of pores. Klein. *Geribde Zee-egel*, Pfeiff.

Found in same state as the former.

TOREUMATICUS. Hemispherical, with ten spaces bifariouly tuberculated, the tubercles crenated and surrounded by a circle of granulations, the larger spaces with four longitudinal grooves, the lesser ones with two grooves. Klein. *Gez. samde Zee-egel*, Pfeiff.

Cinereous greenish or bluish, the base and avenues yellowish; avenues biporous, the pores placed in a thickly-serrated line; vent surrounded with ten scales.

CLYPEUS.

Body shield form; vent vertical; mouth beneath and central.
SINUATUS. Convex; avenues ten, striated; spaces ten; tubercles surrounded with a circle of granulations. Plott.

Found in a fossil state in Britain.

SEMIGLOBOSUS. Hemispheric, cili, grooved, with a flat base, the protuberances placed in rows. Klein.

Found in a fossil state.

QUINQUELABIATUS. Painted with innumerable annulations, with a hollow in the middle, surrounding a five-rayed convex star. Klein. *Vyslip*, Pfeiff.

Found in a fossil state.

CONOIDEUS. Sub-conic, with an elliptic circumference; spaces and avenues ten, the latter transversely grooved, and

porous at the margin, the former divided by a straight future. Leske.

Found in a fossil state.

GALERITES.

Conoid, or oval, with avenues of pores radiating from the summit to the base; mouth central; vent in the margin or inconspicuous.

ALBOGALERUS. Spaces ten; covered with numerous small tubercles, the larger ones united by a ferrate future and transversely lined, the lesser ones terminated by a foramen at the crown; avenues ten and biporous. Gmel. Platt, &c.

A fossil species, met with in various parts of Britain.

DEPRESSUS. Spaces ten, the larger ones divided in the middle by a future; avenues ten, biporous; crown depressed; vent orbicular. Leske. *Eggssteen tienband plattop*, Pfeiff.

A fossil species.

VULGARIS. Orbicular, with ten avenues, two of which are near each other. Morton, &c.

Common in a fossil state in various parts of Europe.

QUADRIFASCIATUS. With four avenues of pores. Gehler, &c.

Found in a fossil state.

SEXFASCIATUS. With six avenues of pores, Gehler, &c.

A fossil species.

DISCOIDEUS.

Body roundish, with the base exactly circular; mouth and vent beneath, small and orbicular.

SUBVUCULUS. Avenues ten, biporous; spaces ten, alternately large and smaller. Klein.

In this species the spaces are beset with very small circles; pores of the avenues very minute, and crowded close together.

Found in a fossil state.

ECHINONEUS.

Body oval or orbicular, and rather depressed; rays of pores numerous and radiate from the summit to the base; mouth somewhat central; vent beneath and near the mouth.

CYCLOSTOMUS. Oblong, sub-depressed; crown with five pores; mouth placed in the middle and round; vent oblong and near the mouth. Leske. *Spatagus pusillus*, Müll. *Rond-mond*, Pfeiff.

Cinereous or yellowish; spaces ten, divided by a serrated line down the middle, and beset with minute tubercles inclosed in a circle; avenues ten, biporous, and extending to the mouth. A fossil species.

SEMILUNARIS. Vent longitudinally oblong; mouth transverse and semilunar. Klein. Mus. *Echinus ovalis*, Telfin. *Spleet-mond*, Pfeiff.

Colour pale yellowish-ash. The species inhabits the Asiatic seas.

SCUTIFORMIS. Mouth pentangular; avenues ten, striated; larger spaces divided into plates, the pieces pentangular. Leske.

Native place unknown.

GALEASTER.

Body usually convex above and flat beneath; base ovate and acute; vent and mouth beneath and opposite.

SCUTATUS. Convex, beneath flat; spaces tuberculated and alternately larger, the large ones divided by a serrated future in the middle; mouth transversely kidney-shaped. Lhuud. *Gulca vertici fentata*, Klein. *Vysblad*, Pfeiff.

Found in a fossil state in Britain.

ECHINUS.

OVATUS. Ovate, divided into plates of an hexangular form; crown naked; vent somewhat oval. Klein.

A fossil species. The shell is composed of twenty rows of plates, which are alternately larger and smaller, and all united by a ferrated suture; mouth round and small; vent slightly oval.

PUSTULOSUS. Spaces obsolete and tuberculated; avenues with raised dots disposed in pairs; crown impressed. Platt, &c.

Found in a fossil state in England and Germany.

QUADRIRADIATUS. With four double rows of dots. Klein. *Echinites Nienserpentis*, M. de lap.

Found in Germany in a fossil state.

MINOR. Ovate, with a flat or concave base; spaces and avenues ten, the avenues biporous; mouth transverse, roundish; vent sub-oval. Leske.

A fossil species.

DEBIUS. Ovate, with ten porous avenues; half the vent marginal. Leske.

The five larger spaces are marked with impressed circles. Found in a fossil state.

CLYPEASTER.

Body irregular, convex above, beneath subconcave; margin angularly sinuous; surface with a quinque-petalous mark of pores; mouth beneath, and central; vent beneath, and near the margin.

ROSACEUS. Flattish, and roundish-oval; avenues five, oval, with a dotted surface. Linn. *Echinanthus humilis*, Klein. *Groot egiel-roosen slomp-blad*, Phell.

Native of the Asiatic seas.

ALTUS. Crown elevated and orbicular; avenues broad, with convergent granulated tips. Walch, &c.

A fossil species.

PENTAPHYLLUS.

Body irregular and ovate, above convex, beneath flat; margin entire; surface with a quinque-petalous mark of pores; mouth transverse; vent marginal.

OVIFORMIS. Convex, beneath flat; avenues ten, biporous, and expanded in a stellated form; crown with four pores. Klein.

Found in a fossil state.

ORBICULATUS. Granulated; avenues biporous, the pores united by a transverse impressed line, and the intermediate spaces divided by a ferrated line in the middle; the rest of the surface quinque-partite. Leske. *Mongstroites minor*, Mercat.

A species of the fossil kind, and perhaps not strictly of this genus.

ECHINODISCUS.

Body flat above and beneath; surface perforated with foramina, and a quinque-petalous mark of pores; mouth central; crown with four pores.

* Section. With sinuate Margin.

BIFORIS. Base with five grooves, and ten flexuous radiated lines; near the vent two oblong foramina. Leske. Native place unknown.

PENTAPHORUS. Avenues emarginate at the tip; vent near the mouth; with five foramina. Klein, &c. *Tyff-vairige egielkoek*, Phell.

Colour above whitish-ash, tinged with reddish, beneath white and yellow, with blue veins; crown marked with a pentagonal star.

Vol. XII.

HEXAPORUS. Orbicular, with narrow avenues, and six narrow foramina near the vent. S. ba, &c.

Inhabits the Indian, American, and South seas. The colour cinereous; crown umbilicated, base rather hollow.

EMARGINATUS. Sub-pentagonal, with ovate avenues; vent oval, more remote from the mouth, with six foramina close to the margin. Leske. *Laufwerk*, Phell.

This is of an oval form, and somewhat heart-shaped; the length above four inches; the crown is petulous base rather flatter, and marked with deep flexuous ramose lines. The species inhabits the island of Bourbon, and is of a greenish-brown colour.

AURITUS. Margin waved, the lower one rounded, the upper one nearly square, and twice divided, with an opening pore between every two of the avenues. Leske. *Georde slomp-keri*, Phell.

Native of the Persian seas. Yellowish-grey, with the upper margin tawny; base flat, punctured, and marked with radiated striae; vent oblong, and placed near the mouth.

INAURITUS. Sub-ordate, and divided into plates, the pieces hexagonal; avenues five, oval, emarginate at the tip, the fifth longer, and a pore between every two of them. Leske. *Ongeorde slomp-hari*, Phell.

Inhabits Amboyna. Height five or six inches, and breadth the same; colour above reddish-ash, beneath violet-red.

TETRAPORUS. Orbicular, slightly sinuous, and perforated each side with four foramina; vent circular. S. ba, &c.

Colour pale yellow-grey. Native place unknown.

** Section. With the Margin toothed or lobate.

DECADACTYLOS. Shell perforated with four oblong foramina; the margin with ten teeth. Leske.

Native place unknown. The shell is rough with granulations, above blueish-green, varied with cinereous; the avenues and sutures pale flesh-colour; base yellowish-flesh-colour, with ten impressed flexuous grooves, bifid at the tip, and greenish-ash; mouth rounded; vent ovate.

OCTODACTYLOS. Anterior part orbicular, and perforated with two foramina; posterior part with eight teeth; avenues lanceolate. Brey, &c.

Whitish-ash, divided into convex plates; crown umbilicate; avenues emarginate. Country unknown.

ORBICULUS. Fore-part orbicular and entire; hind-part unequally toothed; avenues lanceolate, cleft, and bent. Rumpf, &c.

Native of the Indian sea. This shell is flat, sub-orbicular, not perforated, and composed of hexangular pieces; the base flat, with impressed grooves; avenues oval; mouth rounded; vent oval.

ECHINOGLYCUS.

Body flat above and beneath, with entire surface, and quinque-petalous mark of pores; mouth central; crown with four pores.

LAGANUM. Avenues oval, finely striated and cleft at the tip; crown prominent; vent circular and near the margin. Leske. *Zeerel*, Rumpf.

Found in a fossil state.

SUBROTUNDUS. Orbicular, with radiated avenues. Klein. Aldrov, &c.

A fossil species.

RETICULATUS. Ovate, flattish, with five oval avenues; the surface reticulated. Rumpf. *Echinoglycus ovalis*, Phell.

Native of the American and Indian seas.

COROLLATUS. Orbicular, with short, oval, obtuse avenues. Klein.

A mineralized species.

ECHINOCYAMUS.

Body usually globular or oval, with ten avenues on the crown; rays on the surface biporous, straight, and forming a star of five rays; mouth and vent contiguous in the middle of the base.

NUCLEUS. Surface globular, with an orbicular circumference; base narrow and flat in the middle; sides grooved; avenues pulvinate; crown excentric. Klein, &c.

Yellowish-ash; crown perforated with four pores; mouth circular; vent rather oblong, and smaller than the mouth. Native place of this and the two following unknown.

CENTRALIS. Surface globular, circumference orbicular; base pulvinate; sides very finely grooved; avenues slightly pulvinate; crown central.

Allied to the former; the mouth minute and orbicular.

ERVUM. Surface globular, circumference somewhat oval; base a little narrowed; sides furrowed; avenues somewhat pulvinate; crown central. Pheff.

CRANIOLARIS. Surface globular on the anterior part; posterior nearly five-angled, pulvinate, and sloping; circumference elliptic; base a little narrowed; sides grooved; avenues pulvinate; crown excentric. Pallas, &c.

Native of India. The colour white, covered with granulations, surrounded by a hollow line; crown with four pores.

TURCICUS. Surface and base pulvinate, circumference elliptic; sides slightly grooved; avenues sub-pulvinate; crown slightly depressed and central. Pheff.

VICIA. Surface globular, circumference obtusely oval; base a little narrowed; sides grooved; avenues flattish; crown central. Pheff.

Resembles echinus craniolaris, and inhabits the Adriatic.

OVULUM. Surface pulvinate, circumference obtusely oval; sides slightly grooved; crown central. Leske.

LATHYRUS. Surface and base pulvinate; circumference oval; sides slightly grooved; avenues pulvinate; crown nearly central. Pheff.

Colour dull yellowish-grey.

EQUINUS. Surface and base pulvinate; circumference elliptic; sides smooth; avenues sub-pulvinate; crown central. Leske.

MINUTUS. Surface pulvinate and nearly flat, circumference ovate and sub-pentangular; base narrowed; sides grooved; avenues pulvinate; crown central. Pallas, &c.

A small species, found frequently on the sandy coasts of the Netherlands.

FABA. Surface and base pulvinate; circumference obtusely oval; sides hardly grooved; avenues flat; crown a little prominent and central. Pheff.

Very small, ochraceous, and granulate.

INEQUALIS. Surface gibbous on the fore-part, posterior flat and sloping; circumference oblong-oval and nearly pentangular; base globular and rather narrowed; sides grooved; avenues sub-pulvinate; crown central. Pheff.

In this species the back is unequal.

RANINUS. Surface globular, and more sloping behind; circumference acutely oval; base globular; sides grooved; avenues sub-pulvinate; crown central. Pheff.

Resembles echinus minutus.

BUFOIDES. Surface globular; circumference ovate,

heart-shaped, and sub-triangular; base pulvinate; sides slightly grooved; avenues pulvinate; crown nearly central. Much allied to the last.

CASSIDULUS.

Body elliptic or sub cordiform; upper surface with a five rayed star of pores; mouth sub-central beneath; vent above, and near the margin.

AMERICANUS. Body sub-globose; circumference somewhat oval; crown with four pores. Bosc. Inhabits American seas.

SPATANGUS.

Body cordiform or ovate; vent lateral.

Section *. Heart-shaped; the crown grooved.

COP ANGINUM. Above convex, with five impressed quadrifurcately porous avenues, and five spaces. Lhuys, &c. Pockart, Pheff.

A fossil species found in Britain.

LACUNOSUS. Ovate, gibbous, with five depressed avenues. Linn. *Spatangus lacunosus*, Klein. *Groote holblad*, Pheff.

Native of the Indian and European seas.

Section **. Heart-shaped, the crown not grooved.

RADIATUS. Avenues four, with impressed striæ, porous on each side; crown with four pores; spaces ten, divided by a serrated future in the middle, and arched transverse futures. Walch.

Found in a fossil state; the base is flat; mouth rather kidney-shaped, and surrounded with a sub-pentagonal star of pores; vent roundish.

PURPUREUS. Avenues four, petal-shaped and lanceolate; larger tubercles placed in a zig-zag manner; spines acicular, incurved, and white. Klein. *Diehblad*, Pheff. *Pas de pou-lain*, Argenv. *Scalopendrites*, Aldr.

Native of the North seas. The back convex, sides sloping; anterior part with two projections; posterior truncated; beneath flat; surface granulated, and covered with subclavate, and spatulate brittle spines.

FUSILLUS. Oval, with five avenues; vent remote. Müll.

A minute species found in the North seas.

COMPLANATUS. Rather flattened each side; spaces and avenues ten, two of which are placed in the furrows of the back. Klein.

This is of a roundish form, and is found in a fossil state.

SUBGLOBOSUS. Both ends convex, sub-globular, and divided into plates; avenues ten, with biporous striæ; vent ovate. List, &c.

Found in a fossil state in Britain; the shell is granulated, with four pores on the crown; spaces divided by a longitudinal serrated future, and grooved with transverse curved lines; mouth somewhat kidney-shaped, and surrounded with tubercles disposed in a related form.

ANANCHYTIS. Oblong; heart-shaped and sub-conic; the base flatter; avenues and spaces ten; mouth rounded and surrounded with an elevated margin; vent oval and emarginate below. Klein.

A fossil species.

BICORDATUS. With a double crown. Leske.

A rare species, found in a fossil state.

CARINATUS. Middle of the back carinated. Bayer.

Resembles the last, but is narrower behind; mouth kidney-shaped; vent obsolete. A fossil kind.

Section ***. *Body ovate, the avenues grooved.*

SPATAGUS. Ovate, gibbous, with four depressed avenues. Linn.

Native of European seas. Many of the echini tribe are described by Gmeïn as varieties of this species, but which are certainly distinct.

Section ****. *Ovate, the avenues not grooved.*

BRISSEIDES. Oblong; with four biporous ovate lanceolate avenues, united by transverse grooves, with larger tubercles placed archwise between them. Klein.

A fossil species.

TERES. Convex, with four biporous petal-shaped avenues not united. Klein.

Resembles the last, but has the mouth broader.

OLIVA. Above convex, punctured olive, with a double naked band reaching from the mouth to the vent. Lefk. *Kleine eegelnoot*, Phell.

Found in the recent state, the native country unknown; shell with four stellated rays above.

AMYGDALA. Resembling an almond in form. Klein.

Native place uncertain.

OVALIS. Divided into plates; with ten avenues and spaces; the latter divided by a ferrated suture in the middle. Lefk. *Egelschuitje twee top*, Phell.

A fossil species.

PYRIFORMIS. Ovate, and gibbous at one end, the base flat; avenues five, somewhat petal-shaped; and obsolete porous. Klein.

Found in a fossil state.

LAPISCANCR. Obtusely oval, convex; crown excentric, and perforated with four pores; avenues five, biporous, ovate-lanceolate, and cleft at the tip. Klein.

Found in the same state as the former. The base of this shell is flat and slightly excavated.

PATILLARIS. Very much depressed, with avenues resembling a star. Klein.

Circumference ovate; back slightly convex; base rather excavated; sides granulated; mouth orbicular.

A fossil species.

ECHINARACHNIUS.

Body circular; mouth central; vent lateral and square.

PLACENTA. Sub-conic, with ten spaces alternately narrower; avenues five, lax, flat, and gaping at the tip. Bryn.

Native of the Southern ocean. Shell a little convex and conoid, the circumference somewhat angular; the base flat; spaces divided by an obtusely-toothed vertical line; vent placed on the surface, and nearly marginal.

ECHIOIDES, in *Botany.* See LYCOPSIS and MYOSOTIS.

ECHIQUETTE, in *Heraldry.* See CHECKY.

ECHIRE, in *Geography,* a town of France, in the department of the Two Seves, and district of Niort; four miles N. of Niort.

ECHITES, in *Botany,* was so named by Browne, in his *Natural History of Jamaica,* from *εχis*, a *serpent* or *viper*, as professor Martyn presumes, on account of its deleterious quality. Perhaps its smooth twining habit may have confirmed the idea. Linn. Gen. 117. Schreb. 164. Willd. Sp. Pl. v. 1. 1237. Juss. 146. Browne Jam. 182. Class and order, *Pentandria Monogynia.* Nat. Ord. *Centurie*, Linn. *Apocinee*, Juss.

Gen. Ch. *Cal.* Perianth small, deeply five-cleft, acute. *Cor.* of one petal, funnel-shaped, pervious; limb five-

cleft, flat, widely spreading. Nectary five glands placed round the germens. *Stam.* Filaments five, slender, erect; anthers rigid, oblong, pointed, converging. *Pist.* Germens two; style single, thread-shaped, the length of the stamens; stigma oblong-capitate, two-lobed, connected with the anthers by a viscid juice. *Peric.* Follicles two, very long, each of one cell and one valve. *Seeds* numerous, imbricated, crowned with long down, and affixed to a linear receptacle.

Eff. Ch. Corolla contorted, funnel shaped, with a naked orifice. Follicles two, elongated, straight. Seeds with a hairy crown.

Browne founded this genus upon a single species, *E. umbellata* of Linnaeus, Jacq. Amer. t. 22, which Linnaeus was at first inclined to reduce to *Tabernaemontana*. Jacquin, however, confirmed the genus *Echites*, and enlarged it with nine more species. Swartz discovered several others, so that with the addition of a few from the Cape and the East Indies, Willdenow enumerates twenty-two. These are not all perhaps correctly of the same natural genus, at least no one botanist has sufficiently compared them together, to determine this point; but on the other hand, their number is to be augmented by some fine non-descript plants of this genus from Sierra Leone.

The habit of *Echites* is climbing, and for the most part smooth; the leaves opposite, stalked, simple, undivided, entire, shining, with parallel veins interbranching at their extremities. Flowers generally axillary, clustered or umbellate, yellow, white or greenish, rarely red, almost universally, according to Jacquin, without scent. The shape and proportions of the corolla are very different in different species. The seed-vessels are remarkably long and slender. The plants abound with acrid milky juice. Being mostly natives of very hot climates, they have scarcely been introduced, with any success, even into our stoves, though many of them seem highly ornamental.

ECHIUM, supposed to be the *εχιος* of Dioscorides, and to have been so called from *εχis*, a *viper*, either because it cured the bite of that serpent, or because the seeds were shaped like its head. It is not improbable that the mucilaginous juices of this whole family of plants might act like olive oil in allaying the poison of a viper's bite, if applied to the wound. Viper's Bugloss. Linn Gen. 78. Schreb. 103. Willd. Sp. Pl. v. 1. 781. Sm. Fl. Brit. 221. Juss. 130. Gærtn. t. 67. Tournef. t. 54. Class and order, *Pentandria Monogynia.* Nat. Ord. *Asperifoliae*, Linn. *Borraginee*, Juss.

Gen. Ch. *Cal.* Perianth in five deep awl-shaped segments, erect, permanent. *Cor.* of one petal, bell-shaped; tube very short; limb erect, gradually dilated, five-cleft, obtuse; its segments more or less unequal; the two uppermost longest, the lower one smallest, acute, reflexed; orifice pervious. *Stam.* Filaments five, awl-shaped, about the length of the corolla, declining, unequal; anthers oblong, incumbent. *Pist.* Germens four; style thread-shaped, the length of the stamens; stigma obtuse, deeply cleft. *Peric.* none, the hardened calyx protecting the seeds. *Seeds* four, roundish, obliquely pointed.

Obf. In *E. levigatum, italicum,* and *grandiflorum,* the corolla is almost regular.

Eff. Ch. Seeds four, naked. Corolla of one petal, irregular, pervious, and naked. Stigma deeply cleft.

About 35 species of *Echium* are described by authors, Willdenow has 26, all natives of Europe or Africa. Their herbage is clothed with thick-set, rigid bristles, often originating from, or intermixed with, curiously formed callous tubercles, and in some of the more shrubby kinds, natives

of a warm climate, so fine and slender as to be almost silky. The flowers are commonly pink in the bud, blue when expanded, and thence not inconstant; in some they are always red, and in others white. *E. vulgare*, Engl. Bot. t. 181, common with us in dry chalky fields, or waste places, a well-known species, makes a gay appearance in the open country of Cambridgehire. *E. grandiflorum*, Andr. Repert. t. 20, native of the Cape of Good Hope, is perhaps the most handsome of all, being shrubby, with green brittle leaves, and large tubular scarlet flowers. This is with us a tender green-house plant, scarcely perfecting its seeds, and with difficulty increased by cuttings. In a conservatory it soon becomes straggling, naked, and unsightly.

E. giganteum, Linn. Suppl. 131, bears huge dense clusters of innumerable white flowers, and is sometimes seen in our green-houses. Mr. Masson brought it from Teneriffe. The three following new species, discovered in his tour to Greece, by the late Dr. Sibthorp, are as such defined in the Prod. Fl. Græc. v. 1. 125, though not perhaps to be met with in Greece itself.

E. pusillum, leaves linear-oblong, waved, tuberculated, brittle. Stem erect. Spikes lateral. Stamens prominent. Native of Sicily. Biennial.

E. bipidum, leaves linear-oblong, brittle, somewhat tuberculated. Stem erect, very hairy. Spikes lateral. Stamens prominent. Native of the country near Naples. Biennial.

E. diffusum, leaves linear-spatulate, tuberculated, brittle. Stem diffuse. Spikes terminal, solitary. Stamens concealed. Native of Crete. Annual. These two last have scarlet flowers.

ECHIUS, or ECKIUS, JOHN, in *Biography*, was born in Suabia in the year 1486. When he had attained to a proper age, he embraced the ecclesiastical life, and was appointed professor of theology in the university of Ingolstadt. He became celebrated for the part that he took in the public disputes, concerning the reformation, against Luther, Carlostadt, and Melancthon. He began his contests with Luther, on the subject of the propositions against indulgences, and was the means of exciting a great degree of attention to the controversies that were then dying away, but which he rekindled to the injury of the power assumed by the Roman pontiffs. He next challenged Carlostadt to public disputations on the subject of the freedom of the human will, and desired Luther himself to enter the lists with him, while he defended the authority and supremacy of the pope. The disputations were carried on at Leipzig, in the year 1519, before a numerous and highly respectable audience; they were conducted with great skill by all parties, but Echius, who had been the challenger, was generally deemed the vanquished party. His opponents, not satisfied with the mere victory, pursued the blow which they had given to the credit and authority of the pope. Echius could not bear the idea of being thrown in the back ground; his haughty spirit urged to seek for vengeance; but his zeal and fury were fatal to the cause which he espoused, and the doctrines of Luther obtained a rapid progress in Germany. Echius was next employed with Faber and others to draw up a confutation of the famous confession of Augsburg, which, by command of the emperor Charles V., was laid before the diet assembled at that city, and the unlimited submission of the protestants required to the doctrines and opinions contained in it. This confutation was very ably answered by Melancthon, in a work, entitled "The Defence of the Confession of Augsburg." During the rest of his life, Echius was a principal in all the disputes between the catholics and protestants, and was zealous as a writer, as well as a disputant, against the protestants. He died at Ingolstadt, in 1543, in his 58th year.

He was regarded as one of the most learned and able defenders of the pretensions and opinions of the church of Rome. He was author of two treatises, "On the Sacrifice of the Mass," "A Commentary on the Prophet Haggai," "Homilies," in four volumes, and a great number of controversial tracts. Moreni. Mosheim.

ECHO, in *Architecture*, is applied to certain vaults, and arches, most commonly of elliptical or parabolic figures; used to redouble sounds, and produce artificial echoes.

The method of making an artificial echo is taught by the J-uit Blaucan, in his *Echometria*, at the end of his book on the sphere.

Vitruvius tells us, that in divers parts of Greece and Italy there were brazen vessels, artfully arranged under the seats of the theatres, to render the sound of the actors' voices more clear, and make a kind of echo; by which means of the prodigious multitude of persons present at those spectacles, every body might hear with ease and pleasure.

ЕCHO, in *Geography*, a town of Spain, in the kingdom of Aragon; 13 miles N.N.W. of Jaca.

ЕCHO, in *Music*, pieces composed in imitation of echoes. Sometimes also the word echo stands for piano, intimating that the instrument, or voice, is to play, or sing, after a soft and sweet manner. Organs and harpichords have what they call an echo stop.

ЕCHO, (from the Greek *ηχος*, *found*, of the verb *ηχων*, *I found*), in *Natural Philosophy*, is a reflected sound; for sounds are reflected by bodies of certain configurations, somewhat like the reflection of light from polished surfaces; so that if a person, situated before one of those bodies, and at some distance from it, utters a word, he will, a short time after, hear the echo; that is, the repetition of that word, as if another person mocked him.

The ancient philosophers, who were entirely unacquainted with the true nature of the echo, ascribed it to several causes, which are too absurd to deserve any notice in this place. The poets supposed it to have been once a nymph, who pined into a found for love of Narcissus. The modern state of philosophical knowledge, established upon experience, and upon unerring calculation, shews, that sound, or that vibratory motion of the air which constitutes a sound, is reflected by hard solids, and, in certain cases, even by fluids. Thus, the sides of a hill, houses, rocks, banks of earth, the large trunks of trees, the surface of water, especially at the bottom of a well, and sometimes even the clouds, have been found capable of reflecting sounds. The configuration of the surface of these bodies is much more concerned in the production of the echo than their substance. A smooth surface reflects sounds much better than a rough one. A convex surface is a very bad reflector of sound; a flat one reflects very well; but a small degree of concavity, and especially when the sounding body is in the centre, or focus, of the concavity, renders that surface a much better reflector, and the echo is heard considerably louder. Thus, in an elliptical chamber, if the sounding body be placed in a focus of the ellipsis, that sound will be heard much louder by a person situated in the other focus of that ellipsis, than in any other part of the chamber. In this case, the effect is so powerful, that even when the middle part of the chamber is wanting; *viz.* when the two narrow opposite elliptical shells only exist, the sound expressed in one focus will be heard by a person situated in the other focus, but hardly at all by those who stand in the intermediate space.

Without attempting to explain the manner in which the vibrating air impinges upon, and is sent back by the reflecting body, which has not as yet been thoroughly investigated;

gated; the facts which have been ascertained are as follow:

If a person, standing before a high wall, a bank, a rock, &c. at a certain distance, and uttering a word, with a pretty strong voice, or, in short, producing a sound with a hammer, or stone, &c. forms a repetition of that word, or sound; he will find that the time elapsed between his uttering the word, and hearing the echo, is equal to that time which a sound is known to employ in going through an extension equal to twice the distance between him and the reflecting wall, or rock, &c.; for the vibratory motion of the air must proceed from the sounding person to the wall, or rock, and back again from the latter to the former. Now, sound is known to travel equally at the rate of 1142 feet *per* second; therefore, if the person that expresses the word, or any sound whatever, stands at the distance of 1142 feet from the echoing-wall, then two seconds of time must elapse between his uttering the sound and his hearing the echo of it. If the distance be equal to 4568 feet, then eight seconds of time must elapse between the uttering of the sound and the arrival of the echo, and so on. But the same original sound, and the repetition of it, *viz.* the echo, may be heard by other persons situated at different distances, both from the original sounding place, and from the reflecting body. The effect, however, will not be exactly alike; *viz.* those who are nearer to the reflecting body will hear the echo sooner than other persons; those who are farther off, will hear it later; and a situation is easily found, from which they will hear both the original sound and the echo at the same time; in which case they will perceive, as it were, one sound, but louder than they would without the echo.

But though several persons, in different situations, will hear the echo, or repetition, of the same sound; yet, in a particular direction, the echo may be heard much better than in any other direction. Now, if two straight lines be drawn from the centre, or middle, of the reflecting surface, one to the place from which the original sound proceeds, and the other in the above-mentioned best direction; those two lines will be found to make equal angles with, or to be equally inclined to, that surface. Hence, it appears, *that, in the reflection of sound, the angle of incidence is equal to the angle of refraction.* Therefore, if a person wishes to hear the echo of his own voice in the best manner possible, he must stand in a direction perpendicular to the reflecting surface. And this shews, that though sound proceeds from an original sounding body, or from a reflecting surface, in every direction; yet a greater quantity of it proceeds in some particular direction than in any other, which is probably owing to the original impulse being given to the air more forcibly in one direction than in any other, as also to the want of perfect freedom in the motion of the aerial fluid.

Several phenomena may be easily explained upon the above-mentioned property of sound. Thus, for instance, several reflecting surfaces frequently are so properly situated with respect to distance and direction, that a sound proceeding from a certain point is reflected by one surface first, then by a second, soon after by a third, and so forth; but by all in one direction; in which case, a multiple, or manifold, or tautological echo is produced; *viz.* the same word is heard repeated several times successively in the same tone and accent; and the expression of one *ha* will appear like a laughter; a musical instrument, properly played, will produce an agreeable repetition, as if many instruments of the same sort imitated each other.

According to the various distances from the speaker, a reflecting object will return the echo of several, or of

a few syllables, for all the syllables must be uttered before the echo of the first syllable reaches the ear, otherwise it will make a confusion. In a moderate way of speaking, about three and a half syllables are pronounced in one second, or seven syllables in two seconds. From the computation of short-hand writers, it appears, that a ready and rapid orator, in the English language, pronounces from 7000 to 7500 words in an hour; *viz.* about 120 words in a minute, or two words in each second. (Memoirs of Gibbon's Life.) Therefore, when an echo repeats seven syllables, the reflecting object is 1142 feet distant; for, since sound travels at the rate of 1142 feet *per* second; the distance from the speaker to the reflecting object, and again from the latter to the former, is twice 1142 feet. When the echo returns 14 syllables, the reflecting object must be 2284 feet distant, and so on. A famous echo is said to be in Woodstock park, near Oxford. It repeats 17 syllables in the day time, and 20 at night, when the air being somewhat denser, the sound does not travel quite so fast. (Dr. Plot's Nat. Hist. of Oxfordshire.) Another remarkable echo is said to be on the north side of Shipley church, in Suffex. In favourable circumstances it repeats, distinctly, 21 syllables. Harris's Len. Tech. Art. Echo.

Therefore, the farther the reflecting object is, the greater number of syllables the echo will repeat; but the sound will be enfeebled nearly in the same proportion, and, at last, the syllables cannot be heard distinctly. When the reflecting object is too near, the repetition of the sound arrives at the ear, whilst the perception of the original sound still continues, in which case, an indistinct resounding noise is heard. This effect may be frequently observed in empty rooms, passages, &c. especially, because in such places, several reflections from the walls to the hearer, as also from one wall to the other, and then to the hearer, clash with each other, and increase the indistinctness.

From what has been said above, it will be easily conceived, that, with respect to echoes, a vast variety of effects may be produced, by varying the form, the shape, the distance, and the number of reflecting surfaces; and hence we hear of various surprising echoes being met with at different places. At Rosneath, near Glasgow, in Scotland, there is an echo that repeats a tune played with a trumpet three times, completely and distinctly. (Birch's Hist. of the Royal Society, vol. 1. p. 137.) At the sepulchre of Metella, wife of Crassus, there was an echo which repeated a sentence five times. A tower is said to have existed at Cyzicus, where an echo repeated seven times. And there is an echo at Brussels which repeats fifteen times.

Barthius, in his Notes on Statius's Thebais, lib. vi. ver. 30, mentions a very extraordinary echo, and, perhaps, too extraordinary to be entirely believed; however, he assures the reader, that this echo not only repeated words seventeen times, but different from common echoes, where the repetition is not heard till some time after hearing the word spoke; in this, the person who speaks, or sings, is scarcely heard at all; but the repetition is heard very clearly, and always in surprising varieties; the echo seeming sometimes to approach nearer, and sometimes to be farther off. Sometimes the voice is heard very distinctly, and sometimes scarcely at all. One person hears only one voice, and another several; one hears the echo on the right, and the other on the left, &c.

Addison, and other travellers into Italy, mention an extraordinary echo in that country, at Smonetta palace, near Milan. It will return the sound of a pistol fifty-six times, even though the air be very foggy. The echo is heard behind the house, which has two wings; the pistol is discharged from

from a window in one of those wings; and the sound is returned from a dead wall in the other wing, and is heard from a window in the back-front. *Addit. Trav. edit. 1718, p. 32. Ph^o. Transf. N^o 280. p. 220.*

Several authors, who treat of echoes, have used a few peculiar words, which are not in common use, therefore we deem it proper to mention those words and their meanings in this place. That department of philosophy which treats of sound, is called *acoustics*; and this is divided into branches; one of which is called *catacoustics*, and treats of reflected sound, such as the echo, and the effects of the whispering domes, galleries, &c. which also depend upon the reflection of sound. (See *WHISPERING GALLERIES*.) The word *echo* has sometimes been used for denoting the place itself where the repetition of the sound is produced, or heard. In echoes, the sounding point, or place where the person stands who utters the words, &c. has been called the *centrum phonium*, and the object, rock, or place, that reflects the sound, has been called the *centrum phonocampitium*.

ECHO, in *Poetry*, denotes a kind of composition, wherein the last words or syllables of each verse, contain some meaning, which being repeated apart, answers to some question, or other matter contained in the verse.

Such is that famous echo of Erasmus, "Decem annos consumpsi in legendo Cicerone—one," *i. e. c. 01*, *afine*.

The first echo in verse, according to Pasquier, is that in the *Sylve* of Johannes Secundus; but Pasquier is mistaken; for the ancient Greek and Latin poets have wrote echoes. This Martial intimates plainly enough; when, laughing at some sorts of baubles, he says, there is nothing like them among his poems. "Nūquam Græcula quod recantat echo;" by which, on the one side, he shews there were Latin poets, in his time, who made echoes, and, on the other, that the invention came from the Greeks.

Antiphones, in his comedy entitled *Επιταμορταζουσι*, introduces Euripides in the person of Echo; and Callimachus, in the epigram, *Εχουσι το ποιημα το κυλικου*, seems to have intended a kind of echo.

There is a humorous specimen of this kind of poetry in *Hudibras*.

ECHOMETER, in *Musick*, a rule, or graduated scale divided into many parts for the purpose of measuring the length or duration of sounds, determining their different values, and even the ratios of their intervals. The word is derived from the Greek *εχος*, *sound*, and *μετρον*, *measure*. We shall not attempt to describe this machine, as it is never used, and there is no good echometer. Those who wish for more information on the subject, will find it in the *Mem. de l'Acad. des Ins.* for 1701. M. Sauveur suggested the invention.

ECHOS, *εχος*, a *sound*, in *Physic*. In Hippocrates, this frequently imports what the Latins call *sinuus aurium*, and the English a ringing of the ears; a symptom very frequent in acute distempers.

ECHPHYAS, from *εκ* and *φυα*, *I produce*, an exercise, or appendix, a word used by many of the ancient writers in medicine. The appendicula vermiformis is thus called by many authors.

ECHTERNACH, in *Geography*, a small town of France, in the department of Forêts, chief place of a canton, in the district of Billbourg, with a population of 2736 individuals. The canton contains 17 communes, and 10,477 inhabitants, on a territorial extent of 250 kilometres.

ECHTHELYNSIS, from *εχθηλυα*, of *θηλυα*, *feminine*, *I render effeminate*, a term used by the ancient physicians for a laxness, or flabby softness of the flesh of the legs, or any other part of the body. Some have also used the word to express a fault in bandages, when too loose.

ECHTRUS, in *Botany*, from *εχτρος*, *hateful*, or *inimical*. *Lourei.* *Cochinch.* 344. *Class* and order, *Polyadria Montegnia*. A genus founded by Loureiro, but which from his description is evidently nothing else than *Argemone mexicana* of Linnæus. He mentions it as common every where by the way sides in Bengal and the coast of Coromandel, and he applied the above name on account of the innumerable thorns with which the plant is armed.

ECIJA, or *EXIJA*, in *Geography*, a town of Spain, in the kingdom of Seville, delightfully situated on the banks of the Xenil, eight leagues from Cordova. It has pleasant walks, sering, like those of the great cities of Spain, for an evening resort. It contains 28,176 inhabitants, and has six parish churches, eight chapels, 20 convents, and six hospitals. The churches, built entirely of brick, are fitted up in the old taste, and crowded with pillars, which are loaded with preposterous ornaments, and covered with gold. The most extravagant of all is the church of "Nuestra Señora del Rosario," in the convent of the Dominicans, which may serve as a model for the perfection of vitiated taste. The "Plaza Mayor" is a fine object, very spacious and much to be admired for its balconies, occupying the whole front of the houses. The rent of land in the vicinity of this town is high, being commonly two bushels of wheat and one of barley, for every bushel of their feed; or if the rent be paid in money by the occupiers, it is not delivered immediately to the land-owner, but as under-tenants to rich land-jobbers, from whom no moderation can be expected. Inclosed farms let at a much higher rate than those that are open, because the latter are liable to be fed by the Merino sheep; whereas, if they should enter the former, one-fifth of the number trespassing would be forfeited. Hence arise various contentions, which frequently terminate in murders. Wool and hemp are the chief riches of this place. N. lat. 37° 53'. Long. 11° 43' E. of Peak of Teneriffe. *Townsend's Spain*, vol. ii.

ECKARD, in *Biography*, a harpichord-player of great abilities, though little known, except in private, by counoisseurs. There are many great German musicians, dispersed throughout Europe, whose merit is little known in England, or even in their native land; among these is Eckard, who has been 50 years at Paris. We never heard him perform; but his compositions manifest great skill, refinement, and knowledge of his instrument. He is said, but erroneously, to have been one of the first, who, after the manner of the celebrated Alberti, introduced in France a perpetual base in batteries of femiquavers; but Jerig, Edelman, and Balbastre, long before Eckard arrived at Paris, had tired all ears with the abuse of this easy expedient.

The treble part of Alberti's sonatas is so elegant, and so much the melody of songs of the first class, as to make ample amends for the want of variety in the base.

This admirable dilettante (Alberti) who sung as well as played in an exquisite taste, finding that the tones of the harpichord were too transient to sustain vocal passages, and to interest an audience through a whole movement, has given a spirited base, which keeps the tone alive, without calling off the attention from the treble, or disturbing that unity of melody, which Rousseau so strongly recommends, and we believe, in a great measure, formed his precepts upon the examples. Alberti was a Venetian gentleman, extremely admired for his compositions and performance, during the time that Rousseau was resident in that city as secretary to the French ambassador. Now, M. Eckard was in want of no such model; he had resources of his own, which, in extempore playing, could amuse and charm the most fastidious judges for several hours together; and in the lessons which we have seen of his composition, there is an elegance of style

style built upon such sound principles of harmony and modulation as few have surpassed. His variations to the Minuet d'Exaudit, or, as we call it, Marshal Saxe's minuet, are in the highest degree, ingenious, elegant, and fanciful.

ECKARDTSBERGA, in *Geography*, a small town of the kingdom of Saxony, in the circle of Thuringia, with 1200 inhabitants and some manufactures, chiefly of worked stockings and alum works. Of the ancient castle Eckardtsburg, built in the year 998 by margrave Eckard, there are but two towers left, which are kept in repair, and serve as corn magazines.

ECKEREN, a small town of France, in the department of the two Nethes, chief place of a canton, in the district of Anvers, or Antwerp, 27 miles S.W. of Breda, 24 miles S.E. of Bergopzoom, and six miles N. of Antwerp, with a population of 2826 individuals. It is remarkable for the battle which was fought in its neighbourhood in 1703, between the allies and the French. The canton has an extent of 170 kilometres, and contains 10 communes, with 10,764 inhabitants.

ECKERNFORDE, or ECKELNFÖRDE, a small but neat town of Denmark, in the duchy of Sleswick, district of Hutten, situated on the Baltic, with a commodious harbour, 15 miles S.E. of Sleswick. It is remarkable for being the place where the famous count St. Germain, of life elixir notoriety, ended his days.

ECKERO, a small island of Sweden, between the Baltic and the gulf of Finland, W. of the island of Aland.

ECLAMPRIA, or ECLAMPIS, in *Medicine*, is nearly synonymous with *Epilepsy*, which see. The difference between the two diseases, as stated by Sauvages, appears to be altogether hypothetical, and not to be ascertained in practice. Eclampsia, he says, differs from epilepsy, in being an acute, febrile disease, sometimes remittent, or absolutely unceasing, *i. e.* not recurring by distant paroxysms. Thus, under the head of eclampsia, are arranged the convulsions of puerperal women, those occasioned by wounds, by inanition, plethora, dentition, severe pain, fever, &c. Yet under the genus epilepsy, wounds, fever, severe pain, plethora, &c. are also mentioned as causes of the disease, and as serving to discriminate the different species. As the distinction, therefore, is not less useless in a practical view, than it is fanciful in nosology, we shall refer the whole to the article EPILEPSY.

The word eclampsia, probably from *εκλαμψω, effulgeo, I shine*, is used by Hippocrates and Galen under different acceptations. The most obvious origin of its application to epilepsy, appears to arise from the sparkings and flashes of light, which often precede the epileptic convulsion, in many individuals. But the two physicians of antiquity, just named, have also used the word to denote the highest degree of the paroxysm of fever, immediately preceding the crisis, when the heat and violence of the symptoms are at the greatest height.

ECLANUM, in *Ancient Geography*, a town of Italy, called *Æclanum* by Ptolemy. It is situated in the Campania, and now known under the name of "The Colony."

ECLARON, in *Geography*, a small town of France, in the department of the Marne, situated on the river Blaise, 15 miles N.W. of Joinville.

ELECTICS, ELECTICI, a name given to some ancient philosophers, who, without attaching themselves to any particular sect, formed the flattering design of selecting, from the doctrines of all former philosophers, such opinions as seemed to approach nearest the truth, and combining them into one system. But in executing this plan, they only piled up a shapeless and incoherent mass, "rudis indi-

gestaque moles," not unlike that chaos, which they admitted as an essential article in the science of nature. They attempted, however, but without success, to adorn and enrich the system with fancies of their own.

Hence their denomination: which, in the original Greek, signifies, *that may be chosen, or, that chooses*; of the verb, *ελεγω, I choose*.

Laertius notes, that they were also, for the same reason, denominated *analogetici*; but that they call themselves *philalethes, i. e.* lovers of truth.

The chief, or founder of the electici, was one Potamo, of Alexandria, who lived under Augustus and Tiberius, according to Suidas; but it is more probable, from the account of Laertius, that he commenced his undertaking about the close of the second century. This Platonist, weary of doubting of all things with the Sceptics and Pyrrhonians, formed the eclectic sect; which *Vossius* calls the eclectic.

Towards the close of the second century a sect arose in the Christian church under the denomination of Electics, or modern Platonics. They professed to make truth the only object of their inquiry, and to be ready to adopt, from all the different systems and sects, such tenets as they thought agreeable to it. However, they preferred Plato to the other philosophers, and looked upon his opinions concerning God, the human soul, and things invisible, as conformable to the spirit and genius of the Christian doctrine. One of the principal patrons of this system was Ammonius Saccas, who, about the beginning of the third century, laid the foundation of that sect, afterwards distinguished by the name of the new Platonics, in the Alexandrian school. This philosopher was born of Christian parents, and educated in the Christian faith, and probably never deserted the outward profession of this religion, though Porphyry maintains, in opposition to the testimony of Eusebius, that in maturer life he became a pagan; and Fabricius, who is followed by Dr. Lardner, alleges that there were two persons of the same name, the one a heathen philosopher, and the other a Christian writer. Those, who are desirous of acquainting themselves with the grounds of these opposite opinions, may consult Fabricius's *Bibl. Græc. lib. iv. cap. 26. p. 159.* Lardner's *Collection of Jewish and Heathen Testimonies, vol. iii. p. 195, &c.* and Mosheim, *De Rebus Christianorum ante Const. Mag. p. 281, &c.*

It was evidently the design of Ammonius to reconcile and unite all sects, philosophical and religious, and to inculcate a doctrine that should comprehend all, the Christians not excepted, in one common profession. For this purpose he maintained, that the great principles of all philosophical and religious truth were to be found, equally in all sects; that they differed from each other only in their method of expressing them, and in some opinions of little or no importance; and that, by a proper interpretation of their respective sentiments, they might easily be united into one body. Accordingly, all the Gentile religions, and even the Christian, were to be illustrated and explained by the principles of this universal philosophy; and the fables of the priests were to be removed from paganism, and the comments and interpretations of the disciples of Jesus from Christianity. In conformity to this plan he insisted, that all the religious systems of all nations should be restored to their original purity, and reduced to their primitive standard, *viz.* the ancient philosophy of the East, preserved uncorrupted by Plato; and he affirmed that this project was agreeable to the intentions of Jesus Christ, whose sole view, in descending upon earth, was to set bounds to the reigning superstition, to remove the errors that had blended themselves with the religions of all nations, but not to abolish

the ancient logy from which they were derived. He therefore adopted the doctrines which were received in Egypt concerning the universe, and the deity, considered as constituting one great *subole*, concerning the eternity of the world, the nature of souls, the empire of Providence, and the government of the world by demons. He also established a system of moral discipline, which allowed the people in general to live according to the laws of their country, and the dictates of nature, but required the wise to exalt their minds by contemplation, and to mortify the body, so that they might be capable of enjoying the presence and assistance of the demons, and of ascending after death to the presence of the Supreme Parent. In order to reconcile the popular religions, and particularly the Chaldean, with this new system, he made the whole history of the heathen gods an allegory, maintaining that they were only celestial ministers, intitled to an interior kind of worship; and he acknowledged that Jesus Christ was an excellent man, and the friend of God, but alleged that it was not his design entirely to abolish the worship of demons, and that his only intention was to purify the ancient religion. This system, so plausible in its first rise, but so comprehensive and complying in its progress, has been the source of innumerable errors and corruptions in the Christian church. At its first establishment it is said to have had the approbation of Athenagoras, Pantenus, and Clemens the Alexandrian, and of all who had the care of the public school belonging to the Christians at Alexandria. It was afterwards adopted by Longinus, the celebrated author of the Treatise on the Sublime, Plotinus, who continued the school of Ammonius, and completed the eclectic system, Herennius, Origenes, a pagan and a different person from Origen, the celebrated Christian teacher, Amelius, a Tuscan, Porphyry, an inveterate enemy to Christianity, who succeeded Plotinus and taught his doctrines, Jamblichus the disciple of Porphyry, Sopater, Edebius, Eulathus, Eusebius of Mindus in Caria, Maximus of Ephesus, Priscus of Theopontium, who accompanied the emperor Julian to Persia, Chrysanthius, the master of Julian, appointed by him high priest of Lydia, Julian the Apollate, Enoapius, a pupil of Chrysanthius, Hierocles, and many others, both Pagans and Christians.

Such as we have enumerated were the principal promoters of the Eclectic philosophy in Alexandria, and in various parts of Asia. After Greece became subject to Rome, its philosophers were dispersed; but by the favour of the Roman emperors, particularly Adrian and Marcus Aurelius Antoninus, Athens, the ancient seat of wisdom, recovered, in some degree, its former honour. Adrian founded a library, and Aurelius erected magnificent schools, and established professors in rhetoric, and in the principal sects of philosophy. These schools were liberally endowed, and Athens was again distinguished by a numerous train of philosophers and scholars. These Athenian schools, though they suffered great injury, during the incursions of the Goths, at the close of the 4th century, survived that hazardous period, and continued to flourish till after the time of Justinian. It was not till the reign of Julian that the Alexandrian philosophy was publicly professed at Athens. After Chrysanthius, already mentioned, who was appointed preceptor in Athens by Julian, the next professor of this system was Plutarch, the son of Nestorius. He died about the year 435, and left the charge of his school to Syrian, an Alexandrian. Among the pupils of Syrian, his chief favourite was Proclus, and he was allowed to share with him the honours and profits of the Platonic chair. (See PROCLUS.) Upon the death of Proclus in the year 485, the eclectic school at Athens was continued by Marinus, a native of

Sicem in Palestine, and a convert from the Samaritan to the Gentile religion. From him it was transferred to Ildorus, and by Ildorus, on his removal to Alexandria, it was committed to Zenodotus, a pupil of Proclus. The success of the Platonic or Eclectic school in Alexandria terminated in Damascius, a native of Syria. Hycatia, a celebrated female, belonged also to this school, and maintained its honour. (See HYPATIA.) Besides the philosophers of the Alexandrian or Eclectic sect, who have been enumerated, and others of interior note, there were many persons, who, though not philosophers by profession, espoused the doctrines of Platonism, as they were now modelled in this school. Among these there were several celebrated writers; particularly Macrobius, and Ammianus Marcellinus.

The Eclectic sect, as we have already seen, took its rise among the Egyptians, a people peculiarly addicted to superstitution, among whom the art of divination is said to have originated. It was formed in Alexandria, a city colonized from many different nations, whose inhabitants brought with them their respective tenets both in religion and philosophy. From an attentive comparison of various circumstances, which we cannot recite in this place, it would appear, that the Eclectic method of philosophizing began at a period prior to the time of Christ. The dissensions produced by diversity of opinions in the Alexandrian schools, induced many to wish for a general coalition of sects. Ptolemy, as we have seen, first formed this project, and it was carried into execution by Ammonius and his followers. The philosophy of Plato, already united with that of Pythagoras, was made the basis of this new system; whence the sect was considered as a Platonic school, and its followers have been commonly distinguished by the appellation of the later Platonists. With the doctrines of Plato, they attempted to blend those of Aristotle. The Stoic system was also in the Eclectic school accommodated to the Platonic; and the moral writings of the followers of Zeno were explained upon the principles of Plato. The only sect with which the Alexandrian sect could not agree, was that of Epicurus, whose mechanical principles of nature were contrary to the fundamental doctrines of Platonism.

The Platonic sect, we may observe, had leaned, from its first institution, towards enthusiasm. That part of their system, which these later Platonists had borrowed from the oriental philosophy, was wonderfully calculated to cherish the flights of a luxuriant fancy. But in order to mark more precisely some of the more striking features of the Eclectic sect, we may direct our attention to the arts, which the leaders of this sect employed to obstruct the progress of the Christian religion. By combining into one system all the important tenets, both theological and philosophical, which were at that time received, either in the Pagan or the Christian schools, they hoped to confirm the Heathens in their attachment to their old superstitions, and to reconcile the Christians to Paganism. With this view they endeavoured to conceal the absurdities of the ancient religion, by casting over its fables the veil of allegory, and thus representing them as found upon important truths. The numerous train of heathen divinities they represented as emanations from the Supreme Deity, through whom he himself was worshipped. They attempted to incorporate with their own dogmas several of the peculiar doctrines received among Christians, and on many occasions imitated the language of the Christian fathers. In order to counteract the credit which Christianity derived from the exalted character of its founder, and the purity of manners that distinguished his followers, these philosophers inculcated and practised rigour

rous abstinence, and passed whole days and nights in contemplation and devotion. In order to subvert or diminish the authority which the Christian religion derived from miracles, they pretended to a power of performing supernatural operations, and maintained, that the miracles of Christ were wrought by the same magical, or theurgic, powers which they themselves possessed. Moreover, for supporting the credit of Paganism against that of Christianity, they obtruded upon the world many spurious books, under the names of Hermes, Orpheus, and other illustrious ancients.

The Eclectic sect, thus raised upon the foundations of superstition, enthusiasm, and imposture, was the occasion of much confusion and mischief both to the Christian religion and to philosophy. In the infancy of the Alexandrian school, many Christians were so far deluded by the pretensions of this sect, as to imagine that a coalition might be advantageously formed between its system and that of Christianity. The consequence, however, was, that Pagan ideas and opinions were gradually blended with the pure and simple doctrine of the gospel; the fanatical philosophy of Ammonius corrupted the pure religion of Christ; and his church became a field of contention and a nursery of error. A coalition of systems was no less injurious to philosophy. For a further delineation of the Eclectic doctrine in metaphysics, theology, and morals, we shall refer to the biographical articles *Plotinus*, *Jamblicus*, and *Porphyry*. See also *PLATONISM* and *ALEXANDRIA*. And for a more diffuse detail, we refer to Brucker's *Hist. of Philos.* by Enfield, vol. ii. and Mosheim's *Ecl. Hist.* vol. i.

ECLECTICS were also a certain set of physicians among the ancients, of whom Archigenes, under Trajan, was the chief, who selected from the opinions of all the other sects, that which appeared to them best, and most rational; hence they were called eclectics, and their prescriptions *medicina eclectica*.

ECELEGMA, or ECLIGMA, *Εκλεγμα*, or *Eclectos*, in *Medicine*, a pectoral remedy, of the consistence of a thick syrup; called, also, *loboch*, *linxus*, and *lambatio*. The word is Greek, formed of *εκ*, and *ειλεγμα*, *to lick*, because the patient is to take it by licking it off the end of a liquorice stick dip't therein; in order that, being taken thus by little and little, it may remain the longer in the passage, and moisten the breast the better.

There are ecelegmas of the syrups of poppy, others of lentils, others of squills, &c. Their intention is to heal or ease the lungs, in coughs, peripneumonies, &c. They are usually composed of oils, incorporated with syrups.

ECLIPSAEON, in *Astronomy*, is an instrument invented by Mr. Ferguson for exhibiting the time, quantity, duration, and progress of solar eclipses, at all parts of the earth. This machine consists of a terrestrial globe, A, (*Plate X. Astronomy, fig. 74*) turned, by a winch, M, round its axis B, inclining $23\frac{1}{2}^{\circ}$, and carrying an index round the hour-circle D; a circular plate E, on which the months and days of the year are inserted, and which supports the globe in such a manner, that when the given day of the month is turned to the annual index G, the axis has the same position with the earth's axis at that time; a crooked wire F, which points to the middle of the earth's enlightened disc, and shews to what place of the earth the sun is vertical at any given time; a penumbra, or thin circular plate of brass I, divided into 12 digits, by 12 concentric circles, and so proportioned to the size of the globe, that its shadow, formed by the sun, or a candle, placed at a convenient distance, with its rays transmitted through a convex lens, to make them fall parallel on the globe, may cover those parts of the globe, which the shadow and penumbra of the moon

cover on the earth; an upright frame HHHH, on the sides of which are scales of the moon's latitude, with two sliders K and K fitted to them by means of which the centre of the penumbra may be always adjusted to the moon's latitude; a solar horizon C, dividing the enlightened from the darkened hemisphere, and shewing the places where the general eclipse begins and ends with the rising or setting sun; and a handle M, which turns the globe round its axis by wheel work, and moves the penumbra across the frames by threads over the pulleys L, L, L, with a velocity duly proportioned to that of the moon's shadow over the earth, as the earth turns round its axis.

If the moon's latitude* at any conjunction exceeds the number of divisions on the scales, there can be no eclipse; if not, the sun will be eclipsed to some parts of the earth; the appearances of which may be represented by the machine, either with the light of the sun, or of a candle. For this purpose, let the indexes of the sliders K, K, point to the moon's latitude, the plate E be turned till the day of the given new moon comes to G, and the penumbra be moved till its centre comes to the perpendicular thread in the middle of the frame, which thread represents the axis of the ecliptic; then turn the handle till the meridian of London on the globe comes under the point of the wire F, and turn the hour circle D, till XII at noon comes to its index; and turn the handle till the hour index points to the time of new moon in the circle D, and then screw fast the collar N. Lastly, elevate the machine, till the sun shines through the sight-holes in the small upright plates O, O, on the pedestal; or, place a candle before the machine, at the distance of about four yards, so that the shadow of the intersection of the cross thread in the middle of the frame may fall precisely on that part of the globe to which the wire F points; with a pair of compasses take the distance between the centre of the penumbra, and the intersection of the threads, and set the candle higher or lower, according to that distance; and place a large convex lens between the machine and candle, so that the candle may be in the focus of the lens; and thus the machine is rectified for use.

Let the candle be turned backward till the penumbra almost touches the side HF of the frame, and then, turning it forward, the following phenomena may be observed. 1. Where the eastern edge of the shadow of the penumbral plate, I, first touches the globe at the solar horizon, those who inhabit the corresponding part of the earth see the eclipse begin on the uppermost edge of the sun, just at the time of its rising. 2. In that place where the penumbra's centre first touches the globe, the inhabitants have the sun rising upon them centrally eclipsed. 3. When the whole penumbra just falls upon the globe, its western edge at the solar horizon touches and leaves the place where the eclipse ends at sun-rise on his lowermost edge. 4. By continued turning, the cross lines in the centre of the penumbra will go over all those places on the globe where the sun is centrally eclipsed. 5. When the eastern edge of the shadow touches any place of the globe, the eclipse begins there; when the vertical line in the penumbra comes to any place, then is the greatest obscuration at that place; and when the western edge of the penumbra leaves the place, the eclipse ends there, and the times are shewn on the hour-circle; and from the beginning to the end, the shadows of the concentric penumbral circles shew the number of digits eclipsed at all the intermediate times. 6. When the eastern edge of the penumbra leaves the globe at the solar horizon C, the inhabitants see the sun beginning to be eclipsed on its lowermost edge at its setting. 7. Where the penumbra's centre leaves the globe, the inhabitants see the

sun centrally eclipsed; and lastly, where the penumbra is wholly departing from the globe, the inhabitants see the eclipse ending on the uppermost part of the sun's edge, at the time of its disappearing in the horizon.

This instrument will likewise serve for exhibiting the times of sun-rising and setting, and of morning and evening twilight, as well as the places to which the sun's vertical on any day, by setting the day on the plate E to the index G, turning the handle till the meridian of the place comes under the point of the crooked wire F, and bringing XII on the hour-circle D to the index: then if the globe be turned, till the place touches the eastern edge of the horizon C, the index shews the time of sun-setting; and when the place comes out from below the other edge of C, the index shews the time when evening twilight ends; and morning twilight and sun-rising are shewn in the same manner on the other side of the globe. And the places under the point of the wire F are those to which the sun passes vertically on that day. Ferguson's *Astronomy*, p. 298, &c. 4to. edit. or *Phil. Trans.* vol. xviii. p. 520.

ECLIPSE, in *Astronomy*, the disappearance of a heavenly body, caused either by the interposition of an opaque body between it and the observer, or by the loss of the reflected light of the sun.

To the first class belong solar eclipses, and occultations of the fixed stars by the moon or planets; to the second, lunar eclipses, and eclipses of the satellites of Jupiter.

The phenomena of eclipses, considered with a view to illustrate the general principles of the science, are very unimportant: they are merely accidental occurrences, totally unconnected with any theory, and add but little to our knowledge of the great mechanism of nature. But they are of considerable practical utility: they serve to correct and increase the perfection of our solar and lunar tables; and they are highly useful to geography, because they afford a sure and accurate method of determining the relative situation of the distant parts of the globe.

Such is the state of the science of astronomy at present, that it is not by being able previously to announce all the circumstances that will attend these phenomena, that the purpose of general utility is promoted; but the observing them with accuracy when they do occur, and applying the results correctly to future investigation. But as the public will take some interest in these predictions, and consider them as a kind of test of the proficiency of the science, the doctrine of eclipses continues to form a very important part of every treatise of astronomy. It is impossible to produce a stronger instance of the ultimate triumph of truth over error and superstition, than the view we are at present permitted to take of the subject of our present investigation.

The time has not always been when an eclipse was considered only as a subject of calculation for an astronomer, and an object but of slight curiosity even to the public. It was an event that once possessed a great share in the general interests of the moral world. It would be but a melancholy task to dwell on the history of ignorance and superstition. If there are few instances in which it has been more profound than in the opinions that have been entertained relative to eclipses, it must be allowed that no superstition was ever more excusable in its origin, or more innocent in its effects.

Astronomers more especially should regard these errors with indulgence, since the science is indebted to them for its earliest foundation. In all the early nations of antiquity, the science seems originally to have been cultivated only with a view of predicting these phenomena.

That knowledge of cause and effect, which teaches us to

assign the various occurrences of the moral and physical world to their appropriate causes, can only be obtained by the long and refined civilization of many successive ages.

Should we be surpris'd then to find that, in the infant state of the world, moral and physical events should have been improperly associated together? Rather let us admire the successful struggles that the human race have gradually made to emancipate themselves from error; and, by comparing the little that remains with that which once existed, indulge the hope that even that little will in time yield to the superior power of truth and reason.

Astronomy bears the same relation to astrology that chemistry does to alchemy: it is the wife offspring of a foolish parent. The early astronomers, like the early alchemists, in common with the rest of mankind, first deceived themselves; and interested motives afterwards induced them to connive at the deception of others.

To what degree of accuracy the ancients arrived in the art of predicting eclipses, is a question on which writers materially differ. Bailly, in all his astronomical writings, endeavours to prove that the early astronomers were in possession of accurate methods of calculating eclipses, and that these were derived from antediluvian tradition. This theory supposes that the world once existed in a state very different from the present; that it was nearly destroyed by some great and sudden calamity, in which almost the whole human race were involved; that only a few individuals escaped this dreadful catastrophe, who, thus reduced to a desolate state of existence, had to invent again all the arts of life. But he supposes, that in this apparent state of barbarism, traces are still to be found of the former state of civilization and knowledge. This theory is surely little better than a dream: we can scarcely suppose that in a moment of such general conflagration, the object of general subsistence should be to save a table of logarithms, or a compendious method of calculating an eclipse; besides, the whole system is founded, or at least supported, on a mistake relative to the present and former state of the Indian astronomy.

The following extract from Bailly's ancient astronomy, contrasted with the more careful and recent investigations of our own countrymen in India, will be sufficient to convince the reader on what a slight foundation this visionary theory rests for support.

"That which does most honour to the astronomy of the Indians, is their method of calculating eclipses. They perform this with great celerity and precision.

"The Brahmins seem to be machines mounted to calculate eclipses. Their rules are in verse, which they recite during the computation. They make use of cowries, a species of shell, which is used for money in India.

"This method of calculation has the advantage of being easy and expeditious; but the steps cannot be retraced: they are destroyed as the computation advances; and if an error first occur, the whole must be recommenced.

"Their proceedings seem to possess an extraordinary simplicity. The theory of the moon, the most complicated of our modern theories, does not with them require a tedious or embarrassing calculation. They find the diameters of the sun and moon by a very simple process, which we shall insert here as a curious example of these extraordinary rules. They assume the apparent diurnal motion of the moon, and divide it by 25. The result of the division, multiplied by 60 and divided by 25, gives the actual diameter of the moon. They calculate the diameter of the sun, by multiplying its real diurnal motion by 5, and dividing it by 9. It is impossible to avoid thinking that these tables or rules of the Brahmins belong to some learned theory,

theory, the principles of which are now concealed under a blind routine, which by considerable skill is at present rendered simple and easy.

“What is most astonishing is, that these tables of the Brahmans are perhaps of 5000 or 6000 years antiquity.

“Notwithstanding those who occupy themselves with astronomy, that is to say, the Brahmans, may have a correct notion of the new and full moon, the people, plunged into the most profound ignorance, still explain its phases their own way. They pretend that the moon is filled with ambrosia, and that the gods take their repasts from it, which is the cause of the diminution of its light. The regularity of the return of these phases announces that the provision is carefully renewed, and that the gods have very regular appetites.”

Mr. Davis, to whom we are indebted for a most intelligent and accurate account of the method by which the Hindu astronomers calculate eclipses, is of opinion that the Hindu science is as well known now as it ever was among them, though perhaps not so generally, by reason of the little encouragement men of science meet with, compared with what they formerly did, under their native princes. The same writer is of opinion, that the Pandits, learned in the Jyotish Sashtra, have truer notions of the form of the earth, and of the economy of the universe, than are ascribed to the Hindus in general; and that they must reject the ridiculous belief of the common Brahmans, that eclipses are occasioned by the intervention of the monster Rahu, with many other particulars equally unscientific and absurd. But as this belief is founded on implicit and positive declarations, contained in the Vedas and Puranas, the divine authority of which writings no devout Hindu can dispute, the astronomers have, some of them, cautiously explained such passages in those writings as disagree with the principles of their own science; and where reconciliation was impossible, have apologized as well as they could for propositions necessarily established in the practice of it, by observing that certain things, as stated in other Sastras, “might have been so formerly, and may be so still; but for astronomical purposes, astronomical rules must be followed.” Others, with a bolder spirit, attacked and refuted unphilosophical opinions. Bhascara argues, that it is more reasonable to suppose the earth self-balanced in infinite space, than that it should be supported by a series of animals, with nothing assignable for the last to rest upon. And Nerasinha, in his commentary, shews that by Rahu and Cetu, the head and tail of the monster, in the sense they generally bear, could only be meant the position of the moon’s nodes, and the quantity of her latitude, on which eclipses do certainly depend: but he does not therefore deny the reality of Rahu and Cetu; on the contrary, he says, that their actual existence and presence in eclipses ought to be believed, and may be maintained as an article of faith, without any prejudice to astronomy.

Thus it appears, that though the history of eclipses, like that of every part of the astronomy of the ancients, is involved in considerable obscurity, there is no reason to suppose it of antediluvian origin. The first eclipses, particularly of the sun, if total or considerable, must have excited extreme terror; and many ages must have passed away, before mankind could have been led to the discovery of their cause. The nature of the solar eclipse was probably the first that was understood, and that of the moon a subsequent discovery. To watch these phenomena, to discover the cause why they did not happen every month, and to mark down the circumstances under which they appeared, in order to reduce them to some form for future prediction, seems to

have been the only object of the astronomy of many of the early nations. The Chaldeans are said to have watched the heavens without ceasing; and their astronomers relieved each other, like sentinels, that no eclipses might escape them. In following this system, they became acquainted with certain useful periods, which in time brought about a repetition of the same phenomena: but further than this their knowledge never extended. Of the nice modifications which were required to correct this method, they seem to have been entirely ignorant. Solar eclipses seem to have been neglected, as too abstruse and irregular to have been reduced to any given law; and we find that Hipparchus, who assiduously collected the most ancient eclipses he could depend on, from the records of the Chaldean astronomy, was obliged to confine himself to lunar eclipses alone. This circumstance would lead us to suspect that there was but little reliance to be placed on the supposed predictions of ancient eclipses, which are said to have happened on remarkable occasions. The prediction of an eclipse by Thales (said to have taken place during a battle between the Lydians and the Medes) was most probably made long after the event. Perhaps we might carry our scepticism still farther, and doubt the existence of any eclipse at all: for when once great events were supposed to accompany eclipses, tradition would easily supply eclipses to accompany great events.

To understand the doctrine of eclipses, it is necessary to have a clear idea of the nature of the solar and lunar orbit, and of their apparent points of intersection, called the *nodes*. Though the moon’s orbit is infinitely nearer to us than the apparent solar orbit, yet its projection, or perspective representation of it on the great concave surface of the heavens, is a great circle of the sphere. If the lunar orbit was in the same plane as the solar orbit, it would have the same representative circle in the heavens, namely, the ecliptic; but the lunar orbit is inclined to the apparent orbit of the sun, in an angle of about 5° ; and though these orbits can really have no common points of contact, from their great distance from each other, yet the great circles which represent them in the heavens intersect each other in two opposite points, which are called the *nodes*.

New moon is defined to be that situation of the moon, when it has exactly the same longitude as the sun. This phase may take place at any part of the lunar orbit, either in the nodes or at any distance from them. In the first case, she will appear to pass over the disc of the sun; but if at the conjunction, or time of new moon, she should be at some distance from the node, as is usually the case, she will be invisible to us, being wholly enveloped in the rays of the sun; but were she visible at this time, we should see her directly under or over the sun; and the distance would be the greater, the farther the moon was from the node: but this distance never could much exceed 5° , or the angle expressing the inclination of the two orbits.

Full moon is that position of the moon, when her longitude differs 12 signs, or exactly half a circle from that of the sun; that is, its longitude is the same as the longitude of the centre of the earth’s shadow, if we suppose it extended till it meet the ecliptic. This phase of the moon may take place likewise in any part of her orbit; she may therefore be above, below, or in the centre of the earth’s shadow; in which latter case, being deprived of the light of the sun by the interposition of the earth, she will be eclipsed. From this general illustration, we shall now proceed to investigate these phenomena more minutely, beginning with lunar eclipses, which are much the easiest to understand. The calculations that are incident to solar eclipses do not involve any of the higher branches of mathematics: the principles

ECLIPSE.

on which they depend are very simple, but the difficulty arises from the great number of considerations which arise, and which cause no small perplexity even to the experienced astronomer.

Of an Eclipse of the Moon.

The earth being an opaque body enlightened by the sun, it necessarily projects a shadow into the regions of space in a contrary direction; when it so happens that the moon, in the course of her revolution about the earth, falls into this shadow, she loses the sun's light, by which alone she is visible, and appears to us *eclipsed*.

Let us suppose two straight lines drawn from the opposite parts of the solar disc, tangents to the surface of the earth, as *AB, ab*, (fig. 75.) these lines will represent the limits of the shadow, and as the sun is much larger than the earth, these lines will meet at a point, and cross each other behind the earth, and the shadow will thus take the form of a circular cone. When the moon enters this shadow, and a part of its disc is still enlightened by the sun, this part is not terminated by a straight line; it has the form of a luminous crescent, the concave part being turned towards the shade. The same circumstance happens when the moon begins to quit the shadow.

When the moon approaches the terrestrial shadow, she does not lose her light suddenly, but it gradually becomes more and more faint, till the obscurity arrives at its greatest intensity.

To comprehend this phenomenon, we have only to attend to the figure, and observe that an opaque body may be so placed between an object and the sun, as only to intercept a part of his light (suppose the object at *M*), it will then be less illuminated than if it received the whole of the light, but more so than if it was placed at *m* in total obscurity. This intermediate state, comprehended in the angular space *EB C* on one side the *umbra*, and *F B C* on the other, is called the *penumbra*. This is the effect which is observed to take place on the entrance of the moon into the terrestrial shadow.

To find the limits of this penumbra, let two lines be drawn, as *A e, a E*, touching the surfaces of the sun and the earth, so as to cross at a point *e* between them, the angles *E B C, e b c*, will determine the space occupied by the penumbra, for at a point situated without this space, the whole disc of the sun will be visible, but to a point *M* within it, only a part *A l* of the sun's disc will be visible, and the visible portion will diminish from the line *E B* to the line *C B*, when it will entirely disappear; consequently the penumbra will gradually increase from its first limit *E B* till its second *B C*, when it will be united with the umbra.

When the moon enters completely into the shadow of the earth, we do not quite lose sight of it; its surface is still faintly illuminated with a reddish light, something similar to that reflected by clouds after the setting of the sun; this arises from the solar rays that have been refracted by our atmosphere, and afterwards inflected behind the earth. For those rays which are not enough refracted to reach the surface of the earth, continue their course through the atmosphere, and if not entirely absorbed by it, are inflected towards a point, in the same manner as by a convex lens. The light thus reflected behind the earth is very considerable; considering only one luminous point of the solar disc, it can only project one ray to every point into the surrounding space, but by the medium of the terrestrial atmosphere, a cone of luminous points is collected behind the earth, and an object placed in the focus of this cone would be more strongly illuminated than by the direct light of the sun. Every point of the

sun producing a similar effect, the length and extension of the terrestrial shadow are much diminished, and if the atmosphere did not absorb a very great proportion of the sun's rays, the light reflected from the disc of the moon in a lunar eclipse would exceed that of the full moon. We may next consider the measures of these appearances more precisely, and the circumstances which must occur to produce them.

The first thing to determine in this investigation is the length of the conical shadow projected behind the earth, to find if it always extends to the orbit of the moon, omitting the effect of the atmosphere of the earth.

Let *S* be the centre of the sun, *T* that of the earth, supposed spherical, *A B* a tangent to the earth and sun forming the limit of the perfect umbra, *S T* the axis of the cone, and *T C* the prolongation of this cone, which it is required to determine. If the straight line *A T* be drawn to the centre of the earth, the angle *S T A* will be the apparent diameter of the sun, the angle *T A B* will be its horizontal parallax, and as the first of these is the exterior angle of the triangle *T A C*, the angle *T C B* will be equal to the angle *S T A - T A B*, or the semi-diameter of the sun minus its horizontal parallax. The length *T C* may now be easily determined, for in the right-angled triangle *C B T*, the angle *C* and side *T B* are both known. Therefore the length of the conical shadow varies with the apparent diameter of the sun, and consequently with its distance from the earth. The distance of the centre of the earth from the summit of the cone is as follows. It is expressed in terms of the terrestrial radius.

☉'s Perigee	-	-	-	212.873
☉'s Mean distance	-	-	-	216.237
☉'s Apogee	-	-	-	220.207

For if *D* be the apparent diameter of the sun, *E* the horizontal parallax, *R* the radius of the earth, $CT = R \cdot \frac{1}{\sin \left(\frac{D}{2} - E \right)}$

As the angle $\frac{D}{2} - E$ is always very small, we may substitute its sine, for these calculations do not admit of extreme precision: but then we must substitute for radius the number of seconds it contains, namely, 206264.8; we shall then have the distance of the summit of the cone from

the centre of the earth, $CT = R \cdot \frac{206264.8}{\frac{D}{2} - E}$. If for *D*

we take its three values from the tables when the sun is perigee, mean distance, and apogee, we shall obtain the quantities as given above.

By inspection of these values it appears, that the cone becomes longer as the distance of the sun increases.

The great distance of the moon from the earth does not exceed 63,941 radii of the earth, (see *DISTANCE*.) which is much less than the preceding quantities, so that the earth's shadow always extends much farther into space than the orbit of the moon, consequently if this orbit was in the plane of the ecliptic, there would be every month an eclipse of the moon.

To calculate the magnitude and duration of an eclipse, it is necessary to know the diameter of the terrestrial shadow at the place where it is traversed by the lunar orbit. Let *L l* be this orbit, supposed circular, the angle *L T C* will measure the apparent semi-diameter of the shadow seen from the earth, and will be equal to the difference of the angle

angle

ECLIPSE.

angles $\angle I, B, \angle C, I$. But the first of these angles is the horizontal parallax of the moon, and the second is equal to the semi-diameter of the sun minus its horizontal parallax, as we have already demonstrated. These angles being known, give the angle $\angle I, T, C$, or the semi-diameter of the shadow.

To find it, we must add the parallax of the sun to the parallax of the moon, and take from their sum the semi-diameter of the sun; that is, the semi-diameter of the shadow is always equal $P + p - \frac{D}{2}$.

By calculating its value from the known parallax of the moon at its greatest, least, and mean distances, we obtain the following table.

Table of the semi-diameter of the terrestrial shadow at the distance of the Moon.

Sun's perigee.	{	Moon's apogee	-	37'	37"
		Moon in mean distance	-	40	40
		Moon's perigee	-	45	15
Sun in its mean distance.	{	Moon's apogee	-	37	53
		Moon in mean distance	-	40	$56\frac{1}{2}$
		Moon's perigee	-	45	31
Sun's apogee.	{	Moon's apogee	-	38	9
		Moon in mean distance	-	41	12
		Moon in perigee	-	45	46

The greatest apparent diameter of the moon not exceeding $33' 31''$, we see that it may always be contained in the terrestrial shadow, which considerably exceeds it. Therefore, every time that the moon passes through the centre of this shadow, it will be totally eclipsed.

The time that the moon will remain in the shadow depends on the difference between her diameter and that of the shadow. To compute this time, we must calculate this difference, and determine from the horary motion of the moon the time she will employ to describe it.

Hitherto, we have only considered the dimensions of the umbra; the limits of the penumbra are next to be determined.

Let A, b (fig. 76.) be a straight line, at the same time a tangent to the earth and the sun, I, l representing the lunar orbit, the angle $\angle I, T, C$ will be the distance of the penumbra to the axis C, T , but this angle being exterior to the triangle C, T, l is equal to the sum of the two interior, and opposite $\angle T, l, C, T$.

The first of these is the horizontal parallax of the moon, the second equal to $\angle C, A, T + \angle T, A, C$, or the semi-diameter of the sun plus its horizontal parallax, therefore the angle $\angle C, T, l$ is equal to the sum of the parallaxes of the sun and moon + the semi-diameter of the sun.

The magnitude of the penumbra is found by subtracting the semi-diameter of the umbra from the above quantity. But this semi-diameter is equal to the sum of the parallaxes of the sun and moon minus the semi-diameter of the sun; consequently the diameter of the penumbra is equal to the diameter of the sun. We must next consider what alterations will be produced in these results by the effect of the earth's atmosphere.

The umbra, as determined above, has for its limit the radius A, B , which touches the corresponding surfaces of the earth and sun; C is then the summit of the umbra. But if we take into consideration the effect of the atmosphere of the earth, the ray of light A, B will be refracted at the point B , and continuing its path will converge to some point nearer the earth than the point C . A spectator placed beyond this limit, would, by the effect of refraction, not only see the luminous border of the sun's disc, but a lu-

minous zone of it; by receding farther from the earth the disc of the sun transmitted through the atmosphere will be visible in the form of a luminous ring. receding still farther, the rays emerging from the centre of the sun will no longer touch the surface of the earth, but pass higher up in the atmosphere; and lastly, by increasing still more the distance, the exterior limb of the sun will begin to be disengaged from the terrestrial atmosphere, and will appear directly and without refraction.

To determine these different limits, imagine a ray of light S, B , (fig. 77.) proceeding from the limb of the sun, and just touching the surface of the earth at B , the curve described by this ray about the earth will be symmetrical on each side of B , that is, if S, o be its direction when it enters the atmosphere, o, L will be its direction when it passes out of it, and the angles $\angle B, T, l$, $\angle B, b, I$, formed with the tangent $\angle T, l$, will be equal to each other; but the angle $\angle B, T, l$, or $\angle D, T, S$, is very nearly equal to $\angle D, B, S$, or the horizontal refraction, because the point l is very little elevated above B . The angle $\angle B, T, l$ is likewise very nearly equal to the horizontal refraction, consequently the angle $\angle S, I, A$, which expresses the inflexion of the ray, is equal to $\angle B, T, l + \angle B, l, I$, or to double the horizontal refraction.

The effect of the atmosphere, therefore, is to augment by this quantity the apparent semi-diameter of the sun: hence, in computing the distance of the summit of the umbra from the centre of the earth, the semi-diameter of the sun must be increased by double the horizontal refraction, and with this correction alone, the same formulæ may be employed that have been demonstrated above. If instead of considering the ray of light S, B as coming from the exterior limb of the sun, it be supposed to proceed from any point whatever of the disc, at a given distance from the centre; substituting this distance for the semi-diameter of the sun, we shall have the distance from the earth at which this point begins to appear, and thus may be found the successive zones which will begin to be visible at every corresponding distance.

If the horizontal refraction be called r , the same notation being continued as above, the distance of the summit of the shadow from the centre of the earth C, T will be equal $\frac{R}{D} + 2r - L$, and the semi-diameter of the shadow

$P + p - D - 2r$. If now $\frac{D}{2}$ be supposed to express the

distance of any given point in the disc from the centre, we may find by the first formula the distance at which the given point will begin to appear on the edge of the terrestrial surface. Making $D = 0$ we shall have the distance at which the sun begins to be entirely visible, surrounding the earth like a ring. On this principle *De Séjour* has computed the following table.

	Sun's Perigee.	Mean Distance.	Sun's Apogee.
Limb of the sun beginning to appear	12,225	47,013	41,842
$\frac{1}{3}$ the disc of the sun at the circumference of the earth	46,674	46,502	36,408
$\frac{1}{2}$ of the disc \odot at the circumference of the earth	52,236	52,236	52,236
$\frac{2}{3}$ of the disc \odot at the circumference of the earth	59,316	59,820	60,317
The whole disc of the \odot surrounding the earth like a ring	68,283	69,125	69,645

The least distance of the moon being 57,660, and the greatest 63,664, in the most unfavourable circumstances, even at the centre of the shadow, a spectator on the surface of the moon would still see half the disc of the sun through the atmosphere of the earth.

This sufficiently explains, why, in a total eclipse of the moon, her disc is still enlightened enough to be visible, and we must attribute to the thickness of our atmosphere, and to the vapours it contains, the cause of the great diminution of light which sometimes makes the moon almost entirely disappear.

It was, perhaps, an effect of this kind which Sauffure observed on the *Col du Geant*, when he saw, during summer nights, the horizon surrounded by a kind of luminous ring, the small depression of the sun below the horizon might compensate the smallness of the distance from the earth at which the spectator was placed; and this consideration agrees very well with the phenomena of twilight. See CREPUSCULUM, and TWILIGHT.

In the above explanations the moon has been supposed exactly placed in the axis of the terrestrial shadow, and she would be so placed in every opposition if her orbit coincided with the plane of the ecliptic, but since the moon is sometimes elevated above, and sometimes depressed below this plane, it may happen that it will only enter partially into the shadow of the earth, or just touch it with her limb, or even pass without touching it. In the first case, the eclipse is *partial*, in the second, it takes the name of an *appulse*; a *total eclipse* is when the moon is entirely plunged in the shadow, and the eclipse is *central* when the centre of the moon coincides with the axis of the conical shadow.

Central eclipses can only happen when the moon, at the moment of opposition, is in the plane of the ecliptic, and consequently in one of her nodes.

For a total eclipse, it is sufficient that the semi-diameter of the shadow exceeds the latitude of the moon, augmented by her apparent semi-diameter.

That there may be a partial eclipse, it is sufficient that the semi-diameter of the shadow exceeds the latitude of the moon, diminished by her apparent semi-diameter. If these two quantities are equal, the moon will touch the shadow, and there will only be an appulse; if the second surpasses the first, there will be no eclipse.

The latitude of the moon depends on its distance from the nodes of its orbit; it augments as its distance from these points increases; the distance from the node may, therefore, be calculated, at which an eclipse becomes impossible: this is called the *ecliptic limit*. To do this, we must select the most favourable circumstances, or those which give the diameter of the moon, and the terrestrial shadow, the greatest possible values; the sum of these two quantities will give the greatest possible latitude at which the moon can be eclipsed. Having found this latitude, we may determine the distance from the node which corresponds to it; this is done by the solution of a right-angled spherical triangle, formed by the lunar orbit, the ecliptic, and the circle of latitude; in this triangle one of the sides is the latitude above found, the angle is the obliquity of the orbit, which we must take at its least value; the side opposite the right angle is the greatest distance from the node. Since these respective positions of the moon and sun are connected together, by the law of their motions, it is not easy to determine the precise instant in which the re-union of all these circumstances shall be the most favourable to produce an eclipse, and it can only be effected by comparing together a great number of simultaneous positions of the two bodies. According to Delambre (who has taken into the account the effect of the atmospheric refraction),

there cannot happen an eclipse of the moon when the distance from the node surpasses $13^{\circ} 40'$, and there certainly will be an eclipse when the distance is less than $7^{\circ} 47'$. Between these limits, the existence of the eclipse will depend on the particular positions of the sun and moon, and to decide the question we must have recourse to exact calculation in which these circumstances enter, but the preceding results are always extremely useful, because they shew at once a number of oppositions in which no eclipse can happen, so that it only remains to calculate the others to find what species of eclipse (if any) will take place.

Of an Eclipse of the Sun.

An eclipse of the sun is produced by the interposition of the moon between that luminary and the earth, for which reason it can never happen at any other time than at the conjunctions or new moons. Notwithstanding the moon is incomparably less than the sun, yet from its nearness to us it happens that its apparent diameter differs very little from that of the sun, and even sometimes exceeds it. Suppose an observer situated in the continuation of a straight line that unites the centres of the sun and moon, he will see the former of these bodies eclipsed. If the apparent diameter of the moon surpasses that of the sun, the eclipse will be total, and the observer will be entirely plunged in the cone of shade which is projected behind the moon: if the diameters are equal, the point of the cone will terminate at the earth's surface, and there will be a momentary total eclipse. If the diameter of the moon be less than that of the sun, the observer will see a zone of the sun surrounding the moon like a ring, and the eclipse will be central and annular. And lastly, if the observer on the earth's surface is not exactly in the line joining the centres, the eclipse may be partial, that is, a part of the solar disc may be hid, while the remaining part continues perfectly visible. Total eclipses, which are rare, are remarkable for the darkness which accompanies them, and which they spread over different parts of the surface of the earth, in the same manner as the shadow of a cloud carried by the winds, sweeps over the mountains and the plains, depriving them for some instants of the light of the sun. This total darkness, under favourable circumstances, may last about five minutes.

The smallest apparent diameter of the sun is $31' 30''$; the diameter of the moon in its mean distance is $31' 23''$, that is, less than that of the sun; there cannot, therefore, be a total eclipse when the moon is beyond the mean distance. Eclipses of the sun are likewise modified by the height of the moon above the horizon, which increases her diameter. (See DIAMETER.) This change, combined with the effect of parallax, may so much augment or diminish the apparent distance of the moon from the sun, that an eclipse may be seen by one observer at the earth's surface, at the same time that no such phenomenon happens to another. For example, if the horizontal semi-diameters of the earth and moon differ very little from each other, an eclipse may be annular to those countries who observe it in the morning or evening, and central to those who observe it at noon, where the sun and moon are elevated above the horizon. In this, eclipses of the sun differ from those of the moon; the latter are the same to all places where they are visible, but the former are so modified by the position of the observer, by the different distances of the sun and moon from the earth, and from the different distances of the moon from the node, that they are subject to extreme variations; and from the number of elements on which they depend, the calculation of their appearances is very difficult. The diameter of the moon, observed in a solar eclipse, appears something less than at other times:

correction is about $\frac{1}{10}$ th of the semi-diameter of the shadow; or, that you may add as many seconds as the semi-diameter contains minutes. Some computers always add $50''$; but this must be subject to some uncertainty.

As the angle $CIT = (OTA - TOC)$ is known, we have $\sin. TIC : \cos. TIC :: TC : CI$, the length of the earth's shadow.

If we take the angle $ATO = 16' 3''$, the mean semi-diameter of the sun, $TOC = 9''$, the horizontal parallax of the sun, we have $CIT = 15' 54''$: hence, $\sin. 15' 54'' : \cos. 15' 54''$, or $216.2 :: TC : CI = 216.2 TC$.

Let PQ (fig. 97.) represent the section of the earth's shadow at the moon, CN the ecliptic, NL the moon's orbit. Draw Cn perpendicular to CN , and Cm perpendicular to NL ; and let the moon at m just touch the earth's shadow at r externally, so that Cm may be the sum of the radii of the moon and earth's shadow. Then to determine when this happens, we may take the angle at $N = 5^\circ 17'$, which is very nearly its value in all eclipses; the inclination of the lunar orbit being at that time always greatest, as will afterwards be shewn. Hence, $\sin. 5^\circ 17' : \text{rad.} :: \sin. CM : \sin. CN$. Now the greatest value of Cm is about $1^\circ 3' 30''$; hence the corresponding value of $CN = 11^\circ 34'$. When therefore CN is greater than that quantity, there can be no eclipse. According to M. Cassini, if the latitude, Cn , of the moon, at the time of the ecliptic conjunction, exceed the sum of the semi-diameters of the earth's shadow and moon by $18''$, there will be no eclipse; but if it do not exceed that sum by $16''$, there will be an eclipse. If $Cm = Cr - rm$, or the limbs touch internally, the eclipse will be just total: hence, if the distance of the moon's node from the place of the earth be less than the computed value of CN in this case, there must be a total eclipse of some duration. If, therefore, it was before doubtful, and it now appears there will be an eclipse, proceed as follows to compute it:

Let APB be that half of the earth's shadow where the moon passes through, NL the relative orbit of the moon; one figure representing a partial eclipse, the other a total one. Draw Cmr perpendicular to NL , and let α be the centre of the moon at the beginning of the eclipse, m at the middle, ω at the end; ν at the beginning of total darkness, ω at the end. Also, let $A'B'$ be the ecliptic, and Cn perpendicular to it. Now, in the right-angled triangle Cmn , we know Cn the latitude of the moon at the time of the ecliptic conjunction, and the angle Cnm the complement of the angle which the relative orbit of the moon makes with the ecliptic: hence, radius: $\cos. Cmn :: Cn : nm$, which we call the reduction; and radius: $\sin. Cnm :: Cn : Cm$. By logarithms, the calculations are thus:

$$\begin{aligned} \text{Log. cos. } Cnm + \text{log. } Cn - 10 &= \text{log. } nm. \\ \text{Log. sin. } Cnm + \text{log. } Cn - 10 &= \text{log. } Cm. \end{aligned}$$

The horary motion of the moon upon its relative orbit being known, we know the time of describing mn , by saying, $b : mn :: 1^h : \text{the time of describing } mn$. The computation of this is most readily performed by logarithmic logarithms.

Hence, knowing the time of the ecliptic conjunction at n , we know the time of the middle of the eclipse at m . Next, in the right-angled triangle $CM\omega$, we know Cm and $C\omega$, the sum of the semi-diameters of the earth's shadow and the moon, to find $m\omega$, which is done thus by logarithms. As

$$m\omega = \sqrt{C\omega^2 - Cm^2} = \sqrt{C\omega + Cm} \cdot \sqrt{C\omega - Cm}$$

$$\text{log. of } m\omega = \frac{1}{2} \cdot \text{log. } C\omega + Cm + \text{log. } C\omega - Cm.$$

Hence, the horary motion of the moon being known, we know the time of describing αm , which subtracted from the time at m , gives the time of the beginning; added, gives the time of the end. In the same manner, in the right-angled triangle $Cm\nu$, we know Cm and $C\nu$, the difference of the semi-diameter of the earth's shadow and moon: hence, by logarithms,

$\text{log. of } m\nu = \frac{1}{2} \cdot \text{log. } C\nu + Cm + \text{log. } C\nu - Cm$, from whence, as before, we know the time of describing $m\nu$, which subtracted from the time at m , gives the time of the beginning of total darkness; and added, gives the end. The magnitude of the eclipse at the middle is represented by tr , which is the greatest distance of the moon within the earth's shadow; and this is measured in terms of the diameter of the moon conceived to be divided into 12 equal parts, called digits or parts deficient; to find which, we know Cm , the difference between which and Cr gives mr , which added to mt , or if m fall out of the shadow, take the difference between mr and mt , and we get tr . Hence, to find the number of digits eclipsed, say $mt : tr :: 6 \text{ digits, or } 360''$ (it being usual to divide a digit into 60 equal parts, and call them minutes): the digits eclipsed. If the latitude of the moon be north, we use the upper semi-circle; if south, we take the lower.

If the earth had no atmosphere, when the moon was totally eclipsed, it would be invisible; but we have shewn, that by the refraction of the atmosphere, some rays will be brought to fall upon the earth's surface; upon which account, the moon will be visible at that time, and appear of a dusky red colour. M. Maraldi has observed, that in general the earth's umbra at a certain distance is divided by a kind of penumbra, from the refraction of the atmosphere.

This will account for the circumstance of the moon being more visible in some total eclipses than in others. It is said, that in the total eclipses in 1601, 1620, and 1642, the moon entirely disappeared. An eclipse of the moon, arising from its real deprivation of light, it must appear to begin at the same instant of time to every place on that hemisphere of the earth which is next the moon.

Hence it affords a very ready method of finding the difference of longitudes of places on the earth.

The moon enters the penumbra of the earth before it comes to the umbra, and therefore it gradually loses its light; and the penumbra is so dark just at the umbra, that it is difficult to ascertain the exact time when the moon's limb touches the umbra, or when the eclipse begins.

When the moon has entered into the umbra, the shadow upon its disc is tolerably well defined; and you may determine, to a considerable degree of accuracy, the time when any spot enters into the umbra. Hence, the beginning and end of a lunar eclipse are not so proper to determine the longitude from, as the times at which the umbra touches any of these spots.

Example 1.—A computation of a partial eclipse of the moon, on February 3, 1795. For the meridian of the Royal Observatory at Greenwich.

The time of the full moon is $3^d 19^h 59^m 47^s.6$. It appears by the rule already given, that there will be an eclipse.

By computation, the mean time of the ecliptic opposition is at $12^h 46^m 18^s$; from which subtract the equation of time, $14^m 20^s$, and we have $12^h 31^m 58^s$, the apparent time at Greenwich.

To this time compute the moon's place in the ecliptic, and it will be found $4^\circ 15' 15'' 57''$, the opposite point to which is $10^\circ 15' 15'' 57''$, the place of the sun. Compute

ECLIPSE.

also the moon's latitude Cn , and it will be found $37' 39''$ N. ascending.

By the tables, the horary motion of the moon in latitude is $2' 57''$, the horary motion of the sun is $2' 32''$, and of the moon $32' 9''$ in longitude; hence the horary motion of the moon from the sun in longitude is $29' 37''$, consequently, the horary motion of the moon from the sun on the relative orbit is $29' 45''$; also the inclination of the relative orbit is $5^\circ 41' 27''$. The reduction nm is $3' 44''$, reduce this into time by logarithmic logarithms, and the operation is thus:

$3' 44''$	-	-	-	-	1.2061
29 45	-	-	-	-	0.3047
7 32 time of describing $m n$.					0.9014

The nearest approach Cm of the centres is $37' 28''$. From $12^h 31' 58''$, subtract $7' 32''$, and it leaves $12^h 24' 36''$, the middle of the eclipse.

By the tables, the horizontal parallax of the sun is $0' 9''$, and of the moon $56' 30''$. Also, the apparent semi-diameter of the sun is $16' 16''$, and of the moon $15' 24''$. Hence hor. par. $\odot +$ hor. par. \ominus - semi diam. $\odot + 50'' = 41' 13''$, the semi-diameter of the earth's shadow increased by $50''$ for refraction.

Hence, semid. $\ominus +$
 semid. \odot 's shadow $56' 37'' = 3397''$

Nearest approach of
 centres - - - - - $37 28 = 2248$

Sum - - - - - $5645 - \log. 3.751664$
 Diff. - - - - - $1149 - \log. 3.060320$

$2)6.811984$

Log. of $2546''.8 = 42' 26''.8$ mot. of half
 duration - - - - - 3.405992

Reduce this into time by the logarithmic logarithms.

$29' 45''$	-	-	-	-	0.3047
42 27	-	-	-	-	0.1503

$1^h 25' 37''$ half duration - - - - - 0.8456

Subtract this from and add it to $12^h 24' 26''$, and we get $10^h 58' 49''$ for the beginning, and $13^h 50' 3''$ for the end. From $Cr = 41' 13''$, subtract $Cm = 37' 28''$, and we get $mr = 3' 45''$; hence $mr + mt = rt = 19' 9''$: the parts deficient, consequently $15' 24''$: $19' 9''$: 64 , or $360'$: $7^d 27' 36''$ the digits eclipsed.

By logarithmic logarithms the calculation is thus:

$19' 9''$ log. $+ 1$	-	-	-	-	1.4960
15 24	-	-	-	-	0.5960

$7^d 27' 36''$ - - - - - 0.9054

Hence the times of this eclipse are Feb. 3, 1795.

The beginning at	-	-	-	}	Apparent- time at
Middle - - - - -	-	-	-		
End - - - - -	-	-	-	}	Greenwich.
Duration - - - - -	-	-	-		
Digits eclipsed - - - - -	-	-	-	on the moon's fourth limb, as represented in fig. 80, which was constructed for this eclipse.	

Example 2.—A computation of a total eclipse of the moon on December 3d, 1797, for the meridian of the Royal Observatory at Greenwich.

It appears that there will be an eclipse at this full moon.

Vol. XII.

By computation, the mean time of the ecliptic opposition is $3^h 16^m 10^s 46^{\frac{1}{2}}$, to which add $9^m 18^s$, the equation of time, and you get $3^h 16^m 26^s 4^{\frac{1}{2}}$ for the apparent time.

To this time compute the moon's place in the ecliptic, and it will be found to be $2^h 12^m 35^s 10^{\frac{1}{2}}$, consequently the sun's place is $8^h 12^m 35^s 10^{\frac{1}{2}}$. Compute also the moon's latitude Cn , and it will be found $4' 55''$ S. decreasing.

By the tables the horary motion of the moon in latitude is $3' 15''$, the horary motion of the sun is $2' 32''$, and of the moon $35' 14''$ in longitude, hence the horary motion of the moon from the sun in longitude is $32' 42''$, consequently, the horary motion of the moon from the sun on the relative orbit is $32' 50''$; also, the inclination of the relative orbit is $5^\circ 40' 34''$.

The reduction nm is $0' 29''$; reduce this into time by the logarithmic logarithms, and the operation is thus:

$32' 50''$	-	-	-	-	0.2618
0 29	-	-	-	-	2.0939

$0 53$ time of describing $m n$ - - - - - 1.8321

The nearest approach Cm of the centres is $4' 54''$.

To $16^h 26' 4''$ add $53''$, and it gives $16^h 26' 57''$ for the middle of the eclipse. By the tables, the horizontal parallax of the sun is $0' 9''$, and of the moon $59' 9''$. Also the apparent semid. of the sun is $16' 17''$, and of the moon $16' 6''$. Hence hor. par. $\odot +$ hor. par. \ominus - semid. $\odot + 50'' = 43' 51''$, the semi-diameter of the earth's shadow increased by $50''$ for refraction. And as $Cr = 43' 51''$ is greater than $Cm + m_s (= 21')$ the eclipse must be total.

Semid. $\ominus +$ semid. \odot 's shadow } $59' 57'' = 3597$
 Nearest app. of centres $4 54 = 294$

Sum - - - - - $3891 + \log. 3.5900612$
 Difference - - - - - $3303 - \log. 3.5189086$

$2)7.1089624$

Log. of $3585'' = 59' 45''$ mot. of half duration 3.5544849

Reduce this into time by the logarithmic logarithms; but because the fourth term, in this case, would come out a greater quantity than that to which the table extends, we will take the half of $59' 45''$, and then double the conclusion:

$32' 50''$	-	-	-	-	0.2618
29 52.5	-	-	-	-	0.30285
54 34.5					0.04105

Hence $1^h 49' 11''$ is the half duration; which subtracted from and added to $16^h 26' 57''$, gives $14^h 37' 46''$ for the beginning, and $18^h 16' 8''$ for the end. We find the time of half the duration of total darkness thus:

Semid. \ominus 's shadow
 - semid. \ominus $27' 45'' = 1665''$
 Nearest app. of the
 centres - - - - - $4 54 = 294$

Sum - - - - - $1959 - \log. 3.2920314$
 Difference - - - - - $1371 - \log. 3.1370375$

$2)6.4290719$

Log. of $1639'' = 27' 19''$ mot. of $\frac{1}{2}$ dur. of
 total darkness - - - - - 3.2145359

$3 Y$ Reduce

ECLIPSE.

Reduce this into time by the logific logarithms.

52' 50"	0.2618
27 19	0.3417
<hr/>	
49 55 half duration of total darkness	0.0799

Subtract this from and add it to 16^h 26' 57", and it gives 15^h 37' 2" for the beginning of total darkness, and 17^h 16' 52" for the end.

From $C r = 43' 51''$, subtract $C m = 4' 54''$, and we get $m r = 38' 57''$, to which add $t m = 16' 6''$, and we get $t r = 55' 3''$ the parts deficient. Hence 16^h 6^m : 55' 3" :: 6^s, or 360^s : 20' 31" the digits eclipsed.

The operation by logific logarithms is thus:

55' 3" log. + 1	1.0374
16 6	0.5713
<hr/>	
20' 31 0	0.4661

Hence the times of this eclipse are December 3d, 1797.

The beginning at	14 ^h 37' 46"	
Total darkness begins	15 37 2	}
Middle	16 26 57	
Total darkness ends	17 16 52	}
End of the eclipse	18 16 8	
Duration of total darkness	1 ^h 39' 50"	
Duration of the whole eclipse	3 38 22	
Digits eclipsed	20' 31' 0"	

If the time corresponding to the difference between the meridian at Greenwich and that of any other place be applied to the times here found, it will give the times at that place.

In this present year, 1809, there occurs but one visible eclipse, and that is of the moon, 29th April. The computation of its elements is as follows.

To compute the partial eclipse of the moon, which will happen 29th April, 1809.

Ecliptic opposition happens 12^h 41'. The moon's motion in longitude for the preceding 12 hours was 7° 29' 26", and for the succeeding 12 hours 7° 31' 47". The mean 7° 30' 36", which divided by 12, gives 37' 33" for the moon's horary motion in longitude. If we take from this the sun's horary motion, 2' 26", it will leave 35' 7" for the horary motion of the moon from the sun, and which augmented by 8' is 35' 15", which is the relative horary motion of the moon.

The horary motion of the moon in latitude is 3' 27". To find the inclination of the moon's orbit,

Log. 207" = hor. mot. moon in lat.	2.3159703
Co. log. 2115" = hor. mot. moon in long.	6.6746895
<hr/>	
5° 35' 20"	= 8.9906598

And 84 24 40 = its complement = $C n m$.

To find the reduction $n m$. The latitude $D = 33' 50''$. Rad. :: $\cos 84^\circ 24' 40'' :: 33' 50'' = 20' 30'' : m n$.

Log. 2030 = 3.3074960	
Co. 84° 24' 40" = 8.9885139	

$$197'' = 2.2960099 = 3' 17''.$$

This must be reduced into time by logific logarithms thus:

3' 17"	1.2618
35 15	0.2310
<hr/>	
5 36 (time of describing $m n$)	1.0308

Graphical Method of computing the above Eclipse for April 29, 1809.

With a convenient scale of minutes and seconds, (which, for practical purposes, may be taken from a common ruler, divided

(divided into inches and tenths,) take $AC =$ semi diameter of the umbra $= 46' 14''$, and with this radius describe the circle ABD . Draw Cn perpendicular to AB , and make it equal to the latitude of the moon $= 33' 50''$. Make $\angle CnN =$ complement of the angle which the relative orbit of the moon makes with the ecliptic $= 84^\circ 24' 40''$, and produce Nn to L . With a radius equal to the sum of the semi-diameters of the moon and the earth's shadow $= 62' 54''$, set off Cz, Cx ; and let fall the perpendicular Cn ; and with the centres x, m, z , and with a radius equal to the semi-diameter of the moon $= 16' 40''$, describe the circles representing the moon. To find the beginning, middle, and end, the point $n, 12^h 41'$, the time of the ecliptic conjunction must be marked, and set off from n , both ways, an extent equal to the horary motion of the moon upon NL . This interval should be divided into as many equal parts as it will conveniently admit of, and these divisions continued to x and z . The times corresponding to the points x, m , and z , shew the beginning, middle, and end of the eclipse. And if r be measured upon the scale, it will shew the digits eclipsed.

This method will give the time sufficiently near, if it is only required to predict the eclipse, as the time may be depended on to a minute, if the radius CB is six or seven inches. The same method may be employed if the eclipse is total.

The latter part of this method may be more easily understood, by referring to the plate where the whole operation is represented with its corresponding scale. See *Pl. XI, fig. 81.*

To calculate an Eclipse of the Sun.

The calculation of eclipses of the sun, for any particular place, is much longer and more difficult than that of lunar eclipses, on account of the considerations of parallax which necessarily enter into them. The parallax differs for every part of the earth; so that an eclipse of the sun would have a different appearance to different countries. An eclipse of a minute of a degree, and continuing for $20'$ of time, may occur at a spot 60 miles distant from a place where no eclipse is visible. On the contrary, an eclipse of the moon would appear of the same magnitude to all the places where it is visible; for the moon, really losing its light, is dark to the whole world.

If we were placed on a point at the surface of the moon, when it is eclipsed, and we wished to calculate the manner in which this eclipse would appear in this point, determined from the moon, we should equally fall into the difficulty of parallax; for the eclipse, which would then be an eclipse of the sun, taking place successively and differently at the different points of the lunar surface, the parallax must be calculated for that part of the moon where the spectator is situated.

There is a great variety of methods that have been devised by different astronomers for calculating eclipses of the sun; but as they all, more or less, involve the principle of projection, as a preparatory step, it will be necessary to describe the method by which this projection is usually effected. One of the best projections devised for this purpose, was first given by our great astronomer, Flamsteed, and is thus described by Mr. Vince:

On the Projection for the Construction of Solar Eclipses.

As the ecliptic is inclined to the equator, and cuts it in two opposite points, the sun keeps continually approaching to one pole, and receding from the other by turns, and

therefore to a spectator at the sun, the poles must appear and disappear by turns. When the sun is on the north side of the equator, the north pole must appear; and when on the south side, the south pole. When the sun is in the equator, the plane of illumination is perpendicular to the equator, and, consequently, the poles will lie in the circumference of the circle of illumination; when the sun comes to the tropic, the pole will appear in the middle of its path over the circle of illumination; and when the sun comes to the next equinox, the pole will appear on the other side of the circle of illumination. When the sun gets on the other side of the equator, this pole will disappear, and the other will appear in like manner. Hence, to a spectator at the sun, the apparent motion of the pole P (*fig. 82.*) is the same as if the axis Pp of the earth had an annual conical motion $PrQs, pngm$, about an axis GOE , perpendicular to the ecliptic EOC , the angle POG being equal to the greatest declination of the sun. As these circles, $PrQs, pngm$, are parallel to the ecliptic, their planes will pass through the sun, and therefore to a spectator at the sun, the apparent motion of the poles will be in the straight lines PQ, pg ; and as P moves as fast in the circle $PrQs$ as the sun does in the ecliptic, if P be the place of the pole at the equinox, and we take the arc Pv equal to the sun's distance from that equinox, and draw vo perpendicular to PQ , o will be the apparent place of the pole at that time. It is manifest that Pv may be set off upon any circle described on PQ . Hence, also, the angle which the axis vOw makes with the plane of illumination must be equal to the declination of the sun. As this apparent motion of the pole over the enlightened disc of the earth is caused by the motion of the earth in its orbit, the motion of the pole over the disc will be in a direction contrary to the diurnal motion of the disc; if, therefore, P be the position of the pole at the vernal equinox, and PrQ be its motion over the disc of the earth to the next equinox, the diurnal motion of the disc will be made in the contrary direction.

When the sun, and consequently the spectator, who is supposed to be at the sun, is in the equator, the spectator being in the plane of the equator, and, as to sense, in the plane of all the circles parallel to it, they will all appear to be projected upon the circle of illumination into right lines parallel to each other. But when the sun, and consequently the spectator, is out of the equator, the equator, and all the circles parallel to it, being seen obliquely, will appear to be projected into ellipses upon the plane of illumination, as the eye may be considered at an infinite distance; and as the eye has the same relative situation to all these circles, the ellipses must be all similar. When the sun is on the north side of the equator, that part of the ellipse which is the projection of that part of the circle which lies between the north pole and equator on the enlightened hemisphere will be concave to the pole; but when the sun is on the other side of the equator, that part will be convex. That is, let P (*fig. 83.*) be the north pole on the enlightened hemisphere, the sun being on the north side of the equator, and $vxy z, ambn$, the ellipses into which the equator and any parallel to it are projected; then amb is that part of the ellipse which the place on this parallel describes in the day, and the other part bna is that which is described in the night; and the place is at m at 12 at noon, and at n at 12 at midnight. In this case, the other pole p must be considered as being on the other, or dark side of the earth. But if P be supposed on the dark side, and consequently p on the light side, or if the sun be on the south side of the equator, n will be 12 at noon, and m will be 12 at midnight. For if Pp (*fig. 84.*) be the axis, L N the plane upon which the circle ab is to be projected, E

ECLIPSE.

the sun on that side next to the north pole; then, drawing Eam , Fgb the point a answering to noon, the sun being on the meridian, is projected at m , and the point b , answering to midnight, is projected at n ; but when the sun is on the other side of $a b$, as at c , a is projected to n' and b to m' ; therefore n' represents noon and m' midnight. On account of the great distance of the sun, compared with the radius of the earth, the lines Ea , Eb , and ca , cb may be considered as parallel, and the circle ab is orthographically projected upon the plane LN into an ellipse, whose minor axis is mn , or $m'n'$.

The next thing to be done is to determine the magnitude of the ellipse into which the circle ab is projected, and its position upon the plane of illumination. Let Pp (*fig. 85*) represent the axis of the earth, ab a circle of latitude to any place. $LPNp$ the meridian passing through the sun, and LOn the plane upon which the projection is made; then the angle LOP is equal to the sun's declination; draw am , bn , or , perpendicular to LO , and mn is the minor axis of the ellipse; let vs be that radius of the circle ab which is parallel to the plane of projection, and it will be projected into a line equal to itself, and consequently it will be the major axis: hence $2vs$, or $2va$, or 2 *col. lat.* is the major axis of the ellipse; but mn (the projection of ab upon LN): ab :: *fin. mab*, or POl the *dec.*: radius; that is, the axis major: axis minor :: *rad.*: *fin. declination*. And to find the distance Or from the centre of projection to the centre of the ellipse, we have, *rad.* = 1 : *col. vOr* the *dec.*: vO : Or = $vO \times \text{col. dec.} = \text{fin. lat.} \times \text{col. dec.}$ But the radius of the projection is the horizontal parallax of the moon, diminished by the horizontal parallax of the sun; the radius, therefore, thus expressed, being multiplied by the quantities, whose values are expressed when radius is supposed to be unity, give the value in terms of that radius; hence, if *hor. par.* D = *hor. par.* C = b , then $b \times \text{col. lat.}$ = the semi-axis major of the ellipse; $b \times \text{col. lat.} \times \text{fin. dec.}$ = the semi-axis minor; and Or = $b \times \text{fin. lat.} \times \text{col. dec.}$ Thus we have gotten the dimensions and position of the ellipse in terms of the radius of projection. Hence we have the following construction for the apparent ellipse described by any place on the earth's surface to a spectator at the sun.

Let $GCFE$ (*fig. 86*) be that half of the earth which is illuminated, EC the plane of the ecliptic, GOF perpendicular to it: take GQ = GV equal to the sun's greatest declination, join QV , and on it describe the semi-circle $V K Q$, and take Vb equal to the sun's distance from the vernal equinox corresponding to the pole at V , and draw bP perpendicular to VQ , and P is the place of the pole, which we will suppose to be on the enlightened disc of the earth. Put c = *col. Vb*, n = *fin. VG*, m = its cosine, to radius unity; then

$$\begin{array}{l} Pc : cV :: c : 1 \\ cV : OG :: n : 1 \\ \hline \therefore Pc : OG (=b) :: c \times n : 1; \end{array}$$

hence $Pc = b \times c \times n$.

Also, $b \times m = Oc$; hence $b \times m : b \times c \times n :: \text{rad.} : \tan. POc = \frac{c \times n}{m} = c \times \tan. 23^\circ 28' = 0.4341208 \times c$. Draw POp , and upon OP take $Or = b \times \text{fin. lat.} \times \text{col. dec.}$; draw bra perpendicular to OP , and take $ra = rb = b \times \text{col. lat.}$ and $rm = rn = b \times \text{col. lat.} \times \text{fin. dec.}$ and describe an ellipse $ambn$, and it will represent the apparent diurnal path of the place to a spectator at the sun, for the given declination of the sun. If x and z be the points where the ellipse touches the circle $GCFE$,

the part $xambz$ will be on the illuminated part of the earth, and therefore visible to a spectator at the sun, and the part znx on the dark part, P being the north pole, and the sun's declination north; but if the declination be south, xnz will be the part on the illuminated side of the earth, and $zmbax$ on the dark part. Let the declination be north, and a the west side of the disc; then, to find where the given place on the earth's surface, is at any time, we may observe, that the place describing the circle which is projected into the ellipse $ambn$ moves uniformly in that circle, from the uniform motion of the earth about its axis; let, therefore, ayb be a circle; then, if every ordinate be diminished in the ratio of $yr : mr$, the circle will be projected into the ellipse amb ; this semi-circle may, therefore, represent the half of the diurnal motion of the given place, so far as it is necessary to obtain the corresponding positions of the place in the ellipse. For, divide the semi-circle ayb into 22 equal parts from a , at 7, 8, 9, 10, 11, 12, 1, 2, 3, 4, 5, 6, representing the positions of the given place from a at six o'clock in the morning, to b at six in the evening, and these figures will represent the positions of the given place at the respective hours denoted by the figures; and if the dotted lines be drawn perpendicular to ab , the corresponding points denoted by the same figures will represent the positions of the place in the ellipse. This ellipse may be very accurately described, by diminishing each ordinate of the circle perpendicular to ab in the ratio of yr to mr , by taking a proper number of ordinates, and then describing a curva through all the points; and if these lines be continued to the other half of the ellipse, the hours, as there marked, will correspond to the positions of the given place. If each division of the semi-circle be divided into 10 equal parts, and ordinates be drawn to ab , the ellipse will be divided into every six minutes; and if the scale be large enough, and these divisions on the ellipse be subdivided into six equal parts, the ellipse will be divided into minutes, for there will be no occasion to use the circle for this last subdivision. Thus, we can always find the apparent position of any place on the earth's surface to a spectator at the sun.

Draw $11v$ and $11d$ perpendicular to ry ; then $11cv = 11d$ is the sine of 15° to the radius ra ; and, by the principles of projection, $yr : mr :: yd : mv$, therefore, as yd is the versed sine of 15° to the radius yr , mv must be the versed sine of 15° to the radius mr ; hence, if we take the sine and versed sine of 15° to radius unity, and multiply them into ra and rm respectively, they will give the values of $11v$ and mv ; and if rm be multiplied into the cosine of 15° , it gives rv . The same for any other angle.

It has been proved above, that $Or = b \times \text{fin. lat.} \times \text{col. dec.}$ and $ra = b \times \text{col. lat.}$; hence, $Or : ra :: \text{fin. lat.} \times \text{col. dec.} : \text{col. lat.}$; consequently, $Or = ra \times \frac{\text{fin. lat.} \times \text{col. dec.}}{\text{col. lat.}}$.

= $ra \times \tan. \text{lat.} \times \text{col. dec.}$; therefore, if ra and *col. dec.* be constant, Or varies as *tan. lat.* Also, the radius of projection must vary inversely as the cosine of the latitude.

Having determined the situation of the ellipse for any one latitude, in respect to the centre of projection, as the ellipses for all latitudes are similar, if the declination be given, we may make use of the same ellipse for all latitudes, only by altering Or in a proper ratio; for, if ra and the declination remain constant, rO varies as the tangent of latitude. Hence, take $rO : rO'$ as the tangent of the latitude for which the projection was made: tangent of any other latitude, and O' will be the centre of projection, whose radius is also known; and $ambn$ is the ellipse for that latitude.

Let e be any position of the given place, and join eO ; then the angle under which EO appears at the sun is the sun's horizontal parallax; also the angle under which eO appears at the sun must be the parallax in altitude at the point e , for the sun being vertical to O , the arc corresponding to eO is the zenith distance of the sun at the given place, and eO is the line of that arc from the nature of the projection; but the hor. parallax: parallax at any altitude: $rad.$: sine of the zenith distance: $OE:Oe$; hence if OE represent the horizontal parallax, Oe will represent the parallax in altitude at e . Also as e represents the zenith of the given place, eO represents the vertical circle passing through the sun. The use of this projection is to construct the phases and times of a solar eclipse, as we shall now proceed to explain.

Let S (fig. 87.) be the centre of the sun, π the enlightened hemisphere of the earth, which we must conceive to be perpendicular to SC ; draw SD , SV , tangents to two opposite points of the earth, and let $ambn$ be the apparent ellipse described by any point m on the earth's surface; let OC be the distance of the moon from the earth, and $vd, a'm'b'u'$ be the projection of $VD, ambn$ upon a plane at the moon perpendicular to VO , to an eye at S , and $a'm'b'u'$ will be the apparent motion of the centre of the sun at S to the spectator describing $ambn$. The curve $a'm'b'u'$ may be considered as an ellipse; for the angle DSC being only $8\frac{1}{2}''$, DS, CS may be reckoned as parallel, and therefore the projection of DV upon a plane parallel to it may be considered as an orthographic projection, and consequently the two figures may in all respects be considered as similar. Let LM be the orbit of the moon; then if we know at any time the point of the ellipse $ambn$ where the spectator is, we know the corresponding point where the centre of the sun is in the ellipse $a'm'b'u'$; if therefore we determine at the same time the point where the moon is in its orbit LM , we shall know the apparent situation of the moon in respect to the sun. Hence if we find two points, one in the ellipse $a'm'b'u'$ where the centre of the sun is, and another in LM where the centre of the moon is at the same time, and about these centres, with radii equal to the apparent semi-diameters of the sun and moon, we describe two circles, they will represent the apparent situations of the two discs. If that of the moon fall upon the sun, it shews how much the sun is eclipsed at that instant. Now the angle $Ov = COV - OSV$, that is, the radius of projection is equal to the difference of the horizontal parallaxes of the moon and sun. The projection Oe' of Ce is the parallax in altitude of the moon from the sun, supposing the moon to be at the same altitude as the sun; for the radius Ov represents the difference of the horizontal parallaxes of the sun and moon, or the horizontal parallax of the moon from the sun; and as the parallax of each varies as the sine of the apparent zenith distance; the distance, the difference of the parallaxes must vary as the sine of their common apparent zenith distance; hence $Ov:Oe'$: difference of the horizontal parallaxes: difference of the parallaxes at their common apparent altitude; therefore, if Ov represent the third term, Oe' will represent the fourth. In an eclipse of the sun, therefore, this will be nearly true, but not accurately so, except when the sun and moon are at the same altitude. The place of the pole of the earth is here supposed to be fixed during the time of the eclipse, and consequently the earth is supposed to be immovable for that time; the sun's declination is also supposed to be constant for the same time; but as these circumstances do not take place, the projected path of the spectator will not be accurately an ellipse. M. de la Caille observes, that in this projection, all the errors arising from the finite distances of the sun and moon are

supposed to be compensated, by making the semi-diameter of the projection equal to the difference of their horizontal parallaxes; whereas only a part of the lines should be diminished in that ratio. The sun also not being at an infinite distance, the projection will not be an accurate ellipse. The spheroidal figure of the earth is also here not considered. All these circumstances tend to render the method of determining the phases of an eclipse by this construction subject to a certain degree of inaccuracy; but if the construction be made upon a large scale, it will be sufficiently accurate, when we only want to predict an eclipse. If S be a fixed star, the same construction will give the time of its occultation by the moon. In this case, as the fixed star has no parallax, the radius of projection is equal to the horizontal parallax of the moon.

To calculate an Eclipse of the Sun for any particular Place.

Having determined that there will be an eclipse somewhere upon the earth, compute, by the astronomical tables, the true longitudes of the sun and moon, and the moon's true latitude, at the time of mean conjunction; find also the horary motions of the sun and moon in longitude, and the moon's horary motion in latitude; and compute the time of the ecliptic conjunction of the sun and moon, in the same manner as the time of the ecliptic opposition was computed. At the time of the ecliptic conjunction, compute the sun's and moon's longitude, and the moon's latitude; find also the equatorial horizontal parallax of the moon from the tables of the moon's motions, and reduce it to the horizontal parallax for the given latitude, from which subtract the sun's horizontal parallax, and you get the horizontal parallax of the moon from the sun; reduce also the apparent latitude of the place on the spheroid to the latitude on a sphere.

To this reduced latitude of the place, and the corresponding horizontal parallax of the moon from the sun, (which we here use instead of the horizontal parallax of the moon, as we want to find what effect the parallax has in altering their apparent relative situations), at the time of the ecliptic conjunction, compute the moon's parallax in latitude and longitude from the sun; the parallax in latitude applied to the true latitude gives the apparent latitude (L) of the moon from the sun; and the parallax in longitude shews the apparent difference (D) of the longitudes of the sun and moon.

Let S be the sun, (fig. 88.) EC the ecliptic; take $SM = D$, draw MN perpendicular to MS , and take it = L , then N is the apparent place of the moon, and $SN = \sqrt{D^2 + L^2}$ is the apparent distance of the moon from the sun.

If the moon be to the east of the nonagesimal degree, the parallax increases the longitude; if to the west, it diminishes it, hence if the true longitudes of the sun and moon be equal, in the former case the apparent place will lie from S towards E , and in the latter towards C . To some time, as an hour, after the true conjunction if the apparent place be towards C , or if the moon be to the west of the nonagesimal degree; or before the true conjunction if the apparent place be towards E , or if the moon be to the east of the nonagesimal degree, find the sun's and moon's true longitude, and the moon's true latitude, from their horary motions; and at the same time compute the moon's parallax in latitude and longitude from the sun; apply the parallax in latitude to the true latitude, and it gives the apparent latitude (l) of the moon from the sun: take the difference of the sun's and moon's true longitude, and apply the parallax in longitude, and it gives the apparent distance (d) of the moon from the sun in longitude. From S set off $SP = d$, and to EC erect the perpendicular PQ equal to l , and Q is the apparent place of the moon at one hour from the true conjunction; and $SQ = \sqrt{d^2 + l^2}$ is the apparent distance of the moon

moon from the sun; draw the straight line NQ , and it will represent the relative apparent path of the moon, considered as a straight line, in general it being very nearly so; its value also represents the relative horary motion of the moon in the apparent orbit, the relative horary motion is longitude being MP .

The difference between the moon's apparent distance in longitude from the sun at the time of the true ecliptic conjunction, and at the interval of an hour, gives the apparent horary motion (r) in longitude of the moon from the sun; the difference (D) between the true longitude at the ecliptic conjunction, and the moon's apparent longitude is the apparent distance of the moon from the sun in longitude at the true time of the ecliptic conjunction; hence $r : D :: 1$ hour : the time from the true to the apparent conjunction, consequently we know the time of the apparent conjunction. To find whether this time is accurate, we may compute (from the horary motions of the sun and moon) their true longitudes, and the moon's parallax in longitude from the sun, and apply it to the true longitude and it gives the apparent longitude, and if this be the same as the sun's longitude, the time of the apparent conjunction is truly found; if they be not the same, find from thence the true time, as before. To the true time of the apparent conjunction, find the moon's true latitude from its horary motion, and compute the parallax in latitude, and you get the apparent latitude at the time of the apparent conjunction. Draw SA perpendicular to CE and equal to this apparent latitude; then the point A will probably not fall in NQ ; first let it fall in QN , to which draw SB perpendicular, and NR parallel to PM . Then knowing $NR (= PM)$, and $QR (= QP \sim MN)$, we have

$$NR : RQ :: \text{rad.} : \tan. \angle QNR, \text{ or } ASB \\ \text{Sin. } \angle QNR : \text{rad.} :: QR : QN$$

The time of describing NQ in the apparent orbit being equal to the time from M to P in longitude, NQ is the horary motion in the apparent orbit.

$$\text{Rad.} : \text{fin. } ASB :: AS : AB. \\ \text{Rad.} : \text{cof. } ASB :: AS : SB.$$

At the apparent conjunction the moon appears at A , which time is known; when the moon appears at B , it is at its nearest distance from the sun, and consequently the time s that of the greatest obscuration, (usually called the time \circ of the middle,) provided there is an eclipse, which will always be the case when SB is less than the sum of the apparent semi-diameters of the sun and moon. If therefore it appears that there will be an eclipse, we proceed thus to find its quantity, and the beginning and end. As we may consider the motion to be uniform, $QN : AB ::$ the time of describing NQ : the time of describing AB , which added to or subtracted from the time at A , (according as the apparent latitude is decreasing or increasing,) gives the time of the greatest obscuration. Or instead of taking QN , and the time of describing it, we may take AN and the corresponding time, which will be more accurate.

From the sum of the apparent semi-diameters of the sun and moon subtract BS , and the remainder shews how much of the sun is covered by the moon, or the parts deficient; hence, $\text{femid. } \odot : \text{parts deficient} :: 6 \text{ digits} : \text{the digits eclipsed}$. If SB be less than the difference of the semi-diameters of the sun and moon, and the moon's semi-diameter be the greater, the eclipse will be total; but if it be the less, the eclipse will be annular, the sun appearing all round the moon; if B and S coincide, the eclipse will be central.

Let A fall out of QN ; and to increase the accuracy,

near to the apparent conjunction, that is, within 10 or 15 minutes, calculate the apparent longitude mS of the moon from the sun, and the apparent latitude mn ; draw nr parallel to Sm ; and in the triangle Anr , find the angle Anr which is equal to ASB , and compute SB , AB as before. But except in cases where very great accuracy is required, this is unnecessary. If NQ were a perfect straight line, the first operation would give the correct values of AB , BS . Kepler, in an eclipse in 1598, found a curvature of more than $3'$ in three hours, because the moon was very near the nonagesimal. In the eclipse in 1764, M. de la Lande found a curvature of $20'$, but he does not say in what time. It is owing to this circumstance, that is, the curvature of NQ , that it is necessary to find another point near to A , in order to determine accurately the values of AB , SB . Having determined the value of SB , and the time of the greatest obscuration, we thus find the beginning and end.

Produce, if necessary, QN , and take SV , SW equal to the sum of the apparent semi-diameters of the sun and moon, at the beginning and end respectively: then $BV = \sqrt{SV^2 - SB^2}$ (B being now supposed in QN), and $BW = \sqrt{SW^2 - SB^2}$; then to find the times of describing these spaces, say, as the hourly motion of the moon in the apparent orbit, or NQ : $BV :: 1$ hour : the time of describing BV ; and NQ : $BW :: 1$ hour : the time of describing BW , which times respectively subtracted from and added to the time of the greatest obscuration, give nearly the times of the beginning and end. But if accuracy be required, this method will not do; for it supposes VW to be a straight line, which supposition will cause errors, too considerable in general to be neglected, and will never do where great accuracy is required. It may, however, always serve as a rule to assume the time of the beginning and end. Hence it follows, that the time of the greatest obscuration at B , is not necessarily equi-distant from the beginning and end.

If the eclipse be total, take Sv , Sw equal to the difference of the semi-diameters of the sun and moon, and then $Bv = Bw = \sqrt{Sv^2 - SB^2}$, from whence we may find the times of describing Bv , Bw , as before, which we may consider as equal, and which applied to the time of the greatest obscuration at B , give the time of the beginning and end of the total darkness.

To find more accurately the time of the beginning and end of the eclipse, we must proceed thus (*fig. 89*.) At the estimated time of the beginning, find, from the horary motions, and the computed parallaxes, the apparent latitude MN of the moon, and its apparent longitude MS from the sun, and we have $SN = \sqrt{SM^2 + MN^2}$, and if this be equal to the apparent femid. \odot + femid. \odot (which sum call S) the estimated time is the time of the beginning; but if SN be not equal to S , assume (as the error directs) another time at a small interval from it, before, if SN be less than S , but after, if it be greater; to that time compute again the moon's apparent latitude mn , and apparent longitude Sm from the sun, and find $S_n = \sqrt{Sm^2 + mn^2}$; and if this be not equal to S , proceed thus; as the difference of S_n and SN : the difference of S_n and $SL (= S)$: the above assumed interval of time, or time of the motion through N_n : the time through nL , which added to or subtracted from the time at n , according as S_n is greater or less than SL , gives the time of the beginning. The reason of this operation is, that as N_n , nL are very small, they will be very nearly proportional to the differences of SN , S_n , and SL . But as the variation of the apparent distance of the sun from the moon is not exactly in proportion to the variation of the differences of the apparent longitudes and latitudes, in cases where the utmost

ECLIPSE.

utmost accuracy is required, the time of the beginning thus found (if it appear to be not correct) may be corrected, by assuming it for a third time, and proceeding as before. This correction, however, will never be necessary, except where extreme accuracy is required in order to deduce some consequences from it. But the time thus found is to be considered as accurate, only so far as the tables of the sun and moon can be depended upon for their accuracy; and the best lunar tables are subject to an error of 30" in longitude, which, in this eclipse, would make an error of about a minute an half in the time of the beginning and end. Hence accurate observations of an eclipse, compared with the computed time, furnishes the means of correcting the lunar tables, as will be afterwards explained. In the same manner, the end of the eclipse may be computed.

Example.—To compute the Times of the Solar Eclipse on April 3, 1791; for the Royal Observatory at Greenwich.

The time of the mean conjunction is April 3, 2^h 58^m 15^s mean time, at which time we find

Mean long. of the sun	0 ^h 11 ^m 51 ^s 16 ^u
Long. of the moon's desc. node	0 22 14 44
	0 10 23 28
Mean long. of ☉ from α's node	0 10 23 28

Hence there must be an eclipse somewhere upon the earth.

To the mean time of the new moon, compute the sun's and moon's true longitudes, and they will be found to be 0^h 13^m 47^s 43^u, and 0^h 14^m 49^s 24^u; compute also the moon's true latitude, and it will be found to be 38^m 49^s N. descending. At the same time, the sun's horary motion is found to be 2^m 28^s, the moon's horary motion in longitude is 30^m 12^s, and in latitude 2^m 46^s decreasing; and hence the moon's horary motion in longitude from the sun is 27^m 44^s.

By proceeding as before directed, we find the mean time of the ecliptic conjunction of the sun and moon to be 3^h 0^m 48^s, from which subtract 3^m 18^s the equation of time, and it gives the apparent time 3^h 0^m 41^s 30^u; at which time, the sun's and moon's longitude in the ecliptic is 0^h 13^m 42^s 14^u; and the moon's true latitude is 44^m 59^s N. descending. The horizontal parallax of the moon is 54^m 46^s, and of the sun, 9^s; hence the horizontal parallax of the moon from the sun is 54^m 37^s; therefore the moon's parallax in longitude from the sun is — 20^m 56^s, and its parallax in latitude from the sun is — 33^m 44^s; hence — 20^m 56^s is the apparent distance of the moon from the sun in longitude; also the apparent latitude from the sun is 11^m 15^s north.

As the moon is to the west of the nonagesimal degree, assume 1 hour after, or 3^h 1^m 41^s 30^u, at which time (from the horary motions of the sun and moon) the sun's true longitude is found to be 0^h 13^m 44^s 42^u, the moon's true longitude on the ecliptic 0^h 14^m 12^s 26^u, and true latitude 42^m 13^s north descending. The moon's parallax in latitude is — 30^m 41^s; hence the moon's apparent latitude is 11^m 32^s; also its parallax in longitude from the sun is — 28^m 50^s; but the moon's true longitude exceeds the sun's by 0^m 27^m 44^s; therefore the apparent distance of the moon from the sun in longitude is — 1^m 6^s. Hence,

$$\begin{aligned} \text{Moon's apparent dist. in long. at } 3^h 41^m 30^s &= -20^m 56^s \\ &\text{at } 4^h 1^m 30^s = -1^m 6^s \end{aligned}$$

$$\text{Apparent hor. mot. } \alpha \text{ from } \odot \text{ in long. } \quad 19^m 50^s = \text{MP.}$$

Hence 19^m 50^s : 20^m 56^s :: 1 hour : 1^h 3^m 20^s, which added to the time of the true conjunction 0^h 41^m 30^s, gives 1^h 44^m 50^s, the time of the apparent conjunction. Also the apparent horary motion in latitude is 17^m = RQ; hence QN is very nearly equal to MP.

At this time (from the horary motions) the sun's true longitude is found to be 0^h 13^m 44^s 50^u, the moon's 0^h 14^m 14^s 7^u, and the moon's true latitude 42^m 4^s; hence the moon's true longitude is greater than the sun's by 20^m 17^s. The moon's parallax in latitude from the sun is — 30^m 32^s, and in longitude — 29^m 15^s; hence the moon's apparent latitude is 11^m 32^s north; also the apparent longitude from the sun is 29^m 17^s — 29^m 15^s = 2^s, which is what the moon's apparent longitude exceeds the sun's true longitude.

This difference shews the apparent conjunction, found above, to be very nearly true; and to get it accurate, say, 19^m 50^s : 2^s :: 1 hour : 6^s, which (as the moon's apparent longitude is the greater) subtracted from 1^h 44^m 50^s gives 1^h 44^m 44^s, the true time of the apparent conjunction, at which time the moon's apparent longitude is 0^h 13^m 44^s 50^u, the same as the sun's true longitude, that not having sensibly varied in 6^s of time. The apparent latitude is 11^m 32^s. 25. Now at 1^h 41^m 30^s the moon's apparent distance in longitude from the sun has been shewn to be 1^m 6^s; and at 1^h 44^m 44^s the longitude of the sun, and the moon's apparent longitude are equal; therefore in 3^m 14^s the apparent motion of the moon from the sun was 1^m 6^s = 66^s; let this be Sm, or nr; also at 1^h 41^m 30^s, the apparent latitude mn = 11^m 32^s, and at 1^h 44^m 44^s it was 11^m 32^s. 25 = SA; therefore Ar = 0^m. 25. Hence,

$$66^s : 0^m.25 :: \text{rad.} : \tan. Anr, \text{ or } SAB = 13^m 1^s.$$

As the angle Anr is so very small, we may take An = rn = 66^s without any sensible error; and for the same reason SB may be taken = SA = 11^m 32^s.

$$\text{Rad. : sin. } 13^m 1^s :: 11^m 32^s : AB = 2^m.6$$

Hence An = 66^s : AB = 2^m.6 :: 3^m 14^s : 8^m the time through BA, which taken from 1^h 44^m 44^s gives 1^h 44^m 36^s the time of the greatest obscuration at B.

The moon's horizontal semi-diameter is 14^m 56^s, and its altitude at the time of the greatest obscuration (determined by a globe, which is sufficiently near for this purpose) is about 38^m; hence the augmentation of the diameter is 9^m, consequently the apparent semi-diameter of the moon is 15^m 5^s, which added to 15^m 59^s the sun's semi-diameter, gives 31^m 4^s, from which subtract SB = 11^m 32^s, and the remainder is 19^m 32^s the parts deficient; hence 15^m 59^s : 19^m 31^s :: 6 digits : 7^m 19^s 57^u the digits eclipsed at the time of the greatest obscuration.

To find the time of the beginning, we must first get the time nearly. The value of SB = 11^m 32^s = 692^u; and as the apparent semi-diameter of the moon is now 15^m 6^s, we have SV = 31^m 5^s = 1865^u; hence BV = 1732^u. Now as MP is, in this case, nearly equal to QN, we may, for the purpose we here want it, assume the apparent horary motion of the moon from the sun in the apparent orbit equal to that in longitude, which is 19^m 50^s = 1190^u; hence 1190^u : 1732^u :: 1 hour : 1^h 27^m 20^s, which subtracted from 1^h 44^m 36^s (the time at B) gives 0^h 17^m 16^s the time of the beginning, nearly. Let us therefore assume the beginning at 0^h 17^m, at which time we find (from the horary motions of the sun and moon) the sun's true longitude to be 0^h 13^m 41^s 15^u, and the moon's 0^h 13^m 39^s 55^u, whose difference is 1^m 20^s their true distance in longitude; but the moon's parallax in longitude is — 17^m 45^s; hence their apparent distance in longitude is 29^m 5^s = 1745^u. At the same time the moon's true latitude is 42^m 7^s, and its parallax in latitude — 35^m 10^s; hence the apparent latitude of the moon from the sun is 10^m 57^s; therefore SN = $\sqrt{1745^2 + 657^2} = 1864^u = 31^m 4^s$, which being less than 31^m 5^s shews that the eclipse is begun.

Let us next assume 0^h 16^m; and by proceeding in the same manner, we find SN = 1883^u = 31^m 23^s; therefore the eclipse is not begun.

Hence

Hence $31' 23'' - 31' 4'' = 19''$; $31' 5'' - 31' 4'' = 1'' :: 1 \text{ minute} : 3''$, which subtracted from $0^h 17'$, gives $0^h 16' 57''$ for the beginning of the eclipse.

If to $1^h 44' 36''$ we add $1^h 27' 20''$, we have $3^h 11' 56''$; we will therefore assume $3^h 12'$ for the end; and by proceeding as before, we find the apparent distance of the moon from the sun in longitude to be $30' 37''$, and the moon's apparent latitude $16' 48''$; hence the moon's apparent distance from the sun is $\sqrt{1837^2 + 648^2} = 1948'' = 32' 28''$; but the sum of the apparent semi-diameters of the sun and moon is now $31' 2''$; consequently the eclipse is ended.

Let us next assume the time $3^h 6'$, and the apparent distance of the moon from the sun in longitude is $28' 28''$, and in latitude $10' 55''$; hence the moon's apparent distance from the sun is $\sqrt{1708^2 + 655^2} = 1829'' = 30' 29''$, therefore the eclipse is not ended.

Hence $32' 28'' - 30' 29'' = 1' 59''$; $31' 2'' - 30' 29'' = 33''$ is $6' : 1' 39''$, which added to $3^h 6'$, gives $3^h 7' 39''$ for the end.

Hence at the Royal Observatory at Greenwich, the tables give the time of the eclipse on April 3, 1794,

Beginning	-	$0^h 16' 57''$	} apparent time.
Greatest obscuration	+	$4 36'$	
End	-	$3 7 39$	
Digits eclipsed	-	$7^d 16' 57''$	

If it be required to compute the eclipse for any other place, instead of the latitude of Greenwich, use the latitude of the place; and reduce the apparent time at Greenwich to the apparent time at the place, according to the difference of the meridians.

To find what point of the sun's limb will first be touched by the moon, let P (*fig. 90.*) be the pole of the ecliptic ES, Z the zenith, S, M, the centres of the sun and moon when their limbs are in contact at a, and draw MD perpendicular to E S. PZ is the altitude of the nonagesimal degree, and PZS is the sun's distance from that point, both which are found in the computation of the parallax; also MD is the apparent latitude of the moon; hence,

$$\begin{aligned} \text{Rad.} : \tan. PZ :: \sin. SPZ : \tan. PSZ \\ \text{Tan. SM} : \text{rad.} :: \tan. DS : \text{cof. DSM} \end{aligned}$$

If L be the longitude of the nonagesimal degree, then ZSD = $90^\circ - PSZ$; when the sun's longitude is between L and L + 180° ; otherwise, ZSD = $90^\circ + PSZ$; and ZSD + MSD (according as the moon's visible latitude is south or north) gives ZSM, the distance of the point of the limb of the sun first touched by the moon from the highest point of the sun's disc.

In this eclipse, PZ = $50^\circ 7'$, and SPZ = $25^\circ 16'$; hence PSZ = $27^\circ 31'$, which, in this case, added to 90° , gives $117^\circ 31' = ZSD$; also DSM = $20^\circ 42'$, which, (as the moon's apparent latitude is north) subtracted from $117^\circ 31'$, gives ZSM = $96^\circ 21'$, the moon's distance from the zenith of the sun at the beginning of the eclipse. In like manner, the distance at the middle and end of the eclipse may be found, and thence the apparent path of the moon over the sun's disc in respect to the horizon may be described.

In the computation of this eclipse, the moon's true latitude and longitude was at first computed from the tables, and afterwards determined from the horary motions; but as the horary motions may be subject to a small variation in the duration of an eclipse, in cases where the utmost accuracy is required, the true latitude and longitude should be computed every time from the tables; in such cases, the decimals of the seconds should also be taken into consideration, which in this example were omitted. When we want only to predict an eclipse, the method here practised will always be sufficiently accurate, the error being always very small,

compared with the error to which the tables are subject; which may, at its maximum, be $30''$ in longitude. We have followed the same method in computing the occultation of a fixed star by the moon; that computation, therefore, may, if necessary, be rendered more correct in the same manner.

To construct a Solar Eclipse by the Principles of Projection.

According to this projection, the apparent eclipse described by any point on the earth's surface, to any eye at the centre of the sun, is projected upon a plane at the moon perpendicular to a line joining the earth and sun; and the point of the ellipse of projection, corresponding to any point of the other ellipse where the spectator is, is the point where the centre of the sun appears to the spectator. The centre of projection is in the ecliptic. If the lunar orbit be properly laid down and divided, shewing where the centre of the moon is at any time, we shall then have the relative situation of the centres of the sun and moon at any time seen from the given place of the spectator. From these principles of projection, we thus construct the solar eclipse which we have here calculated; assuming such elements as are necessary, from that calculation.

Take a radius OE (*fig. 61.*) equal to $54' 37''$, the difference of the sun's and moon's horizontal parallaxes, and divide it into minutes, and describe the semi-circle EGC representing half the circle of projection, EOC representing the ecliptic, to which draw OG perpendicular. Find P, the projected north pole; from the scale OE, take $Or = 54' 37'' \times \sin. \text{lat.} \times \text{cof. dec.}$ and in a line perpendicular to Or set off both ways $r6 = b \times \text{cof. lat.}$ and $rm = rn = b \times \text{cof. lat.} \times \sin. \text{dec.}$ and describe the ellipse $m6n6$, and divide it into hours; and then subdivide these hours which you will want to make use of, as far as you conveniently can for the size of the figure. From the scale take Ov equal $44' 59''$, the moon's true latitude north descending at the time of the ecliptic conjunction, and draw $L\ vM$, making an angle with Ov equal to $84^\circ 18'$, the complement of the angle which the relative orbit makes with the ecliptic, on the left side, if the latitude be north or south decreasing, and on the right, if increasing; in this example it is on the left side; and $L\ vM$ will represent the moon's relative orbit. Mark upon the moon's orbit, at the point v , $41' 30''$, that being the time after 12 o'clock at which the true ecliptic conjunction happens; and with an extent = $27' 52''$, the horary motion of the moon from the sun in its relative orbit, set off the hours each way from v , and subdivide them into minutes, or as far as the size of the figure will permit. Now to find the time of the middle of the eclipse, take the compass, and find, by trial, what two corresponding times, as at x and y , upon the ellipse and moon's orbit, are nearest together, which will give the time of the greatest obscuration, because the centres of the sun and moon are then at the least distance. To find the time of the beginning, take, with the compass, from the scale, an extent equal to $31' 5''$, the sum of the semi-diameters of the sun and moon, and by trial find two corresponding times, as at s and t , at that distance, and it gives the time of the beginning; and if you find two corresponding times, as at y and w , at the distance $31' 2''$, the sum of the semi-diameters at the end, it gives the time of the end; or you may omit the variation of the diameter of the moon in the interval. For the beginning must be when the centres of the sun and moon arrive at the distance of the sum of their semi-diameters; and the end must be when they have receded till they have got to that distance. To find the digits eclipsed at the greatest obscuration, take eu from the scale, and say, $ze : eu :: 6 \text{ digits} : \text{digits eclipsed}$. To find the digits eclipsed at any other time, take, with the compass, the interval at that time on the ellipse and on the moon's orbit,

and

and apply it to the scale, and then say, $z c$: that distance :: 6 digits: the digits eclipsed.

If by taking the interval of two corresponding times, it appears that it is always greater than the sum of the semi-diameters of the sun and moon, it shews that there will be no eclipse at that place.

From this construction, the position of the moon in respect to the zenith of the sun's disc may be found, and thence the apparent path of the moon over the sun in respect to the horizon. For a line drawn from O (fig. 92.) to any point of the eclipse, where the spectator is, being vertical, from the principles of the projection, the angles $O t s$, $O z x$, $O w y$, shew the angular distance about the centre of the sun from its vertex, to the centre of the moon at the beginning, middle, and end of the eclipse. Hence, let C be the centre of the sun $Z b d a$, Z its zenith; and make the angles $Z C P$, $Z C Q$, $Z C R = O t s$, $O z x$, $O w y$ respectively; take $C P$, $C R$ equal to the sum of the semi-diameters of the sun and moon, $d C s$ = the digits eclipsed, and $S Q = a P$, and with the centres P , Q , R , and radii $P a = Q s = R b$ equal to the semi-diameter of the moon describe three circles, and they will represent the situation of the moon at the beginning, middle, and end of the eclipse, in respect to the vertex Z of the sun, and consequently in respect to the horizon; hence, if we describe a circle through P , Q , R , and with the same radius describe $r s t$ parallel to it, it must very nearly represent the boundary of the eclipse, or of the extreme part of the moon's limb as it passes over the sun, in respect to the horizon.

The eclipse may also be thus calculated from the projection. Assume the time at t of beginning, as determined by the construction; draw $t c$ perpendicular to $O P$, and join $O t$, $O s$. The time from t to m being given, convert it into degrees a' ; then $\sin. a' \times r b = t c$, and $\cos. a' \times r m = r c$, but $O r$ is known, hence $O c$ is known; therefore, in the right-angled triangle $O c t$, we know $O c$, $c t$, to find $c O t$, and $O t$; but $P O v$ is given, therefore, $c O t + P O v = t O v$ is known; also $O v$ and the angle $O v s$ are known by the construction; and the time from t to v being given, and also the moon's relative horary motion in $L M$, we know $v s$; hence, in the triangle $O v s$, we know $O v$, $v s$ and the angle $O v s$, to find $O s$, and the angle $v O s$; hence, we find $t O s = t O v + v O s$; and lastly, in the triangle $t O s$, we know $t O$, $O s$ and the angle $t O s$, to find $t s$, and if this be equal to the sum of the semi-diameters of the sun and moon, the assumed time is true; if it be not equal to the sum, assume another time for the beginning, and find another value of $t s$. In like manner we may find the end. But this method is not subject to the same accuracy as the method of calculation which we have already given.

Sir I. Newton supposes that the aberration of rays in the focus of a telescope makes the image appear greater than it ought; and hence different telescopes will give different measures of the sun's diameter, and consequently make the eclipse appear to begin at different times. That telescope which gives the diameter the least, is the most perfect instrument. The excellent transit telescope at Greenwich makes the diameter of the sun less by $6''$ than that given by Mayer in his tables, as Dr. Maskelyne has found by his observations. The diameter of the sun assumed in these calculations has, therefore, been taken $6''$ less than that which Mayer determined. M. du Séjour supposes that the rays of light coming from the sun are inflected as they pass by the moon, which he attributes to the refraction which they suffer in passing through the moon's atmosphere; on this account the apparent contact of the limbs will not take place so soon as

it otherwise would; this would be the same as a diminution of the moon's diameter: which of these hypotheses ought to be admitted, M. du Séjour endeavour'd to determine from the observations of Mr. Short, on the solar eclipse, April 1, 1764, upon the distance of the horns of the moon, but he could deduce nothing satisfactory from thence. He supposed the inflection $3''.291$, and the diameter of the moon to be diminished by the same quantity, and calculated upon each supposition a great many distances of the horns, and compared them with the observed distances; but he could not decide between the two hypotheses. An inflection of $1''.8$ and a diminution of $1''.5$ of the semi-diameter, he found would satisfy some observations, and he seem'd to think this conclusion most likely to be nearest the truth; but he came at last to no determination upon the subject. All the requisite observations seem not to be capable of being made to that degree of accuracy which is necessary to settle so nice a matter. M. du Séjour, therefore, propos'd the following method to determine whether the rays of light passing by the limb of the moon suffer any deviation. Take a telescope mounted upon a polar axis, with a wire micrometer annexed to it. When two stars come into the field of view together, and one of them is to be eclipsed by the moon, open the wires and bring one star upon one of the wires, and the other star upon the other, and thus follow the stars until one of them be eclipsed, and at the instant before it disappears, observe whether its distance from the other star is changed, that is, whether it be off the wire, the other star remaining upon its wire; if this be found to be the case, the rays must have suffered a deviation. (Traité Analytique, p. 420.) We do not find that an observation of this kind has been ever made.

To trace out the Path on the Surface of the Earth, where the Eclipse will be central, or for any Number of Digits.

Let $E A C D$ (fig. 93.) be the enlightened hemisphere of the earth, O the centre of the disc, or that point to which the sun is vertical; $E O C$ the plane of the ecliptic, $O G$ perpendicular to it; P the north pole; join $P O$, and let $L M$ represent the path of the centre of the penumbra, conceived to be upon the plane into which the disc would be orthographically projected; then, from the nature of that projection, the angles at O upon the surface will be equal to the angles into which they are projected. Now, the place upon which the centre of the moon is projected, is manifestly that point on the earth where the eclipse is central, because the projection is made by lines drawn to the centre of the sun. Let Z be the projected centre of the moon at any time, or the real centre of the penumbra, and $P B$ any given meridian. Now, we know $O v$ the moon's latitude at the time of conjunction, and the angle $O v Z$; and as the time, when the centre of the penumbra is at Z , is given, the time through $Z v$ is known, and the relative horary motion of the moon being known, $v Z$ will be known; hence we can find $Z O$, and the angle $Z O v$; find the angle $P O v$, and we shall have the angle $P O Z$. Now consider $P O$ and $Z O$ as two circles upon the earth's surface, then the angle $P O Z$ between them is equal to the angle $P O Z$ of projection, and therefore known; also the arc $P O$ is the complement of the sun's declination; and to find the arc $Z O$, we must consider $Z O$ in the projection to be the fin of the arc projected; hence the arc $Z O$ is that whose sine is to radius as $O Z$ to $O A$, therefore we know the sine of the arc $Z O$, and consequently we get $Z O$ itself; hence, in the spherical triangle $O P Z$, we know $P O$, $O Z$, and the angle $P O Z$, to find $P Z$ the complement of the latitude of the place where the eclipse is central. Find also the angle

OPZ; then the time at the meridian PB being known, the angle OPB (the sun's distance from the meridian) is known; hence we know the angle BPZ, the longitude of the point Z from the meridian PB; therefore the latitude and longitude of Z being known, the point Z is determined where the eclipse was central at the given time. Make this calculation for every quarter or half hour, for all the time the penumbra is describing de , and you will trace out upon the surface of the earth the path of the centre of the penumbra, or that tract where the eclipse is central. If we bring Z to d , we get the place where the sun rises centrally eclipsed; and if Z be brought to e , we shall find where the sun sets centrally eclipsed. If Z coincide with r , we get the place where the sun is centrally eclipsed upon the meridian. Let y be the centre of the penumbra when it first touches the earth, and x the centre when it leaves the earth, and draw Ov perpendicular to LM. Then, knowing Ov and the angle Ovz , we can find Ov and vOv ; also $Oy = \text{semid. } \odot + \text{semid. penumb. known}$; hence, in the right-angled triangle yOv , we get the angle yOv , and therefore we know yOv ; and POv being already found, we know bOP ; hence, in the triangle bOP , we know bO ($= 90^\circ$), PO , and the angle POb ; hence we find Pb the complement of the latitude of b ; find also $O Pb$, and we get bPB the longitude of b , from the given meridian PB; thus we get the place b where the eclipse first begins at the sun rising. In like manner we get the place a where the eclipse last ends at sun setting.

Example.—In the solar eclipse, which we have here computed, let it be required to find that place upon the earth's surface where the sun is centrally eclipsed at one o'clock, apparent time at Greenwich. In this case, $Ov = 44' 50''$, and the angle $OvZ = 5^\circ 42'$, and as the time at v is $41' 30''$, and the centre of the penumbra is at Z at one o'clock, the time through $vZ = 19' 30''$, which gives $vZ = 9' 33''$; hence $ZO = 35' 59''$, the angle $OZv = 81^\circ 22'$, and $ZOv = 13^\circ 56'$. Now, the radius $OG = 54' 56''$; hence the arc OZ upon the surface (corresponding to its projection = $35' 59''$) = $41^\circ 4'$; also $PO = 84^\circ 30'$, and $POv = 23^\circ 22'$; hence $POZ = 9^\circ 26'$; consequently $PZ = 45^\circ 43'$, the complement of which is $44^\circ 17'$, the latitude of the place; also $ZPO = 8^\circ 51'$; but at one o'clock, apparent time at Greenwich, its meridian BP makes an angle of 15° with PO , Greenwich being upon that meridian at 12 o'clock; hence $BPZ = 23^\circ 51'$ the longitude of the place, west from Greenwich. In like manner may any of the other phenomena be calculated.

Draw OW (fig. 94.) perpendicular to LM, and take $vO = vO$ equal to the sum of the semi-diameters of the sun and moon, and draw dcf , xy parallel to LM; then df and xy will mark out the boundaries of the eclipse, or the places where the limbs of the sun and moon just appear in contact. So that if we take the moon at any place Z, and draw Zr perpendicular to df , and compute the latitude and longitude of the point r in the same manner as we did that of Z in the last article, it will give the place where the limbs of the sun and moon appear in contact outwardly. If we take Zr on the other side of LM, we shall, on that side, get the place where they appear in contact. If we do this for every quarter or half hour, we shall trace the path over the surface of the earth where the limbs of the sun and moon appear in contact, or the boundaries of the eclipse; thus, we can lay down upon the earth's surface that tract over which the penumbra passes. If cv be divided into twelve equal parts, and ck be taken equal to three of them, for instance, and ks be drawn parallel to LM, and the place of r' be computed, it gives the place where the sun will be three digits

eclipsed; and in like manner as before may the tract on the earth's surface be marked out where the sun will appear three digits eclipsed; in the same manner, we may trace out the path for any number of digits. If $va = vb$, and ab be the difference between the apparent diameters of the sun and moon, and va , gb be drawn parallel to LM; then, if the diameter of the moon be greater than that of the sun, the space between va and gb is the limit for the total eclipse; but if the diameter of the sun be the greater, it will be the limit of the annular eclipse. This method of delineating the lines of the phases upon the earth's surface supposes that the apparent nearest distance of the centres of the sun and moon, or of the corresponding horns upon the relative orbit of the moon and upon the eclipse, is in a line perpendicular to the moon's relative orbit; but this is not accurately true, and therefore the delineation cannot be accurate. This line will have different positions at different places for the same phase. M. du Séjour proposes, therefore, to take the mean angle. He found an error of $3^\circ 33' 5$ in longitude, and of $35' 49''$ in time of the contact, for the latitude of $16^\circ 57'$, by supposing it to happen upon a perpendicular to the relative orbit.

M. de la Lande has given the following graphical method. Draw LM on a separate piece of paper, and divide it, so that by moving it you may bring any hour to v . Then, if, for instance, the orbit be moved to the right till the time of falling on v be one hour later than that for which the construction was first made, it is in a proper position for a place 15° to the east of that place. Let pg be any parallel of latitude, and divide it into hours, &c. then move the orbit LM until, with an extent of compass equal to the sum of the semi-diameters of the sun and moon, you can make the points fall on the same hour both on pg and LM, and at the same time that it shall be the shortest distance between any two corresponding hours on pg and LM; then the difference of the hours shewn at v in consequence of the removing of the orbit shews the longitude of the place from that for which the projection was made, and the parallel pg shews the latitude; therefore the place on the earth's surface is determined where the limbs just come into contact, and also the time. This we may repeat for as many parallels of latitude as we please, and thus trace out the curve on the surface of the earth where the limbs just come into contact. In like manner, if we take an extent of compass $\frac{1}{2}$ of the sun's diameter less, we may trace out the path where the sun is one digit eclipsed; and so for any other phase.

But the general phenomena may be much more easily, and with sufficient accuracy, determined by a common globe thus. Bring the sun's place S to the brazen meridian PV (fig. 95.) set the hour index to 12, and bring the sun to the zenith; and from that point on the globe, extend a thread SW perpendicular to the ecliptic EC. Upon a small straight rod LM let there be a moveable circle $adbm$, whose centre r is in the middle of the rod, and let its radius be to the radius of the globe as the semi-diameter of the penumbra is to the horizontal parallax of the moon. Let there be two moveable upright pieces attached to the horizon of the globe, and capable of being fixed at any two points; at a distance Sv equal to the moon's latitude at the time of the ecliptic conjunction, let the rod LM cut the thread in a plane touching the globe at S, and making an angle MvS equal to the angle which the relative orbit makes with a perpendicular to the ecliptic, as before directed; and in this situation let the rod be fixed to the above-mentioned pieces, attached to the horizon; let also LM be divided into time, the time at the point v being that of the ecliptic conjunction; and let the horizon of the globe be fixed exactly parallel

rallei to the horizon; and upon a fine thread ab suspend a small conical weight, with an acute vertex; every thing being thus prepared, we proceed thus; first premising, that the circle $TEVC$ (coinciding with the horizon of the globe) contains all the places where the sun is in the horizon, the western hemisphere containing those where the sun is rising, and the eastern where the sun is setting.

Carry the centre of the penumbra to r where you find, by suspending the line from its periphery, that its projection would just touch the earth at t ; then turn the globe till the index shews the same hour as the point r , and the point t at that time is the place first touched by the penumbra, and the eclipse there begins at sun-rise. Carry the centre of the penumbra to e , a quarter of an hour forwards, for instance, and set the globe again to that time; and with the line find the points x , w , where the projection of the circumference of the penumbra would intersect the circle $TCVE$, and x , w , are two other points where the eclipse begins at sun-rise. By proceeding thus through the western part, we may find as many points as we please, where the eclipse begins at sun-rise, and by drawing a curve through them, we get the tract on the earth's surface, where the eclipse begins at the rising of the sun. But when x comes into the eastern part, we get the places where the eclipse begins at sun-set; consequently the curve passing through them is a continuation of the curve which passes through all the places where the eclipse begins at sun-rising, provided the whole of the penumbra does not fall upon the earth at the middle of the eclipse; that is, if O be the middle of the general eclipse, and OT be perpendicular to LM in the projection, when $OT = R$, is less than the radius (R) of the penumbra. If $OT = R$, the curves touch, and if OT be greater than R , they are separated; because the penumbra then passes over a part of the earth after it leaves the western side before it comes to the eastern, and therefore in that interval the sun is not eclipsed to any part of the circumference $TEVC$.

Draw bra perpendicular to LM , and ac parallel to it; and when w comes to e , the intersection manifestly begins to go back, and the part adb will then cut TCV , and therefore the intersections will shew the points in the horizon where the eclipse ends at sun-set; for the velocity of the penumbra being greater than that of the earth about its axis, the penumbra must leave the point which it then touches. And for this reason the eclipse begins where bta cuts TCV . Hence, as c is a point where the eclipse ceases to begin at sun-rise and begins to end at sun-set, the curve shewing the places when the eclipse begins at sun-rising is continued into the curve, which shews the places where the eclipse ends at sun-rising; and as x and w meet again on the eastern side of the earth, the curves there meet again. When, therefore, $OT = R$ is less than R , (*fig. 96.*) we have a curve. The velocity of the parts of the earth, from its rotation, being greatest towards the equator, the ovals will be more open towards A and B than towards C .

If $OT = R$, (*fig. 97.*) the two ovals touch; but that nearest the pole is double.

If OT be greater than R , (*fig. 98.*) the two ovals will be detached; but if the perpendicular Dz , on LM (in the projection), be less than R , the oval nearest the pole will be double. Two curves $A B$, $C D$, touching the ovals, and formed by the projection of a and b , will shew where the limbs of the sun and moon were in contact.

If LM fall beyond the earth, or if O lie on the other side of T , the curve will be like *fig. 95.* until Dz be greater than R , in which case the curve becomes a simple oval; and when $OT = R$, the oval vanishes. These circumstances, which were given by M. Delambre, appear from this method of delineation.

The projection of ba will give the middle of the eclipse. The western part of TCV , which is cut by ba in the projection, is the point where the eclipse is in the middle at sun-rise; and where the eastern part of the horizon is cut by it, it shews the point where the middle of the eclipse is at sun-set. When a comes to e , the globe being adjusted to that time, e is a point of the former kind, but here the eclipse is only for a moment, or rather there is no eclipse, the moon's limb only touching that of the sun. As the umbra advances, ab will cut TCV at some other point, as w ; to the time denoted by the centre r , adjust the globe, and w is the place upon the earth where the middle of the eclipse is at sun-rising. And thus we may find any number of such places, and draw a curve, as $B D A$, (*fig. 96.*) passing through all the places where the middle of the eclipse is at the rising of the sun. As the line, in this case, must be suspended from ba , it will be more convenient to have the penumbra divided into two parts through ab , so that they may be separated.

To trace out the centre of the penumbra over the earth, bring, by the line, the centre to coincide in the projection with TCV at e , (*fig. 95.*) and adjust the globe to that time, and e will be the place where the centre of the umbra first touches the earth. Carry on the penumbra, a quarter of an hour for instance, and adjust the globe to the time, and project the centre upon the earth, and it gives the point where the eclipse is central at that time. Find thus as many points as you please, and draw a curve through them all, and you get the path of the centre of the penumbra over the earth, shewing all those places where the eclipse was central.

If the penumbra be formed by 12 equidistant concentric wires, the phenomena of any one of the digits may be traced out in the same manner; that is, we can find, for instance, all the places where the sun is three digits eclipsed at its rising and setting, and the tract where the sun is three digits for the time of the eclipse. The globe here used should be one which has the hours marked on the equator.

The method of tracing out the different curves was, we believe, first given by M. de la Caille in his *Astronomy*. M. du Séjour has given an analytical method of laying down the curves in his *Traité Analytique*. But these are matters rather of curiosity than of any real use in astronomy. If we place the circle $ETCV$ perpendicular to the horizon, and vertical to S , a strong lamp be fixed in the principal focus of a double convex lens, so that the rays may be thrown parallel upon the globe and perpendicular to $ETCV$, the shadow of the penumbra will give the points of projection required, instead of the plumb line. Thus we make a common globe answer the purpose of an ecliptaeon, invented by Mr. Ferguson, and described in his *Astronomy*. See **ECLIPSAEON**.

As the analytic method of making astronomical calculations is by many preferred to any other, we subjoin the following formula, which will be found one of the most convenient that has been yet invented.

Let all the points to be considered be referred to three axes, perpendicular to each other, according to the method in use among modern geometers.

Let a line, passing from the centre of the earth to that of the eclipsed planet, be taken for the axis of the y 's; a line perpendicular to the first, in the plane of the ecliptic, for the axis of the x 's, and a third line perpendicular to the two others for that of the z 's. The positive y 's will be directed towards the planet, the positive x 's to the left, following the order of the signs, and the positive z 's, above the plane of the ecliptic, towards the north pole.

Following the example of Dionis du Séjour, a plane perpendicular to the axis of y , should be made to pass through

the centre of the moon. This may be called the plane of projection, and the apparent situation of the centre of the planet, as seen from the place of the observer, is to be determined upon it. This being done, nothing can be more easy than to calculate the apparent distance of the centres, which is the last result of the problem.

If, Let ϕ be the longitude of the planet, ψ its latitude, ϕ' the longitude of the moon, ψ' its latitude: $X, Y,$ and $Z,$ the co-ordinates. Taking the distance of the earth for unity, these equations will be easily found by a simple transformation of the co-ordinates.

$$X = \sin. (\phi' - \phi) \cos. \psi'$$

$$Y = \sin. \psi', \sin. \psi + \cos. \psi', \cos. \psi \cos. (\phi' - \phi)$$

$$Z = \sin. \psi', \cos. \psi - \cos. \psi', \sin. \psi \cos. (\phi' - \phi)$$

It will be seen hereafter, that the value of Y is not required. With regard to the values of X and $Z,$ they will assume this form:

$$X = \sin. (\phi' - \phi) - 2 \sin. (\phi' - \phi) \sin. \psi \frac{1}{2} \psi'$$

$$Z = \sin. \psi (\psi' - \psi) + 2 \sin. \psi \left(\frac{\phi' - \phi}{2} \right) \sin. \psi \cos. \psi';$$

which may be afterwards reduced to this form, which will be found sufficiently approximate:

$$X = (\phi' - \phi) - 2 (\phi' - \phi) \sin. \psi \frac{1}{2} \psi'$$

$$Z = (\psi' - \psi) + 2 \sin. \psi \left(\frac{\phi' - \phi}{2} \right) \sin. \psi$$

And as the terms of the second order will be always very small, they may be taken by inspection in small tables of equations, which are easily calculated. Those which compose table 95, of the collection inserted at the end of the first volume of De La Lande's Astronomy, and which are here given, may be employed; thus these quantities may be obtained by a very simple calculation, or almost without calculation.

2d. If we call r that radius of the earth which passes through the place of the observer, $\alpha,$ the angle which it makes with the plane of $xz, \beta,$ the angle which its projection in the same plane makes with $x; x, y,$ and $z,$ the co-ordinates of the place of the observer, we shall have, by formulas well known,

$$x = r \cos. \alpha \sin. \beta$$

$$y = r \cos. \alpha \cos. \beta$$

$$z = r \sin. \alpha$$

And it is not difficult to imagine, that of these two angles, α and $\beta,$ the first expresses the height of the planet above the horizon, and the second the parallactic angle made by the vertical and the circle of latitude.

3d. If we imagine a visual ray passing from the eye of the observer to the centre of the planet, expressing by ξ and ζ the co ordinates of the point where it meets the plane of projection, respectively parallel to the axes of the x 's and z 's, and by R the distance from the planet to the earth, we shall easily find.

$$\xi = \frac{R - Y}{R - y} x$$

$$\zeta = \frac{R - Y}{R - y} z$$

But calling the horizontal parallax of the moon $p,$ that of the planet $\pi,$ it will be evident that

$$p = \rho$$

$$R = \frac{r}{\pi}$$

Then substituting these values, as well as those of $x, y,$ and $z,$ supposing afterwards $Y = 1,$ and neglecting in the denominator the term $\pi \sin. \alpha$ as very small, compared to unity, we shall find

$$\xi = (\rho - \pi) \cos. \alpha \sin. \beta$$

$$\zeta = (\rho - \pi) \cos. \alpha \cos. \beta, \text{ very simple expressions. If}$$

then the line, which joins the centre of the moon, and the apparent place of the centre of the planet upon the plane of projection, be called $l,$ we shall have $l = \sqrt{[(X - \xi)^2 + (Z - \zeta)^2]}$.

Now this line may be considered as perpendicular to the visual ray of the observer. On the other hand, the distance of the latter from the plane of projection is equal to $Y - y.$ The expression for the apparent distance of the centres then will be $\frac{l}{Y - y}.$ Moreover, let D be the horizontal semi-diameter

of the moon; $\frac{D}{Y - y}$ will be this semi-diameter, augmented for its altitude. Let Δ be the semi-diameter of the planet; the sum of the apparent semi-diameter will be $\frac{D}{Y - y} + \Delta.$

But when this sum becomes equal to the apparent distance, the eclipse will be either at its beginning or end. At each of these two moments $\frac{l}{Y - y}$ will be equal $\frac{D}{Y - y} + \Delta,$ or

multiplying the whole by the denominator $Y - y,$ supposing $Y = 1,$ and substituting the value of $y,$ we shall get $l = D + \Delta - p \Delta \sin. \alpha.$ Now the term $p \Delta \sin. \alpha$ never will exceed $15'';$ it may therefore be taken by inspection of a table. Thus the whole is reduced to the calculation of the quantity $l,$ which expresses the apparent distance of the centres measured on the plane of projection.

To explain better the advantage of this method, it is reduced to a species of table, which may be compared with that given by M. Cagnoli in his Trigonometry.

Let it be required whether at a given moment the eclipse is commenced. Find for this moment

The longitude of the planet	-	-	-	-	-	ϕ
Its latitude	-	-	-	-	-	ψ
Its right ascension	-	-	-	-	-	e
Its declination	-	-	-	-	-	n
Its angle of position	-	-	-	-	-	θ
Its horizontal parallax	-	-	-	-	-	π
Its horizontal semi diameter	-	-	-	-	-	Δ
The longitude of the moon	-	-	-	-	-	ϕ'
Its latitude	-	-	-	-	-	ψ'
Its horizontal parallax	-	-	-	-	-	ρ
Its horizontal semi diameter	-	-	-	-	-	D
The geocentric latitude of the observer's place	-	-	-	-	-	λ
The right ascension of the middle of the heavens	-	-	-	-	-	m
Make $\sin. \alpha = \sin. \lambda \sin. n + \cos. \lambda \cos. n \cos. (m - e)$						

$$\sin. S = \frac{\cos. \lambda \sin. (m - e)}{\cos. \alpha}$$

$$\beta = S - \theta$$

$$\zeta = (\rho - \pi) \cos. \alpha \cos. \beta$$

$$\xi = \zeta \text{ tang. } \beta$$

$$X = \phi' - \phi - 2 (\psi' - \psi) \sin. \psi \frac{1}{2} \psi'$$

$$Z = \psi' - \psi + 2 \sin. \psi \left(\frac{\phi' - \phi}{2} \right) \sin. \psi$$

(Terms of the second order become equal to nothing in eclipses of the sun, and in other cases may be taken by inspection of the little tables.)

$$\text{Tang. } M = \frac{Z - \zeta}{X - \xi}$$

$$l = \frac{X - \zeta}{\cos. M} \text{ Let the sum of the hori-}$$

zontal diameters be $D + \Delta.$ In eclipses of the sun, subtract the small quantity $p \Delta \sin. \alpha,$ which we take by inspection of a table, the remainder compared with the value of l will show whether or not the eclipse is already commenced.

ECLIPSE.

TABLE to be used in calculating Solar Eclipses.

Reduction to a great Circle which is to be subtracted from the Difference of Longitude of the Moon and the Sun, or a Star.

Latitude of the Star which is in Conjunction.

Diff. of Longitude.	Latitude of the Star which is in Conjunction.

4	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0

ECLIPSE.

The greatest number of eclipses that can happen in one year is seven; in which case five are of the sun and two of the moon, as in the year 1787: the least number that can happen is two, and then they are each solar: this happened in 1767, 1781, 1785, and 1792: generally in the space of 18 years there are 70 eclipses, 29 of the moon, and 41 of the sun. According to Cassini no lunar eclipse can happen farther than $14\frac{1}{2}$ from the node, and there will be an eclipse if the distance is less than $7\frac{1}{2}$. Delambre makes the limit $13' 21''$ and $7' 47''$.

The obscurity during a total eclipse of the sun is not quite equal to a very dark night, the stars of the second magnitude, and a few perhaps of the third only appear, if the sun is near the meridian, Venus and Mercury are seen near him in great splendour.

According to M. Séjour, the greatest duration of a total eclipse of the sun is $7' 58''$, and $12' 24''$ of an annular eclipse, but it is not in the places where the eclipse is central that the duration is the longest.

A total eclipse of the sun is a very rare occurrence in a given place. Louis XV. was desirous of knowing how many eclipses would happen in a certain number of years, and it appeared that at Paris, between 1769 and 1900, there would be 59 visible eclipses, without one being total; and one only annular on the 9th Oct. 1847. Very considerable eclipses will happen in England on Oct. 9. 1847; March 17, 1858; Aug. 19. 1887; April 17, 1912; April 8, 1921; Feb. 15, 1961; Aug. 11, 1999.

Since eclipses depend on the position of the sun and moon with respect to the nodes, it is obvious that when they are in the syzygies, and have the same situation with respect to the nodes, the eclipses will return and appear as before. The space of time after which the same eclipses return again is called the period of eclipses. Now as the nodes have a retrograde motion of $10\frac{1}{2}''$ every year, they would pass through all the points of the ecliptic in eighteen years and 223 days, and this would be the regular period of the return of eclipses, if any complete number of lunations were performed in it without a fraction, but this is not the case. However, in 223 mean lunations after the sun, moon, and nodes have been once in a line of conjunction, they return so nearly to the same state again, that the same node which was in conjunction with the sun and moon at the beginning of these lunations will be within $28' 12''$ of the line of conjunction, when the last of these lunations is completed; and in this period there will be a regular return of eclipses, till it be repeated about 40 times, or about 720 years, when the time of the nodes will be $28' \times 40'$ from the conjunction, and will consequently be beyond the ecliptic limits; this is called the Plinian period, or Chaldean era. It contains, according to Dr. Halley, 18 Julian years, 11 days, 7 hours, 43 minutes, 20 seconds; or, according to Mr. Ferguson, $28' 11' 7'' 42' 44''$. In an interval of $557' 21'' 18' 11' 51''$, in which there are exactly 6890 mean lunations, the conjunction or opposition coincides so nearly with the node, as not to be distant more than $11''$. It, therefore, to the mean time of any solar or lunar eclipse, we add this period, and make the proper allowance for the intercalary days, we shall have the mean time of the return of the same eclipse. This period is so very near, that in 6000 years it will vary no more from the truth, as to the restitution of eclipses, than $8\frac{1}{2}$ minutes of a degree.

The curiosity of astronomers has been exceedingly gratified within these few years, by a number of very interesting communications that have been given to the world relative to the state of the Hindu astronomy, and particularly as to their methods of calculating eclipses: it has been observed

in the introductory part of this article, how entirely Cassini seems to have been mistaken in his opinions on this subject.

Some difference of opinion still exists among the learned as to the precise date of the Hindu tables, but all agree that they are very far from being founded on antediluvian tradition.

We are indebted to Mr. Davis for a most intelligent account of the method of calculating eclipses. As it contains much novelty, and throws great light on the system of that very singular race of mankind; we shall conclude this article by subjoining his account of it.

Hindu Computation of an Eclipse.

Let it be premised that the position of the sun, moon, and nodes, by calculation, will on the first of next Vaisakh be as here represented in the Hindu manner, excepting the characters of the signs.

By inspection of the figure, (Plate XII. fig. 99.) and by considering the motion of the sun, moon, and nodes, it appears that, when the sun comes to the sign Tula (Libra) corresponding with the mouth of Cartic, the descending node will have gone back to Aries; and that consequently a lunar eclipse may be expected to happen at the end of the *pur'nima tit'hi* or time of full moon, in that month.

First operation—To find the number of mean solar days from the creation to some part of the *pur'nima tit'hi* in Cartic, of the 4891st year of the Cali Yug.

Years expired of the Calpa to the end of the Satya Yug,	1970784000
Deduct the term of Brahma's employment in the creation,	17064000
<hr/>	
From the creation, when the planetary motions began, to the end of the Satya Yug,	1953720000
Add the Treta Yug,	1296000
Dwaper Yug,	864000
Present year of the Cali Yug,	4890
<hr/>	
From the creation to the next approaching Bengal year,	1955884890
<hr/>	
Or solar months, ($\times 12$)	23470618680
Add seven months,	72
<hr/>	
	23470618680

As the solar months in a Yug, 51840000, are to the intercalary lunar months in that cycle, 1593336, so are the solar months 23470618687, to their corresponding intercalary lunar months 721384977; which added together, give 24192003764 lunations. This number multiplied by thirty, produces 72576010920 *tit'his*, or lunar days, from the creation to the new moon in Cartic; to which add fourteen *tit'his* for the same, to the *pur'nima tit'hi* in that month 72576010934. Then, as the number of *tit'his* in a Yug, 1603000000, is to their difference exceeding the mean solar days in that cycle (called *es'haya tit'hi*) 25082252, so are 72576010934 *tit'his* to their excess in number over the solar days 11356017987, which subtracted, leaves 7144048947, as the number of mean solar days from the creation, or when the planetary motions began, to a point of time which will be midnight under the first meridian of Lanca, and near the time of full moon in Cartic. In the year of the Cali Yug 4891, corresponding with 1196 Bengal style, and with the month of October or November (hereafter to be determined) in the year of Christ 1789. The first day after the creation

being

ECLIPSE.

being *Ravi-war*, or Sunday, divide the number of days by seven for the day of the week, the remainder after the division being two, marks the day *Soma-war*, or Monday.

Second operation.—For the mean longitude of the sun, moon, and the ascending node. Say, as the number of mean solar days in a Maha Yuga is to the revolutions of any planet in that cycle, so are the days from the creation to even revolutions, which reject, and the fraction, if any, turned into lines, &c. is the mean longitude required.

* This longitude, assigned to Bhagalpur, is erroneous; but the error does not in the least affect the main object of the paper.

Third operation.—For the equated longitude of the sun and moon, &c.

1st. *Of the Sun.*

The mean longitude of the sun is 6° 21' 42" 35" 12"; of the apogee 2 17 15, the difference, or mean anomaly, 4° 4' 25" 20"; its complement to 6 lines or distance from the perigee 1° 25' 34' 40", the equation for which is re-

quired. This may either be taken from the foregoing table, translated from Macaranda, or calculated in the manner explained as follows:

$$\begin{aligned} & \text{The sine of } 1^\circ 25' 34' 40'' \text{ is } 2835' 31'' \text{ and } \frac{2825' 31'' \times 20'}{3438} \\ & = 14' 30'' \text{ to be subtracted from the paridhi degrees in fama; } 14^\circ - 14' 30'' = 13^\circ 53' 30'', \text{ the circumference of epi-} \\ & \text{cycle in this point of anomaly; and } \frac{13^\circ 43' 30'' \times 2835' 31''}{360^\circ} \end{aligned}$$

= 108' 61" the sine of the angle of equation, considered as equal to its arc, or 1° 48' 6", to be deducted from the mean, for the true longitude; 6° 21' 42' 35" - 1° 48' 6" = 6° 19' 54' 29" for midnight agreeing with mean time; but as, in this point of anomaly, the true or apparent midnight precedes that estimated for mean time, for which the computation has been made, a proportionable quantity must be deducted from the sun's place, which is thus found: say, as the minutes contained in the ecliptic arc to the sun's mean motion in one day 59' 8", so is the equation of his mean to his true place 180' 6", to the equation of time required, 0' 18" (= $\frac{59' 8'' \times 108' 6''}{21600}$) and 6° 19' 54' 29" - 18" = 6° 19' 54' 11" the sun's true longitude for the apparent midnight.

For the sun's true motion. The co-sine of the sun's distance from the perigee is 1941' 0" 1", and $\frac{1941' 0'' \times 134330}{360^\circ}$ = 74' the cosine of the epicycle, and $\frac{59' 8'' \times 74}{3438}$ = 1' 16" equation, to be added to the mean for the true motion, 59' 8" + 1' 16" = 60' 24" per day, or 60' 23" per danda.

2^d. *Of the Moon.*

The moon's mean longitude for the mean midnight is 0° 20' 2' 25", which exceeds her mean longitude for the true midnight, but $\frac{108 \times 790 \cdot 135}{21600}$ = 3' 57", her motion in the difference of time between the mean and true midnight 0° 21' 2' 25" - 3' 57" = 0° 20' 58' 28" mean longitude, for which the anomalistic equation is to be found. Place of the apogee 11° 7' 8" 55" and the moon's distance from it 1° 13' 49' 33". The sine of the latter, 2379' 39". By the rule before explained $\frac{2379' 39'' \times 20'}{3438}$ = 13' 51", and $32^\circ - 13' 51'' \times 2379' 39''$ = 210' the sine of the angle of equation equal to its arc, or 3° 30" to be subtracted, 0° 20' 58' 28" - 3° 30" = 0° 17' 28" 28" the moon's true place, agreeing with the true apparent midnight.

For the moon's true motion. The co-sine of her distance from the apogee 2479' 13". Circumference of the epicycle 31° 46' 9", and $\frac{31^\circ 46' 9'' \times 2479' 13''}{360^\circ}$ = 218" 47" co-sine in the epicycle. The moon's mean motion from her apogee is 790' 35" - 6' 41" = 783' 54", and $\frac{783' 54'' \times 218' 47''}{3838'}$ = 45' 53" the equation of her mean to her true motion, to be subtracted, 790' 35" - 45' 53" = 740' 42" the moon's true motion per day, or 740" 42" per danda.

For the place of the moon's apogee reduced to the apparent midnight. The motion of the apogee is 6' 41" per day, $\frac{108' 6'' \times 6' 11''}{21600}$ = 2", 11° 7' 8" 57" - 2" = 11° 7' 8" 55" its place.

For the fame of the node. Its motion *per day* is $3' 11''$, and $\frac{108^{\circ} 6'' \times 3' 11''}{21000} = 1''$, and $4^{\circ} 29' 27' 36'' - 1'' = 4^{\circ} 29' 27' 35''$ its place.

The true longitude and motion, therefore, for the apparent time of midnight at Bhagalpur, 714404082947 solar days after the creation, or commencement of the planetary motions, will be

	Longitude.	Motion per day.
	s o ' "	'' "
Of the Sun,	6 19 54 11	60 24
Moon,	— 17 28 28	740 42
Sun's Apogee,	2 17 17 15	inconcalculable
Moon's Apogee,	11 7 8 53	6 41
Moon's Node,	4 29 27 35	3 11

Second operation.—Having the longitude and motion as above, to determine the *tithi* and time remaining unexpired to the instant of opposition, or full moon.

The moon's longitude subtracted from the sun's, leaves $5^{\circ} 27' 34' 17''$, or $10654' 17''$, which, divided by $720'$ the minutes in a mean *tithi*, quotes fourteen even *tithis* expired, and the fraction, or remainder $574' 17''$, is the portion expired of the 15th, or *purnima tithi*, which subtracted from $720'$, leaves $145' 43''$ remaining unexpired of the same; which, divided by the moon's motion *per danda* from the sun, will give the time remaining unexpired from midnight to the instant of the full moon with as much precision as the Hindu astronomy requires. Deduct the sun's motion $60'' 24''$ *per danda* from the moon's $740'' 42''$, the remainder $680'' 8''$, is the moon's motion from the sun; by this divide the part remaining unexpired of the *purnima tithi* $145' 43''$.

$$\frac{145' 43'' = 52450''}{680'' 8''} = 77 \text{ D. P.}$$

$$680'' 8'' = 40818'' = 12 \text{ 51}$$

therefore 12 dandas, 51 palas after midnight will be the end of the *purnima tithi*, or instant of opposition of the sun and moon.

Fifth operation.—Having the instant of opposition as above, to find the true longitude and motion of the sun and moon, the latitude of the latter and the place of the node.

Add the mean motion of each for $12^{\circ} 51'$ to the mean places, found before for the true midnight; and for the mean places so found, compute again the anomalous equations. This being but a repetition of operation the third is unnecessary to be detailed. The several particulars are as follows:

	Mean longitude for midnight.	Mean longitude at full moon.	Equation.	True longitude at full moon.
	s o ' "	s o ' "	'' "	s o ' "
Of the Sun,	6 21 42 17	6 21 54 17	147 50	6 20 7 7
Moon,	— 20 58 28	— 23 47 30 20	— 20 7 27	
Moon's Apogee,	11 7 8 53	11 7 10 21		
Moon's Node,	4 29 27 35	4 29 28 16

	'' "	'' "	'' "
Of the Sun,	54 6	X 1 16	60 24
Moon,	760 35	— 47 28	741 7

Hence it appears that, at the opposition, the moon will be near her descending node; for, $4^{\circ} 29' 28' 17'' \times 6' = 10^{\circ} 29' 28' 16''$, the place of the descending node in antecedentia, and $12^{\circ} - 10^{\circ} 29' 28' 16'' = 1^{\circ} 0' 31' 44''$ its longitude according to the order of the signs, and $1^{\circ} 0' 31' 44'' - 20^{\circ} 7' 27'' = 10^{\circ} 24' 17''$ the moon's distance from her descending node, which, being within the limit of a lunar eclipse, shews that the moon will be then eclipsed. For her latitude at this time, say, as radius is to the inclination of her orbit to the ecliptic, $4^{\circ} 30'$ or $270'$, for as the sine of her distance from the node $620' 57''$, to her latitude of $45' 43''$ ($= \frac{270'' \times 620' 57''}{3438'}$).

Sixth operation.—From the elements now found, to compute the diameter of the moon and shadow, and the duration of the eclipse.

	Yojan.
The Sun's mean diameter is	6500
Moon's	480
Earth's	1600
Sun's mean motion,	59' 8"
Moon's,	790 35
Sun's true motion,	60 24
Moon's,	743 7
Moon's latitude,	48 45

As the moon's mean motion is to her mean diameter, so is her true motion to her true diameter for the time of op-

position $\frac{743' 7'' \times 480}{790' 35''} = 45' 11$ Yojan, which, divided by 15 quotes $30' 5''$ of a great circle.

As the sun's mean motion is to his mean diameter, so is his true motion to his diameter at the instant of opposition

$$\frac{60' 24'' \times 6500}{59' 8''} = 6639 \text{ 14 Yojan.}$$

As the moon's mean motion is to the earth's diameter, so is the moon's equated motion to the Suchi, or a fourth number, which must be taken as the earth's diameter, for the purpose of proportioning its shadow to the moon's distance and apparent diameter $\frac{1600 \times 743' 7''}{790' 35''} = 1503 \text{ 56 Yojan, the}$

Suchi.

Equated diameter of the sun,	6639 14
Of the earth,	1503 56
Difference,	5039 14

As the sun's mean diameter is to the moon's diameter, so is the difference above 5039 14, to a fourth number, which, deducted from the Suchi, or equated diameter of the earth, leaves the diameter of the earth's shadow at the moon,

$$\frac{480 \times 5039 \text{ 14}}{6500} = 372 \text{ 7 and } 1503 \text{ 56} - 372 \text{ 7} = 1131 \text{ 49}$$

Yojan, which divided by fifteen, quotes $75' 27''$ of a great circle for the fame.

From the half sum of the diameters of the moon and shadow $\frac{75' 27'' \times 30' 5''}{2} = 52' 46''$ subtract the moon's latitude

$48'' 45''$, the remainder is the Chh'anna, or portion of the moon's diameter eclipsed, $4' 1''$ of a great circle, and by the nature of a right-angled triangle the square root of the difference of the squares of the moon's latitude, and the half sum of the diameters of the shadow and moon, will be the path

ECLIPSE.

path of the moon's centre, from the beginning to the middle of the eclipse.

The diameter of the shadow is,	75 27
Of the moon, - - - - -	39 5
Sum, -	105 32
Half sum,	52 46

The moon's latitude is, - - - - - 48 45

$\sqrt{52\ 46^2 \times 48\ 45^2} = 20' 11''$, which divided by the moon's motion from the sun, quotes the half duration of the eclipse in dandas and palas, or Hindu mean solar hours,

$$\frac{20' 11''}{683'' 43''} = 1\ 46\ 25; \text{ which doubled, is } 3\ 32\ 50,$$

the whole duration of the eclipse; which will be partial, the moon's latitude being greater than the difference between the semi-diameters of the moon's disc and the earth's shadow.

Seventh operation.—To find the position of the equinoctial colures, and thence the declination of the sun, the length of day and night, and the time counted from sun-rise, or hour of the civil day when the eclipse will happen.

1st. For the ayanansa or distance of the vernal equinox from

the 1st of Mesha, $\frac{714404082047 \times 600}{1577917828} = (271650) 8' 4''$

$81' 30'' 52'''$ of which take the bhujas $8' 4'' 31' 30'' 52''' - 6'$ or $2' 4'' 31' 30'' 52'''$ which multiply by three and divide by ten, $\frac{64' 31' 30'' 52''' \times 3}{10} = 19' 21' 27''$ the ayanansa, which in

the present age is added to the sun's longitude, to find his distance from the vernal equinox. The sun's equated longitude is $6' 19' 54' 11''$, and $6' 19' 54' 11'' + 19' 21' 27'' = 7' 9' 15' 38''$ his distance from the vernal equinox.

2d. For the declination, right ascension, and ascensional difference. The sun's place is $7' 9' 15' 38''$, and $1' 9' 15' 38''$, his distance from the autumnal equinox; the sine of which is $2174' 41''$, and as radius is to the sine of the greatest declination 24° , termed the *paramaparacramajya* 1397, so is $2174' 41''$ to the sine of his declination $883' 40''$, the arc corresponding with which, in the canon of sines, is $14^\circ 53'$,

$$\left(\frac{1297' \times 2174' 48''}{3483} = 883' 40''\right).$$

The equinoctial shadow at Bhagapuri is 5, 30, and, as the Gnomon of twelve angulas is to the equinoctial shadow, so is the sine of the declination

$$883, 40, \text{ to the cshitjya, } \frac{530 \times 883' 40''}{3438} = 405' 1''.$$

And as the co-sine of the declination is to the radius, so is the cshitjya to the sine of the chara, or ascensional difference, $\frac{64051 \times 3438}{332250} = 419' 4''$: its arc is $42' 9' 56''$ the ascensional difference.

3d. For the length of the day and night.

The modern Hindus make their computations in mean solar time: the Surya Siddhanta directs, that they should be made in sidereal time. A sidereal day contains sixty dandas; each danda, sixty viculas; and each vicula six respirations, in all 21600 respirations, answering to the minutes of the equator. A naeshatra day is exceeded in length by the fava, or solar day, by reason of the sun's proper motion in the ecliptic, the former measures time equally, but the latter varies in its length from the inequality of the sun's motion, and the obliquity of the ecliptic. The sun's equated motion for the middle of the eclipse was found $60' 24''$; and

the oblique ascension for the eighth sign from the vernal equinox, in which he will be found at that time, is taken from the foregoing table 543 palas, or 2085 respirations. As the number of minutes contained in one line 1800, is to the number of respirations, or the arc of the equator in minutes answering to the oblique ascension of the line, the sun is in 2085, as above, so is the equated motion $60' 24''$, to the excess in respirations of the fava or solar day over the naeshatra or sidereal day $\frac{2085' \times 60' 24''}{1800} = 69' 3''$, which, added

to $21600'$ gives the length of the solar day by civil account from sun-rise to sun-rise, sidereal time $21609\ 3'$ respirations. From one-fourth of this deduct the ascensional difference, the sun being declined towards the south pole, for the semi-diurnal arc; and add it for the feminocturnal arc: the former is $14997' 19''$, and the latter $5837' 11''$; which may be reduced to dandas, or Hindu hours, by a division of 360.

Hence half the day is $13\ 52\ 53$, and half the night $16\ 12\ 52$. The whole day added to half the night shews the hour

counted from the preceding sun-rise to midnight $43\ 53\ 38$, to which add the time at midnight unexpired of the *purvima tithi*, for the hour of the civil day corresponding with the middle of the eclipse. The hour from midnight to the end

of the *purvima tithi* is already found $12\ 51$ in mean solar time, and to reduce it to sidereal time, say, as $21600'$ is to $21600'$

$$\times 59' 8'', \text{ so is } 12\ 51, \text{ to sidereal hours } 12\ 53, \text{ equal to } 2\ 51 \text{ solar hours.}$$

From the preceding sun-rise to midnight is $43\ 59 -$
At midnight will remain of the *purvima tithi*, $12\ 53 -$

Hour of the civil day at the middle of the } $56\ 52 -$
eclipse, - - - - - }
Deduct the half duration, - - - - - } $1\ 46\ 25$

Beginning of the eclipse, - - - - - } $55\ 5\ 35$
Add the whole duration, - - - - - } $3\ 32\ 50$

End of the eclipse, - - - - - } $58\ 58\ 25$

And the day and night containing together $60\ 11\ 30,$

the eclipse should end $1\ 33\ 5$ before sun rise, according to this calculation.

The first day of the creation, according to the Hindus, was *Ravi-var*, or Sunday: the number of days for which the above calculation has been made, is 714424082047 , which, divided by seven, the number of days in a week, are 12057726135 weeks and two days; the astronomical day therefore of *Soma-var*, or Monday, will end at midnight preceding the eclipse; but the *Soma-var* by civil computation will continue to the next ensuing sun rise; and this *Soma-var*, by calculating the number of days elapsed from the instant the sun entered the sign Tula, to his advance of $10^\circ 54'$ on that sign, will be found to fall on the 19th of the month Cartic, answering to the third of November.

The time of the full moon and the duration of the eclipse, found by this computation, differ considerably from the Nautical Almanac. The Siddhanta Rahasya and Grabalaghava, comparatively modern treatises, are nearer the truth, yet far from correct. The Hindus, in determining these phenomena, are satisfied when within a few minutes of the true time.

ECLIPSE.

A comparative Statement of this Eclipse as predicted in the Nautical Almanac, with computations of it made by different Hindu books. Those marked (*) are made for different meridians, the last we believe for Tirhut.

Names.	Equated longitude for midnight at Bhagalpur, supposed in 8° 50' E. from Latica, and 88° E. from Greenwich.

Various machines have been contrived to explain and illustrate the doctrine of eclipses. In all the mathematical shops are to be found telluriums and lunariums, which are said to be made for this purpose; for which, in fact, they are utterly unfit. For those conversant on the subject, machines are unnecessary; for those who are not, particularly young people, these machines are only calculated to give them erroneous notions. What little difficulty there is in the general principle, that requires this kind of illustration, is not to show how there is an eclipse, but how it happens that most often there is not; now, in the above-mentioned instruments, the moon is in eclipse for nearly one-half of the month, and the sun during the remainder. This great defect arises from the impropriety of attempting to introduce the sun, moon, and earth, on one machine, intended to illustrate appearances in astronomy, the particular modifications of which depend altogether on the relative magnitudes and distances of the bodies which produce the phenomena.

In the lectures which were given this year at the Royal Institution by Mr. Pond, a machine was exhibited, which was entirely free from these objections. The sun was altogether omitted, and supposed to be at a great distance, for instance, a mile: by this means, the magnitudes of the earth and moon, and the proportionate dimensions of the lunar orbit, were preserved. The machine being adjusted for the present year, the moon revolved round the earth at her proper distance, and became, in the course of the year, twice eclipsed on the days marked in the ephemeris. An index, pointing to the sun, carried a small circle of card, representing the solar ecliptic limit: twice in the course of the year the moon came within the circumference of this card, indicating that there would be a solar eclipse. The machine is extremely simple in its construction: it was made under the direction of Mr. D. Adams of Fleet-street, by Mr. R. Newman, a very intelligent and ingenious workman, who is very well known in his profession.

The following description, illustrated with a plate, will give the reader a perfect idea of the nature of it.

Description of the Machine, to illustrate the Phenomena of Eclipses.

This instrument has the earth in the centre, half an inch in diameter, on which is fixed a piece of black wood, about 15 inches long, to represent the shadow of the earth from the sun; this earth, with the shadow, has a revolution on its axis in 365 days 6 hours. Underneath the earth, on the same centre, is a socket going round in 27 days 8 hours, on which is fixed an arm for carrying a small ball, to represent the moon; 15 inches in length, that the moon may pass clear of the end of the earth's shadow. This ball, which represents the moon, is about one-third the diameter of the earth.

Underneath the socket that carries the moon is another socket, going round retrograde, or contrary to the signs in the ecliptic, in 18 years 225 days, on which is fixed a circle with the moon's nodes, and latitude for every part of her orbit. This circle inclines to the ecliptic in an angle of $5^{\circ} 18'$, giving the moon's orbit an angle of $5^{\circ} 18'$ with the ecliptic.

Underneath the socket that carries the moon's orbit, and near the large plate on which is engraven the signs and degrees of the ecliptic, and the months and days of the month answering thereto, is a socket carrying round an index, to show the sun's place in the ecliptic, in 365 days 6 hours. This index points to the day of the month and sun's place in the ecliptic through the year.

On the arm that carries the above index is fixed a circle,

divided into $29\frac{1}{2}$ for shewing the moon's age in any part of her orbit.

On the ecliptic plate is a circle, divided into twice 12 hours, for shewing the hour of the day or night, by an index that moves round by the machine in 24 hours.

This instrument is constructed for shewing the mean time of all the new and full moons, and solar and lunar eclipses, for any given year.

The above being the particulars of the different parts of the machine, we shall now show that the machine, so constructed, will exactly answer the intended purposes.

In the first place, the earth being half an inch in diameter, and the moon nearly one-third the diameter of the earth, the true proportional distance of the moon from the earth will be about 30 times the diameter of the earth, equal to 15 inches.

The moon moves round the earth, from any particular meridian to the same meridian again, in 27 days 8 hours; (the moon's orbit inclining to the ecliptic $5^{\circ} 18'$;) but from the sun to the sun again, in 29 days 12 hours; the sun having gone about 28° in the ecliptic, while the moon makes one revolution round the earth, and overtakes the sun again in about 2 days 4 hours after passing the same meridian on the earth it set out from: the sun, with the annual index moving round in the exact time with the earth's shadow, throws the earth's shadow always in its true place.

To find the time that the new and full moons and eclipses will happen, on any given year, by the machine.—First, by an ephemeris, find the exact time of the first new or full moon in January; set the annual index to the day of the month in the ecliptic; bring the earth's shadow opposite the sun; if for new moon, bring the moon by turning the winder exactly between the sun and earth; but if for full moon, bring the moon opposite the sun, with the earth between the sun and moon; set the hour-index to the time in the hour-circle; then find the place in the ecliptic of the ascending or descending node, and set to its place in the ecliptic. This done, the instrument is rectified for use.

We will now suppose the instrument set to the first new moon in January: turn the winder, until the moon comes opposite where it set out from, which will be about the 15th day of the moon's age, in the circle of $29\frac{1}{2}$; the annual index will point out the day of the month of the full moon; and the hour-index, the hour the moon is full; turn the winder, until the moon comes exactly between the sun and the earth, and you will have the exact time of new moon; and so on, for every new and full moon throughout the year.

As no solar eclipse can happen but at new moon, nor lunar eclipse can happen but at full moon, continue turning the winder, until you see the moon enter the end of the earth's shadow, and the annual index will shew the day, and the hour-index will shew the hour, the first lunar eclipse will happen on that year, for then the moon will be in the node of her orbit; and when the moon comes between the sun and earth in her node, it will be the first solar eclipse; and so on for every eclipse through the year. At new or full moon, when there is no eclipse, the moon will pass either above or below the earth's shadow, according to the moon's latitude at the time.

In the figure (*fig. 100.*) in which this machine is represented, *E* represents the earth's shadow, *E* *x* a fine wire or index in the same straight line as the shadow, which always points to the same place. The arm carrying the moon has a hinge, by which means it always falls, and runs upon a small wheel on the inclined plane, which represents the moon's orbit; the plane of the dial-plate represents the plane of the ecliptic. The rest will easily be understood by inspection.

ECLIPTA,

ECLIPTA, in *Botany*, from *εκλινα*, to be deficient, alluding, as it should seem, to the want of a crown, or wing, to the seeds, one of the chief characters that distinguish it from *Verbescina*, with which it had formerly been confounded by Linnaeus himself. Linn. Mant. 2. 157. Schreb. 569. Willd. Sp. Pl. v. 3. 2217. Juss. 187. Mart. Mill. Dict. v. 2. Gartn. t. 169. (Eupatoriobalacron, Vaillant Mem. de l'Acad. des Sc. for 1720. Dill. Elth. 138. t. 113.) Class and order, *Syngenesia Polygamia-superflua*. Nat. Ord. *Compositae, oppositifoliae*, Linn. *Corymbifera*, Juss.

Gen. Ch. *Common Calyx* of many lanceolate nearly equal leaves, in a double row. *Cor.* compound, radiated; florets of the radius very numerous; female frap-shaped, extremely narrow; those of the disk hermaphrodite, tubular, four-cleft, erect, nearly on the outside. *Stam.* (in the latter.) Filaments four, very short; anthers forming a cylinder. *Pist.* (in the same.) Germen oblong; style moderately long; stigma of two spreading lobes. Germen in the female florets triangular; style and stigma as in the others. *Peric.* none, except the permanent calyx. *Seed* of the disk oblong, compressed, crenulated, obtuse, naked; of the radius triangular, oblong, crenulated, obtuse, naked. *Recept.* flattish, clothed with very narrow upright scales.

Obs. It differs from *Verbescina* in having the florets of the disk four-cleft, and naked seeds; and from *Cotula* in its scaly receptacle.

Ess. Ch. Receptacle chaffy. Seed-down none. Florets of the disk four-cleft.

The number of species in Willdenow is seven, annuals of a very mean aspect, growing on waste, or cultivated ground, in the East Indies, or warmer parts of America. Their stem is branched. Leaves opposite, lanceolate, or ovate, acute, serrated, rough, more or less stalked. Flowers small and inelegant, whitish, or yellowish, on long, simple, slender, lateral, axillary, or terminal, stalks. Scales of the calyx broad and hairy. Michaux describes one species, his *E. brachypoda*, Fl. Boreal. Amer. v. 2. 150, as having the florets five-cleft. *E. erecta*, from South America, and *E. prostrata*, from the East Indies, have been introduced into our flowers, certainly rather for curiosity than ornament. *E. punctata* is said to afford a juice which turns black, when exposed to the air, and is used by the negroes in the West Indies to deepen the colour of their skin.

ECLIPTIC, **ECLIPTICUS**, something belonging to eclipses. All new and full moons are not eclipsic, *i. e.* eclipses do not happen every new and full moon, though there be then an interposition, either of the earth between the sun and moon, or of the moon between the sun and earth. The reason is, that the interposition is only as to longitude, and not as to latitude. The sun is always in the ecliptic, but the moon is not; she deviates from it above five degrees, and $\frac{1}{2}$, sometimes on the north side, and sometimes on the south. But every five months, or thereabouts, she cuts the ecliptic; and it is only about those times, that there can be eclipses either of the moon or sun. The places wherein she cuts the ecliptic, are called the nodes of the moon. See **ECLIPSE**.

ECLIPTEIC bounds, or limits, are the greatest distances from the nodes at which the sun and moon can be eclipsed. See **ECLIPSE**.

ECLIPTEIC digits, digiti ecliptici. See **DIGITS**.

ECLIPTEIC, in *Astronomy*, a great circle of the sphere in which the sun describes his annual course.

It is sometimes defined the projection in the heavens of the line described by the centre of gravity of the earth and moon, as seen from the centre of the sun.

To have determined the exact path described by the ap-

parent motion of the sun, must have required the continued observations of many centuries. The path of the sun, resulting from the combination of its annual and diurnal motion, is, in fact, a spiral, and may be represented by winding a thread round that part of the celestial globe which comprehends the annual motion of the sun, beginning at either solstice, and making as many turns between it and the equator, as the sun employs days to traverse that part of his annual path. But the distance between the consecutive threads would not be equal; they would almost coincide with each other near the solstices, and would gradually widen as they approached the equator. An observer at the pole, if it were habitable, would see the whole of this spiral; and it is easy to conceive how familiar he might be with this phenomenon, without any idea of such a circle: as the ecliptic ever suggesting itself to his imagination.

This spiral motion of the sun may be conceived as produced by a motion nearly uniform, combined with a rectilinear motion extremely unequal. It may be represented by drawing a line on the celestial globe from the equator to the solstice, the globe being, at the same time, supposed to be in motion round its axis; but the line must not be drawn with a uniform motion, but gradually retarded as the tracing point approaches the solstice.

This may seem a very complicated way of arriving at a knowledge of the ecliptic; but we must recollect, that the problem is really represented to us in this form by nature. The Greeks were acquainted with the irregular spiral above described long before they had any conception of the existence of such a curve as the ecliptic. With them the difficulty of the problem consisted in reconciling this irregular motion of the sun, from north to south, with that simplicity they were accustomed to attribute to the operations of nature; and they were at a loss to conceive what impeded the sun met with in his path that could thus retard his progress, and compel him to return. Their philosophers, who had more imagination than judgment, explained this phenomenon something in this manner. They supposed that the sun, as he approached the north, was impeded in his course by the increasing thickness of the atmosphere, which, by continually increasing the difficulty of his progress, at length induced him to alter his course; that when, on his progress back again towards the south, he crossed the equator, finding there the climate more congenial to his nature, he proceeded with vivacity; but on again approaching the more intemperate regions, he found the climate too contrary to his nature, that he was again compelled to return.

Though the explanation of the phenomena, arising from the sun's annual and diurnal motion, was known to the Eastern nations at a very early period of antiquity; yet the merit of the discovery has by some writers been attributed to Anaximander, an astronomer of the Ionian school, who flourished about 600 years before the Christian era. He was a disciple of Thales, who seems to have acquired his knowledge from the astronomers of Egypt. Both Thales and his successors explained the motion of the sun as we do at the present day. They appear distinctly to have understood how the above-mentioned spiral arose from the simple combination of two circular motions.

The nature of the ecliptic being once understood, the next object was to determine its inclination to the equator. The most ancient instrument for this purpose was, no doubt, the gnomon, or upright pillar to cast a shadow of the sun: the length of this shadow was observed throughout the year, particularly at the solstices, by which means the sun's greatest and least altitude was obtained: half of this difference, namely, half the difference between the altitude at the longest, and

the altitude of the shortest day, was evidently the obliquity of the ecliptic. This being once determined, it became requisite to devise some method of placing this circle in its position on the celestial sphere; for, we should observe, that none of the preceding observations give us any insight into the true situation of the equinoctial points in the heavens. It was easy to determine, by the foregoing methods, the situation of the sun at any moment, with respect to the equinoctial points; but to place the ecliptic on the sphere, it was requisite to know, at the same moment, the situation of the sun, with respect to some given star.

Before the invention of the pendulum this was an operation of great difficulty; for the sun never being visible, at the same moment, with any of the fixed stars, it was not easy to measure his distance from any of them. The ancient astronomers had recourse to the moon as an intermediate object of comparison. The moon is often visible at the same time with the sun; it was, therefore, practicable to measure the distance from the sun to the moon; they then waited till the sun descended below the horizon, and then measured the distance between the moon and any remarkable star, and, by allowing for the motion of the moon in its orbit during this short interval, they thus accomplished their purpose. Modern astronomers effect this by comparing the meridian transit of the sun with that of the principal fixed stars, and thus determine the right ascension of each. See TRANSIT and RIGHT ASCENSION.

This great circle of the sphere being once placed in its proper position among the constellations of the fixed stars, according to the method above described, it was natural to suppose it would retain its position constantly the same; but, when practical astronomy had attained to some considerable degree of perfection under the astronomers of the Alexandrine school, Hipparchus, by comparing his observations with those of his predecessors, observed, that the ecliptic had certainly changed its situation relative to the equator. If this discovery of Hipparchus appeared to him entirely new, (and there is no reason to doubt it,) it is a proof of the great decline of astronomy in Egypt in his time; for certainly this phenomenon, now called the precession of the equinoxes, must have been known, in some form or other, to the more early astronomers, as the effect of it is to render inaccurate the rules laid down by ancient authors for the regulation of the seasons. Ancient zodiacs, likewise, prove that the ecliptic and equator were known to intersect each other, in points very different from those determined by the predecessors of Hipparchus. There is, however, some obscurity in these zodiacs; the equator and ecliptic are not laid down in the distinct manner they are on our globes, but often in a rude and unintelligible manner. One of those, however, lately found in Upper Egypt, seems to refer to a period about 2000 years before the Christian era. The writings of Herodotus, from similar considerations, appear to refer to the year 900 A. C.; therefore, the effects of this phenomenon must have been known: but, perhaps, before the time of Hipparchus, they had never been attributed distinctly to their proper cause. The ecliptic, being divided into four equal parts by the equinoctial and solstitial points, the sun was naturally supposed to describe them in four equal portions of time; for the ecliptic, being a great circle, and every part of a circle bearing the same relation to its centre, what reason could be given why the sun should describe equal portions of the ecliptic in unequal periods of time? Yet Hipparchus, when he came to examine more attentively, than had been done before, the circumstances of the sun's motion, found, that the sun took above eight days more to

perform the summer half than the winter half of the ecliptic at the time of his passing through the two equinoxes was likewise unequally divided by the solstices. This unexpected phenomenon led to a more mathematical investigation of the nature of the sun's orbit. Hipparchus, and succeeding astronomers, explained this phenomenon, by supposing it was only an optical illusion, caused by the earth's being placed in an eccentric position relative to the orbit of the sun, which they imagined to be a perfect circle, described with a motion, likewise, perfectly uniform: this theory continued, till the beautiful discovery of Kepler demonstrated the sun's apparent orbit to be an ellipse, and that the centre of motion was in one of the foci. In this ellipse, the sun describes equal areas in equal times. But in either hypothesis, there are two points of the apparent orbit of the sun, in which he is at his least and greatest distance from the earth; these points are called the *perigee* and *apogee*. To complete, therefore, the theory of the ecliptic, it was necessary to determine the situation of these two points. This was done by Hipparchus, who determined the position of the perigee, about 150 A. C. to precede the winter solstice.

These points, like the equinoctial points, do not remain at rest, but their motion is in an opposite direction. It was Abategnius, an Arabian astronomer, who flourished in the middle ages, who first discovered the motion of the perigee; it advances 15" with respect to a given fixed star, and 63" with respect to the equinoxes.

The great circle in the heavens then, which we call the ecliptic, is the perspective representation of the apparent orbit of the sun, and necessarily partakes of all the irregularity of the original, in whatever relates to the sun's motion. We thus see the reason why the seasons are divided unequally, for the winter and summer half year can never be equal, but in the rare occurrence of the coincidence of the perigee with the vernal or autumnal equinox. It is a very curious circumstance, that this coincidence did actually take place at the period in which chronologists place the creation of the world, that is, about the year 4000 A. C. Each hemisphere of the earth had then an equal portion of the light and heat of the sun, but as the perigee continued to advance on the ecliptic, the northern hemisphere gradually obtained the greatest share, and about the year 1250 it attained its maximum of advantage; since that time the advantage in favour of the northern hemisphere, though still very considerable, continues to diminish, and will do so till the year 6470, when the perigee will coincide with the vernal equinox, and produce again a perfect equality between the two hemispheres. After this period, the southern hemisphere will obtain the advantage, and preserve it in the same manner during another period of upwards of ten thousand years.

But these are far from being the only irregularities to which the solar orbit is subject, and which find their corresponding ones in the ecliptic.

It not only continually changes its obliquity with respect to the equator, but also its position relatively to the fixed stars. Its position has varied slowly in the course of many ages, so that its most northern point is now more remote from the pole star than it was in the time of Eratosthenes, who observed its place 230 years before the birth of Christ. It appears from La Grange's calculations, that the limit of its greatest variation among the fixed stars is about 10° or 12°, but the obliquity of the ecliptic to the equator never can differ more than two or three degrees, since the equator will follow, in some measure, the motion of the ecliptic.

On the Obliquity of the Ecliptic.

Sufficient proofs may be drawn from ancient observations of the diminution of the obliquity of the ecliptic; but whether the fact was known to the ancient astronomers, from a comparison of still more ancient observations, may admit of some doubt. Herodotus relates that the Egyptians had a tradition that the ecliptic was once perpendicular to the equator; this we know could not be true, but it indicates a theory of continued diminution, which might easily have assumed the form of a tradition; but considering what exact observations must have been necessary to have established this theory, it is not impossible that it was only a fortunate conjecture.

Ptolemy expressly says (*Almag. l. 11.*) that he found, during many years, the distance of the tropics 47° , with two-thirds of a major portion, (or of a degree), and three-quarters of a minor portion, (or of a minute), that is to say, $47^{\circ} 40' 45''$, the half of which is $23^{\circ} 50' 22''$.

This, he adds, is nearly the same result which was found by Eratosthenes, and of which Hipparchus has made use; for the distance of the solstitial points is according to them, $\frac{1}{2}$ of the circumference of the meridian; which makes it $23^{\circ} 51' 20''$, about 250 years before our era.
